MESSAGE FROM CONFERENCE CHAIRMAN

Due to the unexpected COVID-19 pandemic, the entire humanity has faced many devastating challenges. As a consequence, we had to postpone our 23rd WHEC from July 2020 to June 2022 with the hope that we will successfully organize the conference. Its format will this time be hybrid to cover both onsite and online presentations along with the exhibitions in both manners.

WHEC is a unique scientific event, as initiated by Prof. T. Nejat Veziroglu and his Colleagues back in 1974, and it aims to bring all researchers, scientists, academicians, and professionals working in the field of hydrogen energy systems, ranging from production to storage and end-use options, such as fuel cells for a common goal to hydrogen civilization. This time I have the privilege to chair this conference which provides both online and onsite platforms for contributions to the development and enhancement of hydrogen energy systems; as well as a place to interact with researchers from all around the world to gain a better understanding of the use of hydrogen energy systems for a sustainable future. Much like past WHECs, WHEC-2022 does not only provide an outlook on the current research activities, but also helps in shaping the future of hydrogen energy technologies.

Furthermore, Istanbul, as an ancient city that connects two continents of Asia and Europe, has always been strategically very important, and hosting such a conference in Istanbul will attract researchers from every part of the world to promote hydrogen energy systems and share their innovative ideas and future plans. Moreover, one has to keep in mind that Turkey is dedicated to increase the share of renewables in its energy supply and consider hydrogen energy systems as potential solutions. In conjunction with this, Turkey has expanded its research, innovation, and technology development activities to produce, store, and use hydrogen in an affordable, reliable, safe, clean, and sustainable manner. Given these activities as well as the financial investment and dedication to hydrogen energy systems in Turkey, Istanbul is undoubtedly the perfect host city for this event. Under the shelters of the prestigious International Association for Hydrogen Energy (IAHE) and Turkish National Hydrogen Association, we are now ready to host you for the 23rd WHEC in Istanbul and make it a success story with the strongest online and onsite participations. In this regard, I would like to take this opportunity to warmly thank everyone who has contributed to this success story.

Enjoy the Conference and enjoy your stay in Istanbul.

Prof. Dr. Ibrahim Dincer

Conference Chairman, WHEC-2022

President, National Hydrogen Association

MESSAGE FROM HONORARY CHAIRS

Welcome to the 23rd World Hydrogen Energy Conference (WHEC-2022) held from 26-30 June 2022 in Istanbul, Turkey.

Fossil fuels (i.e., petroleum, natural gas and coal), which meet most of the world's energy demand today, are being depleted fast. Also, their combustion products are causing global problems, such as global warming, climate change, ozone layer depletion, acid rain, oxygen depletion and pollution, which pose a great danger for our environment and, eventually, for life on our planet. Many engineers and scientists agree that the solution to these global problems would be to replace the existing fossil fuel system with the Hydrogen Energy System. Hydrogen is the lightest, most efficient, and cleanest fuel. Its use will produce no greenhouse gases, no ozone layer depleting chemicals, no acid rain ingredients, no oxygen depletion, and no pollution.

Around the world, there is extensive Research and Development work on Hydrogen Energy. Internal combustion engines are being modified for hydrogen fuel. Many types of fuel cells – to convert hydrogen efficiently to electricity – are being developed. Hyundai, Toyota, Honda, and Mercedes started selling hydrogen fueled cars. Many bus companies are selling hydrogen fueled buses. Siemens is selling hydrogen fuel cell powered submarines. Hydrogen fueled appliances based on catalytic combustion have been built. There is research and development work on hydrogen hydride refrigeration and air conditioning systems. Aircraft manufacturers are working on hydrogen fueled subsonic and supersonic transport planes.

Scientists and Engineers from many countries of the world will gather at the 23rd WHEC-2022 Conference to present their papers covering the recent advances in hydrogen energy and technologies. All these will no doubt speed up the conversion to a hydrogen economy eliminate global environmental problems and provide the humankind with higher living standards. I congratulate the organizers of this conference and wish all the participants a very fruitful meeting and pleasant days in the historic capital of two world empires, Istanbul, Turkey.

T. Nejat Veziroğlu

Honorary Chair, 23rd WHEC-2022

Founding President, International Association for Hydrogen Energy

MESSAGE FROM HONORARY CHAIRS

Welcome to the 23rd World Hydrogen Energy Conference.

The demand for hydrogen is predicted to increase fivefold by 2050, driven primarily by the transport, maritime and aviation sectors, according to the recent Global Energy Perspective report developed by Energy Insights, the global market intelligence and analytics group of McKinsey & Company. This report predicts the role of electricity in the global consumption of energy to grow from approximately 20% today to 40% by 2050. Renewable energy is predicted to account for 80 to 90% of the global electric power generation by 2050.

As a result, green hydrogen is predicted to account for approximately 28% of the electric power demand by 2050. Despite creating additional electric demand, dispatchable electrolyzers will permit the integration of intermittent renewable energy sources resulting in more resilient and sustainable energy systems. Green hydrogen is predicted to serve as an energy storage for electric power generation. Gas turbines and compression-ignition, internal combustion engines converted to hydrogen can provide additional flexibility when integrated with power-to-power smart grids, especially stand-alone microgrids.

Finally, three fundamental enablers will be needed for the development of our hydrogen economy: the timely deployment of infrastructure and supply chain; cost reduction from technology advancement and manufacturing scale-up; and government support and targeted actions.

I wish you Godspeed in your endeavors for a bright and sustainable future.

John W. Sheffield, Ph.D.

President – International Association for Hydrogen Energy

FORMAT OF THE CONFERENCE

WHEC-2022 will include both inspiring technical programs as well as enjoyable social events. The technical part of the WHEC-2022 will include sessions where plenary, keynote, invited and general speakers will deliver talks on their work and research in hydrogen energy. The conference will also include several specialized sessions and panel discussion sessions. There will also be numerous poster sessions where the poster presenters will have an opportunity to directly discuss their research outcomes with the conference participants. The social events will include a welcome reception, a gala dinner, and an optional tour of historical places. The conference will also include many other opportunities to socialize and connect with participants. The conference will offer both onsite and online presentations and exhibitions. The official language of the event is English. All papers must be presented in English. There will not be simultaneous translations.

PRESENTATIONS

Papers are to be presented in “Oral” or “Poster” Sessions. Speakers are requested report to the session chair 10 minutes before the start of the session. During the Oral Sessions each speaker is allocated for her/his presentation an estimated time of 12 minutes + 2-3 minutes for questions and answers. All posters will be shown on digital boards. Onsite presenters should be near the digital boards for taking any comments or questions at the break following the session scheduled in the conference program. Both online and onsite presenters should include an e-mail address on the poster. We will ask the participants to ask the questions by e-mail or via the conference website to the online presenters. Online participants may post questions to onsite participants via the conference website. So, we kindly encourage onsite/online poster presenters to visit the conference website regularly to follow up on the possible questions. There will be technical assistant in each room in case you have technical issues.

PUBLICATIONS

WHEC-2022 conference proceedings will be available for download right after the conference. The short papers of the authors who presented their papers in the conference will be included. The authors will have a chance to extend their papers and submit extended versions of their papers to special issues in prestigious journals associated with the conference. The selection and invitation process of the special issues will start after the conference ends. The authors will be informed of this process via e-mail.

PHOTOCATALYTIC WATER SPLITTING FOR LARGE SCALE SOLAR HYDROGEN PRODUCTION

Water splitting to hydrogen and oxygen using particulate photocatalysts is one of the potential candidates to produce green hydrogen at low cost and on a large scale. To achieve solar hydrogen production based on such systems in a near future, there are several problems that need to be solved, such as development of efficient and durable photocatalysts, cost effective reactors, efficient hydrogen separation systems, ensuring safety issues, and so on. In this talk, recently developed photocatalysts, water splitting reactors and hydrogen separation systems being developed in our project will be introduced. In addition, safety issues of the total solar hydrogen production system based on particulate photocatalysts for water splitting will be discussed.

Stuart Hawksworth

SafetyStuart.hawksworth@hse.gov.uk

SAFETY OF HYDROGEN IN THE ENERGY SYSTEM

This presentation will give an overview of the activities of the International Association for Hydrogen Safety (IAHYSAFE) and their impact in the hydrogen safety space. It will also provide an overview of current hydrogen safety projects and how their outputs will be applied in Regulations, Codes and Standards. The presentation will then:

- describe current priorities addressing transport, heat, and power applications in the hydrogen
- discuss future technical challenges in hydrogen safety and the importance of addressing them to enable future progress and innovation in hydrogen technologies.
- discuss broader challenges around education and training in hydrogen safety as uptake in technologies grows.

The presentation will draw on inputs such as IAHYSAFE Research Priorities Workshop.

GREEN HYDROGEN PRODUCTION USING BIOMASS IN NEXT GENERATION MICROBIAL ELECTROLYSIS CELLS AND IMPAIRED WATER IN NOVEL WATER ELECTROLYZER SYSTEMS

The promise of widespread use of H_2 for heavy duty transport and many other applications will depend on developing both green (no net carbon dioxide emissions) and inexpensive methods to produce H_2. The US DOE has set a goal of 1:1:1 (1 kg for $1 USD, within 1 decade) for green H_2. In this talk I examine two of the main methods being examined by the DOE: microbial electrolysis cells (MECs), and novel water electrolyzer systems (WEs). My laboratory is developing next-generation MECs based on using zero-gap architectures incorporating an anion exchange membrane and a vapor gas phase cathode chamber for electrochemical H_2 evolution. We have recently achieved an order of magnitude increase in volumetric production rates. MECs have the advantage of using a favorable anode reaction (biomass utilization by exoelectrogenic bacteria) and therefore they have lower power requirements than WEs. WEs can achieve much higher current densities than MECs but they currently require ultra-pure water, and the cost, process intensification, and potential impacts of brine production for making this water could impact overall WE costs. Therefore, we are looking at novel architectures and materials that could enable the use of impaired (slightly salty) water in WEs. One approach is to use thin film membranes, such as those used for reverse osmosis (RO) desalination. RO membranes are $1/10^{th}$ the price of proton exchange membranes (PEMs), they can withstand high pressures, and unlike PEMs there is no use of PFAS chemicals to make RO membranes. Another WE approach is to use a vapor phase anolyte for water splitting to minimize salt crossover to the anode that can result in unwanted reactions such as chlorine gas production. Innovations in MECs and WEs such as those presented here have great promise to provide new and green methods of H_2 generation in many different locations around the world.

Technical University of Berlin, Germany

pstrasser@tu-berlin.de

ELECTROCATALYSIS OF HYDROGEN TECHNOLOGIES

Electrified solid-liquid interfaces of catalytic materials orchestrate the conversion of free electrons to molecular bonds and back. That is why they play such a key role for the performance of electrochemical energy conversion devices such as water electrolyzers and hydrogen fuel cells.

This talk will highlight advances, challenges and prospects in the quest and development of ever improved electrocatalysts and electrodes for hydrogen-based electrolysis and fuel cell technologies.

THE ESSENTIAL ROLE OF NUCLEAR-GENERATED CLEAN HYDROGEN IN ACHIEVING A NET-ZERO ECONOMY

We are faced with an unparalleled challenge as we plan our future energy systems. Various studies have painted a rather bleak future, calling on all of us to take action to change our habits to reduce temperature rise, or to face the dire consequences to our ecosystems and way of life. All of this comes as we are also working to provide many communities greater access to electricity, clean water, and other resources that many of us in developed nations take for granted every day. Those communities can't be denied the opportunity to improve their quality of life, which means that energy demands will continue to increase, even as developed nations flatten or reduce energy demands through energy efficiency measures.

In light of these challenges, numerous decarbonization commitments have been announced by nation states, municipalities, and private companies, with many seeking to decarbonize the electricity sector by 2035 and to achieve net-zero emissions economy-wide by 2050. Traditionally, electricity generation and management and meeting energy demands for industry and transportation are considered independently. As we seek to achieve net-zero, we need to reassess energy demands, and energy carriers. When we consider overall energy use, only one-third is in the form of electricity. Additional energy demands are in the form of heat or steam for industrial processes, as well as transportation. These sectors are much harder to abate, and electrification may not be the best option—hydrogen, when produced without concurrent emissions, is an enabler to many clean energy solutions. Reducing environmental emissions at an affordable cost, while maintaining grid reliability and resilience, will require all clean energy resources available. That means coordinating the use of nuclear, renewables, and fossil fuels with carbon capture to meet growing demands for electricity, industrial applications, and mobility.

The DOE Office of Nuclear Energy (DOE-NE) Program on Integrated Energy Systems (IES) is led by researchers at Idaho National Laboratory (INL) and work is conducted in partnership with an array of other DOE laboratories, industry, and academia. The primary focus of IES research is to assess the technical and economic potential of IES to enhance the flexibility and utilization of nuclear reactors working alongside renewable generators to meet an array of energy demands—thereby maximizing the utilization of clean energy resources across all energy sectors. Various energy applications and product streams beyond electricity are being evaluated, ranging from generation of potable water to production of hydrogen and hydrogen-based products such as fertilizers, synthetic fuels, steel, and various chemicals. This presentation will highlight the wide array of R&D being conducted across multiple DOE-funded programs to develop and deploy nuclear-based IES that will be key to achieving our net zero goals. By working with key collaborators in the nuclear industry, analytical studies are now becoming a reality in nuclear-generated hydrogen demonstration projects.

Xianguo Li

THE DEGRADATION AND DURABILITY OF HYDROGEN PEM FUEL CELLS

Hydrogen PEM (proton exchange membrane) fuel cells have made significant technical progress and have reached early stage of commercial applications. However, cost reduction and durability improvement, the two interrelated technical challenges, are required for widespread commercial adoption. In this presentation, the degradation mechanism leading to the durability reduction is summarized, including thermal degradation, chemical degradation, and mechanical degradation; efforts for their analyses and simulations are described, interactions between the different degradation mechanisms are outlined for accelerated degradation. Various test protocols for the accelerated stress tests (ASTs) will be previewed, and methods to mitigate the various degradation mechanisms will be discussed. Finally, some of our own efforts in the field will be shared. The current effort will be presented with the objective of achieving low cost, highly performing and durable hydrogen fuel cells with high power density. To achieve this technical target, it is necessary to combine the efforts in the development of low cost, highly performing and durable fuel cell materials, fuel cell manufacturing/processing techniques and design optimization, with a good understanding of fundamentals and command of applied aspects for the technology development, involving phenomena at the nano-, micro-, and macro-scales.

HYDROGEN STORAGE BY HYDROGEN STORAGE ALLOYS – FUNDAMENTALS AND APPLICATION

With the development of FC technology, hydrogen technology is spreading rapidly. The development and establishment of large-scale hydrogen generation, transportation and storage technology are very important issues. In the growing awareness of the global environment, clean hydrogen from renewable energy is attracting high attention. However, on the other hand, hydrogen production from fossil fuels such as LNG and lignite is also practical at present. For example, Japan, which aims to realize a hydrogen society, plans to produce a large amount of hydrogen from Uruguay's LNG, and from Australian lignite and transport it to Japan using tankers. A large amount of hydrogen on land is mainly stored as liquid hydrogen or high-pressure hydrogen gas.

As a project of Japan's Ministry of the Environment, we have developed a mass production technology of nanostructured FeFi hydrogen storage alloy and succeeded in reducing the price to one-third compared with those of conventional alloys. As a result, renewable energy such as wind or solar energy can be stored easily with hydrogen, and output/input fluctuation can be controlled well using the developed alloy.

In this lecture, at first, the basic reaction mechanisms between hydrogen gas and metal, and then the surface or bulk process controlling the rate of hydrogen absorption/storage will be explained. In applications of hydrogen storage alloys, the reaction rate is determined by the surface process and heat transfer factors depending upon density of alloy in a tank and materials contacting alloy. Secondly, the application of hydrogen storage alloys will be mentioned; (1) the application of the exothermic / endothermic heat reaction that occurs during hydrogen absorption / desorption reactions to agriculture and fish breeding, and (2) the renewable energy storage and fluctuation control by the nanostructured FeTi alloy will be reported.

COMMON MISCONCEPTIONS ABOUT HYDROGEN AND HOW TO DEBUNK THEM

Hydrogen is now in a focus of interest, not only in EU, and mass deployment of hydrogen from production to applications is being planned on the highest level. However, there are still skeptics that need to be convinced that hydrogen is not only a viable but the key technology for full or deep decarbonization of energy supply. Some people, even experts, usually focus just one aspect, such as efficiency or storage size or perceived danger, and jump to conclusions without considering a wider picture. Common misconceptions about hydrogen typically include:

- Hydrogen is not an energy source. Indeed, hydrogen is an energy carrier like electricity.
- Hydrogen is (mainly) produced from fossil fuels (natural gas). That is true today, however in a decarbonized energy system hydrogen will be produced exclusively from renewable energy sources
- There is no hydrogen infrastructure. That is true today, it needs to be built. There was no infrastructure when the first cars appeared or when the first power plants were built.
- There is no hope for hydrogen fuel cell electric vehicles – BEV are so much better. This is true for light vehicles and relatively short distances. Hydrogen storage onboard is at least two times lighter than the batteries and hydrogen refueling takes a fraction of time that batteries charging takes.
- It is inefficient to produce hydrogen and then to convert it back to electricity. Compared to batteries that is inefficient indeed. However, for storing large amount of energy for relatively long time (seasonally) we do not have a better option.
- Hydrogen is bulky. Compared to gasoline or diesel hydrogen is indeed bulky. However, car manufacturers managed to fit bulky hydrogen tanks in vehicles without sacrifices
- Hydrogen does not create pollution, but its use will produce huge amounts of water. Use of hydrogen, combustion or electrochemical conversion creates exactly the same amount of water as it was used for its generation.
- Hydrogen is extremely flammable and explosive, thus dangerous. Many safety studies and use records have shown that hydrogen is not more dangerous than other fuels.

Hydrogen should not be judged by these individual properties, but by its ability to decarbonize those energy sectors that would be hard to decarbonize otherwise.

Wei-Hsin Chen

National Cheng Kung University, Taiwan

chenwh@mail.ncku.edu.tw

OPERATION AND SYSTEM OPTIMIZATION FOR HYDROGEN PRODUCTION AND SEPARATION

Over the last several decades, hydrogen has been considered as a promising green fuel to substitute fossil fuels for heat and power generation. In recent years, the development of hydrogen technology and economy has attracted a great deal of attention because it is a promising route to achieve deep decarbonization of the global energy system. Hydrogen is a non-carbon fuel; therefore, no air pollutants are emitted when hydrogen is burned. Meanwhile, hydrogen is a potential energy carrier, so it can be delivered to the appropriate places for its usage. In recent years, significant progress in proton exchange membrane fuel cell (PEMFC) has been made. Accordingly, hydrogen can be applied in the transportation sector through the applications of PEMFC. On account of a foreseeable hydrogen-based society in the future, hydrogen production and separation with high-efficiency routes become a crucial task in the implementation of hydrogen technology. In this study, a number of operation and system optimization methods for hydrogen production from thermochemical methods (such as gasification, catalytic partial oxidation, and autothermal reforming) and for hydrogen separation using palladium membranes will be illustrated. The introduced optimization methods include the Taguchi method, response surface method (RSM), and Nelder-Mead method. From these methods, the influences of operating conditions (e.g., temperature, steam-to-carbon ratio, oxygen-to-carbon ratio, and GHSV) on hydrogen yield and recovery can be figured out. The performances of the optimization methods will also be addressed.

Francesco Ganda

yunhangh@mtu.edu

THERMO-PHOTO CATALYTICAL HYDROGEN PRODUCTION

The critical issues of fossil fuels are their limited natural sources and their contribution to the increase of atmospheric greenhouse gases. To solve those issues, hydrogen is being developed as a promising alternative fuel. Furthermore, solar energy is the largest energy source and technologies are being developed to exploit solar energy efficiently. Visible-light photocatalytic splitting of water to hydrogen is attractive, but its efficiency is poor due to insufficient driving force. In recent years, Prof. Hu's group demonstrated a new strategy by introducing thermal energy as kinetic energy to increase the driving force for the visible light photocatalytic process, leading to 100 times increase in efficiency. Actually, this created a new type of catalysis, "Thermo-Photo Catalysis". In this talk, he will discuss the thermo-photo catalytic hydrogen production from water with emphasis on the reaction mechanism and the synergetic effect of thermal/photo energies.

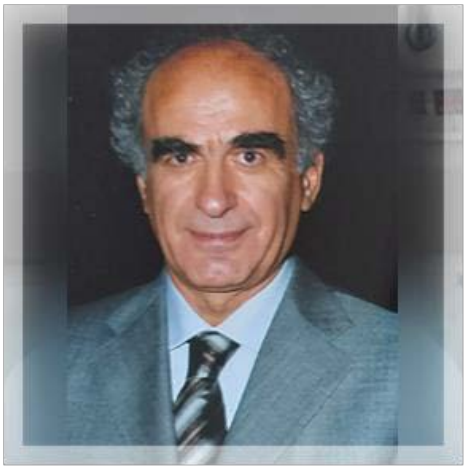
ARTIFICIAL INTELLIGENCE IN SUSTAINABLE ENERGY

Artificial Intelligence (AI) has a significant impact on achieving sustainable development goals. Shaping many sectors, AI is one of the most important technologies in the transformation of the energy sector for sustainable development. Intelligent software is used in many areas from energy production to supply and demand management, from integration of renewable resources to price estimation. As sustainable energy is predicted to become the essential provider of global energy demand, the role of AI is paramount in accelerating, maintaining, and expanding this adoption on which civilization is run on clean and dependable energy with minimal impact on the environment. In this presentation, the applications of Artificial Intelligence, especially for sustainable energy purposes, how AI techniques outperform the classical models, and the future directions will be discussed.

Michaela Kendall



Adelan, UK

THE UK HYDROGEN STRATEGY AND TECHNOLOGY SUPPLY CHAINS

In 2017, Dr Kendall published the first UK Fuel Cell and Hydrogen Strategy devised by colleagues that created the Midlands Hydrogen and Fuel Cell Network, a regional trade association representing the pioneers of the early hydrogen economy. In August 2021, Minister Kwarteng published the second Hydrogen Strategy committing to a 5 GW hydrogen production target for the UK; only 8 months later, the target doubled to 10 GW.

The UK Hydrogen Strategy has been in the making for several decades, and the history of fuel cells and hydrogen globally is depicted in the Adelan book “Hystory”. The story is one of remarkable serendipity and chance for such an important topic as low carbon energy, driven by pioneering characters inspired by international events and coincidences. The UK is a key nation in the innovation narrative, but other countries namely the USA and China have been much more successful at clustering expertise, supporting infrastructure investments, commercializing technologies, and creating momentum in the growing global hydrogen economy. Turkey played an incredibly important role in the story of hydrogen by hosting the UN Hydrogen Centre in Istanbul, forming a global nucleus of scientists, engineers, businesses, and international agencies to build critical networks that remain today, especially in Europe.

This talk will examine the history of hydrogen to predict the net-zero technologies and fuels of the future. Important top-down lessons have been learned to date related to the role of hydrogen technology policy, early market clustering, market barriers, accelerating scale-up, and investment bottlenecks. Reflecting on past successes and failures will support the creation of a more resilient global hydrogen economy from the ground up.

NOBLE METAL NANOCATALYSTS FOR HYDROGEN GENERATION FROM THE HYDROLYSIS OF AMMONIA BORANE

Ammonia borane (AB) is the most promising solid hydrogen storage materials, and its catalytic hydrolysis is the best way of releasing H_2 at ambient conditions. Noble metal nanoparticles (NPs) are the most active catalysts providing high TOF for hydrogen generation from the hydrolysis of AB. However, high price of the precious noble metals hampers their large-scale applications in catalysis. Achieving high catalytic performance with the smallest amount of metal is critical for any catalytic applications of noble metals. While continuous efforts have been devoted to improve the catalytic activity of non-noble metals in hydrolytic dehydrogenation of AB, an immense challenge is the enhancement of utilization efficiency and thus, ultimately lowering the cost of noble metal catalysts. The following approaches can be used for increasing the catalytic efficacy of noble metal nanocatalysts. (i) Reducing the particle size from macroregime to nanoregime increases the surface area and thus, the number of active sites. For example, using the colloidal NPs can increase the catalytic activity tremendously compared to the bulk metals. However, colloidal NPs are unstable and tend to aggregate to larger particles, which greatly hampers their recyclability/reusability and catalytic performance. (ii) Adding a suitable ligand into the suspension can stabilize the colloidal NPs though the activity may decrease as well. (iii) Another way of stabilizing noble metal NPs is to support them on the surface of solid materials such as metal oxide or carbonaceous materials whereby catalytic activity is expectedly enhanced by the large surface area. The catalytic activity and stability of supported noble metal NPs depend on the particle size distribution, surface area of support, and strength of metal-support interaction. Selecting suitable supports is of paramount importance in obtaining NPs which are stable and still catalytically active. (iv) Downsizing the NPs can also increase the catalytic activity of supported noble metal nanocatalysts. (v) Using reducible oxide as support is found to enhance the catalytic activity of noble metal NPs significantly. (vi) Increasing the lifetime and reusability of nanocatalysts can certainly help to improve the atom efficiency of noble metal nanocatalysts. (vii) Making the NPs magnetically separable significantly improves the reusability of noble metal nanocatalysts. The results on rhodium and platinum nanoparticles will be discussed for each approach to demonstrate that the catalytic efficiency of noble metal nanocatalysts in hydrolytic dehydrogenation of ammonia borane can be increased by a suitable combination of all the available methods.

CRITICAL ASSESSMENT OF THE PRODUCTION SCALE REQUIRED FOR FOSSIL PARITY OF GREEN ELECTROLYTIC HYDROGEN

Hydrogen produced from renewable electricity through Power-to-Hydrogen can facilitate the integration of high levels of variable renewable electricity into the energy system. An electrolyser is a device that splits water into hydrogen and oxygen using electricity. When electricity is produced from renewable energy sources, electrolytic hydrogen can be considered to be green. Key green hydrogen production technologies, mostly PEM and alkaline electrolysers, are still further maturing, both in technical (efficiency), economical (CAPEX), and durability (lifetime) performance. Nonetheless, we will show in this contribution how fossil parity for green hydrogen, i.e., a Total Cost of Ownership (TCO) similar to grey H_2 coming from CO_2 intensive SMR processes, can already be achieved today. Moreover, this can be realised at a scale which corresponds to the basic units of renewable electricity generation, i.e., a few MW.

CODES AND STANDARDS FOR HYDROGEN ENERGY SYSTEMS

Codes and standards enable widescale commercialization of hydrogen energy systems. FCHEA facilitates industry participation to ensure that developing requirements reflect industry best practices and facilitates harmonization of technical requirements throughout national and international codes and standards. This presentation will describe current efforts and explore the importance of interdisciplinary collaboration on technical requirements for hydrogen energy systems in emerging markets.

LIQUID HYDROGEN STORAGE IN MICROGRAVITY

Cryogens such as liquid hydrogen are frequently stored over long periods of time particularly in space applications. The operating conditions of cryogenic storage systems are strongly influenced by several factors including heat leak. Cryogens are stored at temperatures close to their respective boiling points. As a result, any addition of energy could lead to the vaporization of a portion of the liquid cryogen. In the absence of gravity, gaseous cryogens could form a vapor bubble, the shape and location of which are not known a priori. The boil-off losses associated with the storage, handling, and transportation of cryogens can result in severe losses. Heat leak causes an increase in the internal pressure of the dewar. Several mechanisms influence the size and position of the vapor bubble in the dewar. Understanding these mechanisms is important to designing storage vessels under optimum conditions and also to the development of cryogenic transfer systems. The work upon which this presentation partially reports aimed at investigating some of the fluid physics observed in a cryogenic dewar under microgravity. The objective is to quantify changes in the storage pressure and temperature and the amount of boil-off observed in a typical dewar under microgravity conditions.

HYDROGEN PRODUCTION BY ELECTROLYSIS TO CLEAN REALITY

Alternative energy sources like solar, wind, thermal, ocean, geothermal, thermonuclear, hydrogen etc., are being considered as possible sources of energy to meet the growing demand. However, none of these energy sources except hydrogen has all the desirable qualities to replace petroleum and natural gas. For example, some are only intermittently available; others are available away from the consumption centers and cannot be used as fuel for transportation. Therefore, out of the above alternative energy sources, hydrogen is considered the best option, which could form the link between the new energy sources and the user. Hydrogen is the clean fuel and when used as a fuel, produces only water. In the hydrogen energy system, it is envisaged that hydrogen will be produced from non-fossil energy sources and will be used in every application where fossil fuels are used today. Over the last decade there have been increasing research efforts to investigate the various aspects of the hydrogen energy systems like production, storage and transport and its applications.

Generation of hydrogen via electrolysis is a well-known and established technology. There are two main types of electrolyser [Alkaline and Proton Exchange Membrane (PEM)] and both are well proven and long-lived. Electrolysis has been traditionally based on an alkaline technology, but Proton Exchange Membrane (PEM) electrolysers are now coming to the forefront. However, due to the high cost of both electricity and material, only a small proportion (4 -5%) of the worldwide hydrogen production comes from electrolysis. Yet electrolyser costs are expected to drop within the few years as a consequence of standardization, mass-production, and a greater competitiveness. The demand for clean-produced hydrogen and its storage potential spell enormous possibilities for renewable electrolysis in the future. Even non-renewable electrolysis is bound to play an important role in the short-term as a source of moderate amounts of hydrogen for small fuelling stations and domestic applications.

In future low-carbon economics, electrolyser technology could provide a central solution to meeting both the power management needs of the electricity sector and the needs of the transport and industrial sectors for low/zero carbon fuels. Electrolytic hydrogen could thereby displace large proportions of non-electricity fuel consumption. Hence, the new market potential for electrolyser dwarfs the existing market potential and on a global scale it is truly vast.

In this talk some of the important and recent developments in the electrochemical alternatives with newer materials for hydrogen generation are discussed. The talk also covers hydrogen-based technologies developed at CSIR-CECRI.

ABSTRACT

Hydrogen is considered one of the most promising energy carriers for the future. Increasing the share of renewable energy and large-scale deployment of carbon capture, utilization, and storage (CCUS) technologies are also important for reducing the greenhouse gas emissions to combat climate change actively. This work is aimed to evaluate the hydrogen production by biogas catalytic reforming processes equipped with CO_2 capture feature. The size of evaluated designs is 100,000 Nm^3/h hydrogen with purity higher than 99.95% (vol.). The assessed carbon capture options involved conventional gas-liquid absorption and innovative chemical looping cycle using iron oxide as an oxygen carrier. The evaluated schemes were modeled and simulated using the process flow modeling software ChemCAD. The mass & energy balances were used to quantify the key plant performance indicators. As the results show, the chemical lo”oping option is very promising in term of increasing the overall energy efficiency (61.02% vs. 54.53%) and the carbon capture rate (95 vs. 70%) as well as reducing specific CO_2 emissions (29.42 kg/MWh vs. 206.89 kg/MWh) than the reactive gas-liquid absorption.

Keywords: Hydrogen production, Biogas catalytic reforming, Carbon capture, Utilization and storage (CCUS).

INTRODUCTION

The need to develop low carbon energy systems is of paramount importance to actively combat global warming by reducing greenhouse gas emissions (mainly CO_2). Along this line, hydrogen-based energy conversion systems attract much interest in last years as they involve no CO_2 emission at the point of use. The reduction of fossil CO_2 emissions can also be achieved by Carbon Capture, Utilization and Storage (CCUS) technologies. Renewable energy sources are also important for the future low carbon economy. To promote the transition for low carbon economy, the European Union enforced the energy and climate package which set quantifiable targets for the member countries [1].

Biogas production and utilisation got significant attention as a renewable energy source and an energy-efficient way of converting various wastes into energy. This article is evaluating the biogas conversion via catalytic reforming into hydrogen coupled with two carbon capture technologies. Since the biogas has a substantial content of CO_2, the catalytic reforming was done in dry (see Eq. (1)) or semi-wet (see Eq. (2)) conditions according to the chemical reactions:

$$CH_4 + CO_2 \Leftrightarrow 2CO + 2H_2 \quad (1)$$

$$CH_4 + H_2O \Leftrightarrow CO + 3H_2 \quad (2)$$

Semi-dry reforming conditions are better in order to avoid side reactions (e.g., carbon deposition on the catalyst). Dry reforming can also be seen as a CO_2 utilisation method in which CO_2 captured from different energy-intensive applications (e.g., heat and power production) can be used to react with natural gas [2]. The syngas produced by biogas reforming is then subject of pre-combustion CO_2 capture by two reactive gas-liquid and gas-solid methods:

1. Reactive gas-liquid absorption using alkanolamines; Methyl-DiEthanol-Amine (MDEA) was considered as an illustrative example in this analysis. The main reaction involved in syngas decarbonisation is the following [3]:

$$CO_2 + MDEA + H_2O \Leftrightarrow MDEA^+ + HCO_3^- \quad (3)$$

2. Iron-based chemical looping cycle involves utilisation of three looping Circulating Fluidized Bed (CFB) reactors which convert the syngas into hydrogen simultaneously with CO_2 capture. The following chemical reactions take place [4]:

- Fuel reactor:

$$CO + H_2 + Fe_2O_3 \Leftrightarrow CO_2 + H_2O + 2Fe \quad (4)$$

- Steam reactor:

$$3Fe + 4H_2O \Leftrightarrow Fe_3O_4 + 4H_2 \quad (5)$$

- Air reactor:

$$2Fe_3O_4 + 1/2O_2 \Leftrightarrow 3Fe_2O_3 \quad (6)$$

CONCEPTUAL DESIGNS, MAIN DESIGN ASSUMPTIONS, SIMULATION AND THERMAL INTEGRATION ASPECTS

The following hydrogen production concepts were investigated: Case 1: Biogas catalytic reforming without carbon capture; Case 2: Biogas catalytic reforming with pre-combustion carbon capture by gas-liquid absorption (MDEA); Case 3: Biogas catalytic reforming with pre-combustion carbon capture by iron-based chemical looping cycle. Fig. 1 presents the conceptual layout of biogas catalytic reforming with pre-combustion carbon capture used for hydrogen production.

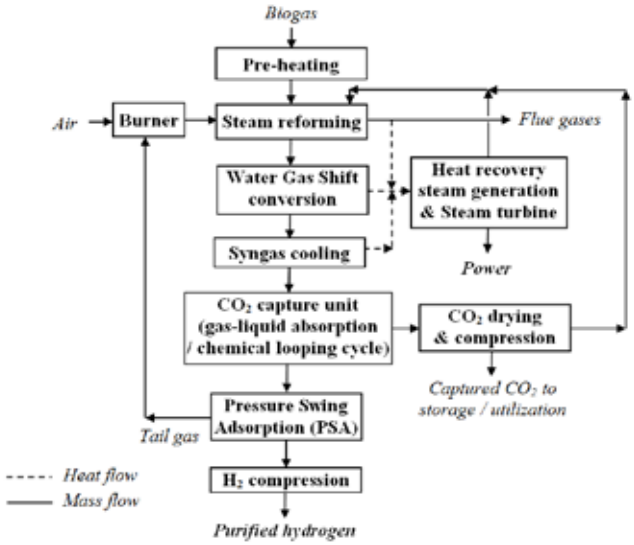

Fig. 1. Conceptual layout of hydrogen production via biogas reforming with carbon capture

The evaluated concepts were modeled and simulated using ChemCAD software. The main design assumptions are presented in Table 1 [3]. All evaluated concepts were subject of detailed thermal integration analysis (using pinch methodology) for optimization overall plant energy efficiency. As an illustrative example, Fig. 2 presents hot and cold composite curves for Case 3: Hydrogen production by biogas reforming with iron-based chemical looping cycle.

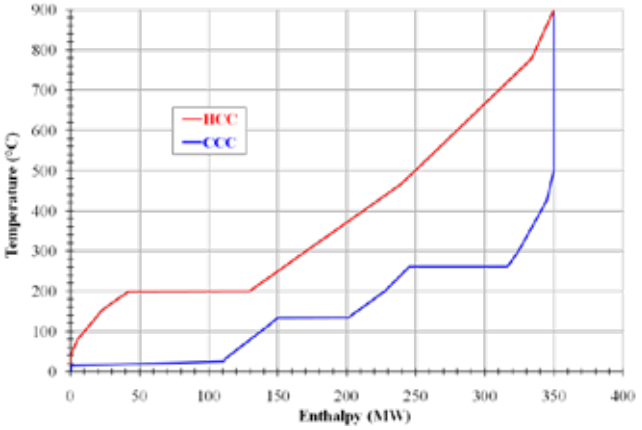

Fig. 2. Hot and cold composite curves for iron-based chemical looping design (Case 3)

Table 1. Main design assumptions of evaluated biogas catalytic reforming concepts

Plant sub-system	Design parameters
Biogas composition (% vol.)	67% CH_4, 30% CO_2, 2% N_2, 0.1% O_2, 0.9% H_2O; Prior desulfurized by ZnO guard bed
Reforming island	Ni-based catalytic reforming reactor; Operating pressure: 30 bar; Pressure drop: 1 bar Reformer outlet temperature: 900°C; Thermal operational mode: heat exchanger
Water gas shift conversion	Two catalytic reactors; Pressure drop: 1 bar / reactor; Thermal operational mode: adiabatic
CO_2 capture by reactive gas-liquid absorption	MDEA aqueous solution 50% wt.; Absorber / desorber columns: 30 / 20 stages Solvent regeneration: thermal; CO_2 removal efficiency: 90%
CO_2 capture by iron-based chemical looping	Oxygen carrier: Fe_2O_3; Fuel reactor: 700 - 750°C; Steam reactor: 725 - 800°C Air reactor: 900 - 1,000°C; Pressure drop: 1.5 bar / reactor; Reactor type: Gibbs free energy
Hydrogen purification unit	Capacity: 100,000 Nm^3/h; Purity: > 99.95% (vol.); Plant delivery pressure: 60 bar
CO_2 conditioning unit	Delivery pressure: 120 bar; Drying solvent: TEG; Quality specification (% vol.): CO_2 > 95%; CO < 2,000 ppm; O_2 < 10 ppm; H_2O < 250 ppm; H_2S < 100 ppm; other gases < 4%

RESULTS AND DISCUSSION

The mass and energy balances were used to quantify the main performance indicators (see Table 2). The introduction of carbon capture step involves an increase of ancillary energy consumption due to CO_2 capture and conditioning units. For gas-liquid absorption, the CO_2 capture energy penalty is about 3.2 net energy percentage points. For chemical looping case, the overall energy efficiency is higher even compared to non-capture design (Case 1) due to higher energy conversion efficiency of the looping cycle. In terms of capture rate and specific CO_2 emissions, the chemical looping is also more promising than gas-liquid absorption (95% vs. 70% and 29.42 kg/MWh vs. 206.89 kg/MWh respectively).

Table 2. Overall key performance indicators of evaluated hydrogen production systems via biogas catalytic reforming

Main plant data	Units	Case 1	Case 2	Case 3
Biogas thermal energy (A)	MW_{th}	552.85	552.85	516.50
Gross power output (B)	MW_e	24.12	12.55	23.52
Ancillary power consumption (C)	MW_e	5.25	11.01	8.33
Net power output (D=B - C)	MW_e	18.87	1.54	15.19
Hydrogen thermal output (E)	MW_{th}	300.00	300.00	300.00
Net power efficiency (D/A * 100)	%	3.41	0.27	2.94
Hydrogen thermal efficiency (E/A * 100)	%	54.26	54.26	58.08
Cumulative plant energy efficiency ((D+E)/A * 100)	%	57.67	54.53	61.02
Carbon capture rate	%	0.00	70.00	95.00
Specific CO_2 emissions	kg CO_2/MWh	652.17	206.89	29.42

CONCLUSIONS

The presented work evaluates via computational tools various hydrogen production concepts based on biogas catalytic reforming with and without carbon capture. Two carbon capture technologies were assessed: reactive gas-liquid absorption using alkanolamines (MDEA) and iron-based chemical looping cycle. The quantifiable results show that the innovative chemical looping concept is very promising in delivering higher cumulative plant energy efficiency (about 61%) and carbon capture rate (95%) and reduced specific CO_2 emissions than the reactive gas-liquid absorption.

ABSTRACT

Ammonia decomposition reaction produces green hydrogen without CO_x emission and has a simple process without post treatment like water-gas shift reaction unlike the conventional natural gas reforming reaction. At the point of end use, ammonia has been considered as a promising hydrogen carrier due to a high volumetric energy density and gravimetric energy density. Liquid hydrogen makes it difficult to handle and store due to cryogenic temperature (-253°C) and boil-off loss (2-3% per day), while ammonia is feasible to liquefy at room temperature (8-10 bar) and utilize established infrastructures for storage and transport. Herein, we present the results about the catalytic performance of Ru-coated metal structured catalysts (monolith, foam) in ammonia decomposition. Metal structured catalyst has been highlighted as an alternative to ceramic pellet catalyst which causes some problems such as pressure drop, low thermal conductivity, and slow response in fixed bed reactor. We tested the metal structured catalysts at various temperatures (550-700°C) and gas hourly space velocities (GHSV = 3,000-10,000 h^{-1}) in ammonia decomposition reaction. It was confirmed that the monolith catalysts with large geometric surface area showed a high NH_3 conversion at low temperature below 650°C, while the foam catalysts showed good catalytic performance at high GHSV.

Keywords: Ammonia decomposition, Hydrogen, Ru catalyst, Metal structured catalyst

INTRODUCTION

There is currently a growing need to move away from a carbon-based economy dominated by fossil fuels to a sustainable hydrogen-based economy due to acute environmental problems such as air pollution, global warming, and fine dust. Interest about not only hydrogen fuel cell electric vehicles (FCEV) but also CO_x-free hydrogen production picks up. Hydrogen is an eco-friendly fuel that emits only water when burned but handling safety and solving storage and transportation problems are crucial. In particular, hydrogen requires expensive storage tanks at very low cryogenic temperatures (-253°C) for liquefaction and there is no qualified hydrogen supply infrastructure. As an alternative, ammonia with a higher hydrogen storage density per unit volume than liquefied hydrogen is drawing attention as a hydrogen carrier. It can be easily liquefied under the conditions of room temperature and an operating pressure of 8-10 atm. In addition, ammonia is currently imported/exported or locally distributed via well-established infrastructures around the world, and can be stored in large amounts [1,2]. Furthermore, when ammonia is decomposed, it only produces nitrogen and hydrogen, which are not harmful to the environment; this means that its products are eco-friendly. Ammonia decomposition reaction has a simple process without post treatment like water-gas shift reaction unlike the conventional natural gas reforming reaction. However, ammonia is a toxic substance, and safety issues must be resolved [3]. In this study, CO_x-free hydrogen was produced over metal structured catalysts via ammonia decomposition reaction. Owing to an excellent heat and mass transfer properties, the metal structured catalyst such as monolith and foam can be replacing the ceramic pellet catalysts in typical chemical processes. Since a metal structured catalysts provide a large geometric reaction surface area to reaction volume (S/V) and increase the heat transfer rate per unit volume of process flow (US/V), it enables a compact reactor design [4]. Moreover, the radial concentration and temperature gradient as well as pressure drop can be minimized by the well-behaved uniform flow of the metal structures through the regular channel [5]. However, there is a key challenge to address the detachment of catalyst coating layer on the metal substrate due to the difference in the thermal expansion coefficient between the ceramic catalyst layer and metal substrate. Herein, we coated the Ru/Mg-Al oxide catalyst uniformly on the surface of FeCralloy monolith and foam using a proprietary KIER coating technique based on precipitation method and evaluated the catalytic performance in the ammonia decomposition for CO_x-free hydrogen.

MATERIALS AND METHODS

FeCralloy (Fe:72.8, Cr:22, Al:5, Y:0.1, Zr:0.1wt%) monolith and foam were used as metal structured carriers. The diameter of monolith was 22 mm, the height was 20 mm, and the cell density was 600-1000 cpi (cells/in^2). The foam

with 6.35 mm thickness and porosity of 20 and 40 ppi was used by cutting round in diameter of 22 mm. Metal structured carriers were rinsed with acetone and then pre-calcined at 900°C to form Al_2O_3 layer on the metal substrate. The Ru/Mg-Al oxide-coated metal structured catalysts were prepared by the proprietary KIER coating technique based on precipitation method [6]. Magnesium nitrate ($Mg(NO_3)_2 \cdot 6H_2O$, Aldrich), aluminum nitrate ($Al(NO_3)_3 \cdot 9H_2O$, Aldrich), and Ruthenium(III) nitrosyl nitrate solution ($Ru(NO)(NO_3)_x(OH)_y$, Aldrich) were used as metal precursors. For comparison, commercial Ru/Al_2O_3 pellet catalyst (3mm x 3mm, AlfaAesar) was used as a reference. The Ru content, surface area, metal dispersion and surface morphology of prepared metal structured catalysts were analyzed by ICP-MS, BET, CO-chemisorption, and SEM. The NH_3 decomposition test was carried out in a 1-inch Inconel tubular reactor under reaction conditions of T = 550-700°C and GHSV = 3,000-10,000 h^{-1}. The catalysts were reduced at 600°C for 3 h under 10%H_2/N_2 before the reaction. The effluent consisted of H_2, N_2, and NH_3 and the residual NH_3 concentration was analyzed using a gas analyzer by tunable diode laser absorption spectroscopy (TDLAS).

RESULTS AND DISCUSSION

Table 1 summarizes the Ru content, Ru dispersion, and Ru metal particle size of metal structured catalysts and pellet catalyst. The geometric surface area of monolith and foam affected the characteristics and Ru loading amount. In particular, compared to the pellet catalyst, the amount of Ru metal used in the metal structured catalyst was about 1/10 or less based on the same reaction volume, and a very small amount of Ru was uniformly coated on the metal substrate. The surface morphology and shape of Mg-Al oxide support layer and Ru metal particles were observed by SEM analysis. Thin plate-like shaped Mg-Al oxide support layer was formed evenly on the metal substrate while nano-sized Ru metal particle was highly dispersed on the surface of Mg-Al oxide layer (Not shown here). It was noted that the proprietary KIER coating method allows the uniform coating of catalysts on the various metal substrates regardless of the geometric shape.

Table 1. Characteristics of Ru-coated metal structured catalysts and pellet catalyst

Catalyst		Ru content (wt%)[a]	Ru content (g)	Ru dispersion (%)[b]	Ru particle size (nm)[b]
Monolith	**600 cpi**	0.036	0.0024	19.3	6.92
	800 cpi	0.020	0.0015	12.5	10.7
	1000 cpi	0.025	0.0023	15.7	8.53
Foam	**20ppi**	0.021	0.0012	16.0	8.37

Pellet catalyst		0.40	0.016	34.6	3.9

(a) Determined by ICP-MS. (b) Estimated from CO-chemisorption at 50°C.

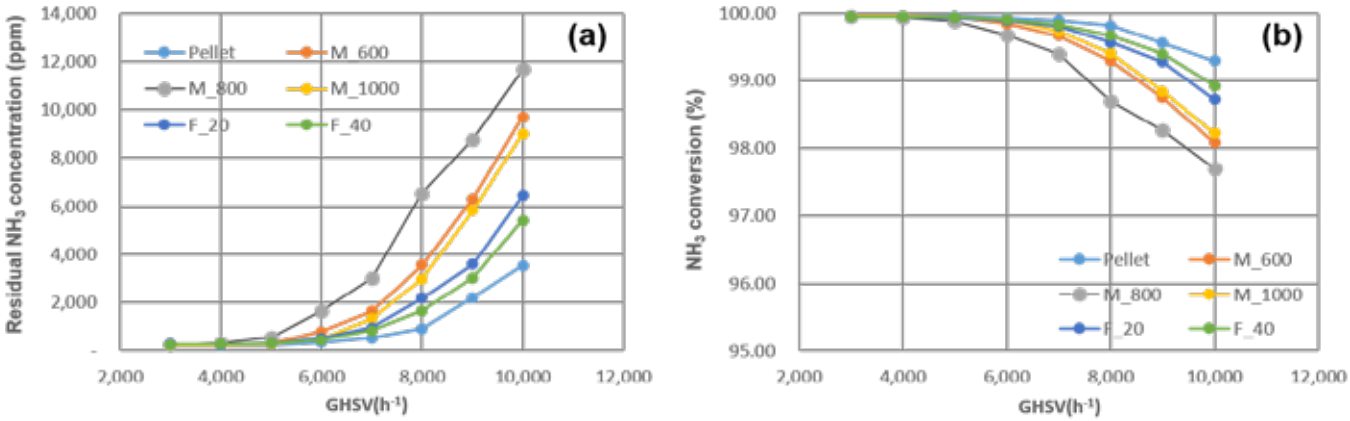

Fig. 1. (a) Residual NH_3 concentration and (b) NH_3 conversion of metal structured catalysts and pellet catalyst in NH_3 decomposition reaction (reaction condition: T_{cat} = 700°C, GHSV = 3,000-10,000 h^{-1})

The Ru/Mg-Al oxide coated metal structured catalysts were tested in the ammonia decomposition at 550 - 700°C. As increasing the reaction temperature, the unreacted residual NH_3 concentration decreased while the metal structured catalysts had the same NH_3 conversion as the pellet catalyst at over 650°C. It was confirmed that the monolith catalysts with large geometric surface area showed a high NH_3 conversion at low temperature below 650°C (Not shown here). Fig. 1 shows the unreacted residual NH_3 concentration and NH_3 conversion of metal structured catalysts and pellet catalyst corresponding to a change in the reaction gas flow rate at 700°C. Since the increase of GHSV causes a mass transfer limitation owing to an increased diffusion resistance, the unreacted residual NH_3

concentration increases [7]. Moreover, the heat transfer is important from heat source to catalyst bed due to the fact that the required reaction heat increases greatly with increasing GHSV in endothermic reactions like ammonia decomposition. It was confirmed that the foam catalyst exhibits better catalytic activity than the monolith catalyst at high GHSV owing to good heat transfer.

CONCLUSIONS

CO_x-free hydrogen was produced via ammonia decomposition over Ru/Mg-Al oxide-coated metal structured catalysts. Ru/Mg-Al oxide catalyst could be coated uniformly on the metal substrate by KIER coating method regardless of the geometric shape of metal structured catalysts. Nano-sized Ru metal particles were highly dispersed on the surface of thin plate-like shaped Mg-Al oxide support layer. The geometric surface area of metal substrate and Ru content have a significant effect on the catalytic activity in the ammonia decomposition reaction. The metal structured catalysts showed similar NH_3 conversion to the pellet catalyst at temperatures above 650°C even though the amount of Ru metal was below 1/10. Furthermore, the foam catalyst showed better catalytic performance than monolith catalyst at higher GHSV due to enhanced heat transfer.

ABSTRACT
In this study, a novel photoelectrochemical reactor for hydrogen and clean water production is designed, constructed, and experimentally investigated. TiO_2 photocatalyst is used in a photoelectrochemical (PEC) reactor, which cleans the water via Fenton-like process and produces hydrogen. A novel dual anode structure is used in the experiments. The TiO_2 nanoparticle deposited photoanode induces electro currents for hydrogen production and produces hydroxyl ions, which assist the removal of chemical oxygen demand (COD) process. The second anode is a stainless-steel plate, which is used as a sacrificial anode to electrogenerated iron ions for the Fenton process. It is aimed to reduce the anode cell half potential and energy consumption by replacing oxygen evaluation with the iron oxidation process. The overall energy and exergy efficiencies of the system are 81% and 80% respectively. After 40 minutes of the operation time of the PEC reactor under 2.3V and 60°C of cell potential and temperature, the reactor produces 22.6 mg of hydrogen and removes 87% of the COD.

Keywords: Hydrogen, Electrolysis, Photoelectrochemistry, Effluent treatment, Titanium dioxide, Fenton reagent, Energy, Exergy, Efficiency

INTRODUCTION
Energy and fresh water are one of the most vital issues for society, international politics, and the environment. The finite existence of these elements emerges the need for sustainable solutions. Consequently, reactors become popular that produce hydrogen as the energy carrier simultaneously with the wastewater treatment process. Simultaneous hydrogen production-wastewater treatment reactors can be built via biological, electrochemical, photochemical and hybrid (combining one or more these processes). The electrochemical processes can provide high hydrogen purity. However, these reactions require relatively high electrical potential, which increases the production costs of hydrogen. One way to reduce the energy need in the electrolyzer is by replacing the anodic reaction of the O_2 generation with an alternative reaction that requires less energy. It could be achieved by anodic oxidation of iron via electrogeneration. Fenton reaction in a PEM electrolyzer was tested only once in the literature before (Navarro-Solís, Villalba-Almendra, & Alvarez-Gallegos, 2010). Promising results were obtained for the decolorization of water. However, photocatalysts assisted the photoelectron-Fenton process in a PEM electrolyzer has not been studied for both hydrogen production and water treatment before. In this study, a PEC reactor for simultaneous wastewater treatment and hydrogen production is used. A novel dual anode structure is used in the experiments. The TiO_2 nanoparticle deposited photoanode induces electro currents for hydrogen production and produces hydroxyl ions, which assist the removal of chemical oxygen demand (COD) process. The second anode is a stainless-steel plate, which is used as a sacrificial anode to electrogenerated iron ions for the Fenton process. It is aimed to reduce the anode cell half potential and energy consumption by replacing oxygen evaluation with the iron oxidation process. Under different conditions, hydrogen output and COD reduction rates of the designed system are examined. Thermodynamic system analyzes are carried out and the system performance is evaluated both energetically and exergetically.

EXPERIMENTAL SET-UP AND PROCEDURE
The photo-electrochemical system for simultaneous wastewater treatment and hydrogen production system consists of a PEC reactor, light source, power source, flowmeter, liquid column (manometer) and a quartz glass case. The Photo-electrochemical reactor experiments are tested under the solar simulator (artificial light) illumination. The experimental configuration is presented in Fig. 1(a) and the basic reaction mechanism takes place in the PEC reactor is demonstrated in Fig. 1(b). The photoelectrochemical reactor consists of a SS sacrificial anode, a PtB- IrRuOx coated Nafion membrane, SS cathode and TiO_2-coated photoanode. Due to its strong moisture resistance, reactor casing material is selected as high-density polyethylene (HDPE). In addition, HDPE is also resistant to most of the chemicals, flame retardant and machinable. This device has two parallel anode plate, unlike traditional PEM electrolyzer setups. Since the TiO_2 deposition limits the electrogeneration of iron ions, the reactor is equipped with a

stainless-steel anode. The titanium dioxide-coated photoanode is placed almost adjacent to the quartz glass to ensure that a sufficient amount of Ultraviolet light hits the photoactive layer. Like in the typical PEM electrolyzer, a sacrificial anode is placed near the proton exchange membrane.

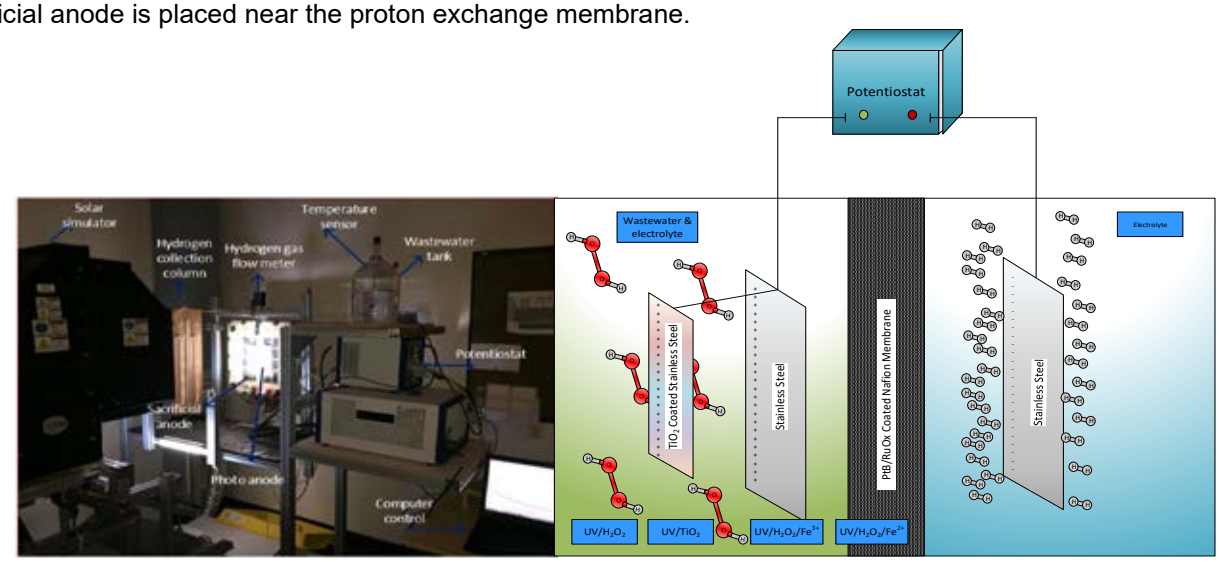

Fig 1. (a) The experimental setup, (b) The reaction mechanisms

In this study, Gamry 3000 high-performance Potentiostat/Galvanostat/ZRA is used, which has a maximum electrical potential and current of ±32 Volts and ±3 A respectively. In order to provide additional supply to the potentiostat, Gamry Reference 30K Booster is connected to the potentiostat which raises the current limit up to ±30 Amps with compliance limits of +20 and -2.5 V. Characterizations of photoanodes are performed with the potentiostat in various modes including linear voltammetry, cyclic voltammetry, potentiostatic, galvanostatic and open circuit potential. The potentiostat is also used for supply and record electrical input to the reactor. Also, analytical methods are used to determine chemical oxygen demand, decolorization and electro-generated iron ions are introduced. Open and colorimetric closed reflux methods measure the COD. Mercury (II) sulfate, sulphuric acid, potassium dichromate used as the digestion solution, while sulphuric acid and silver sulfate is used as the sulphuric acid reagent. Iron concentration and decolorization assessments are performed based on spectrophotometric methods.

ANALYSIS

The reactions of an anode and cathode of a PEM electrolyzer for water splitting can be given as follows:

$$H_2O \rightarrow O_2 + 2H^+ + 2e^- \quad (1)$$

$$2H^+ + 2e^- \rightarrow H_2 \quad (2)$$

This reaction requires 1.23V theoretically in acid mediums. However, the true cell voltage is higher such as 1.8-2.0 V. Hydrogen production is directly linked to the features of the O_2 evolution at the anode side. One of the methods to reduce the energy requirement in this process is replacing the anodic reaction of the oxygen generation with the oxidation of iron ions electrochemically (Navarro-Solís et al., 2010). The theoretical energy demand of the reaction is $\Delta G^0 = 74.2\ \mathrm{kJ/mol}$, which is 162.9 kJ/mol less than the oxygen evaluation reaction in water electrolysis. The Fenton type reactions take place with the presence of H_2O_2 and iron ions in an acidic medium. Hydrogen peroxide reacts with the iron catalyst and generates hydroxyl radicals. (Ghiselli, Jardim, Litter, & Mansilla, 2004) where the addition (or generation from Fe^{2+}_{aq}) of Fe^{3+}_{aq} increases the radical chain mechanism. Any process that speeds up the reduction of ferric ions to ferrous can be used for the reaction chain as a catalyst. This is accomplished electrochemically in electro-Fenton processes. A method to speed up this reaction is through Ultraviolet/V light irradiation (Machulek, Quina, & Gozzi, 2012). The ultraviolet light can also be applied in the mechanism of H_2O_2 decomposition through photochemical reactions for the production of hydroxyl radicals (Bensalah, Chair, & Bedoui, 2018). The performance evaluation of PEM electrolyzers can be made via several criteria. Among them, energy efficiency is one of the most commonly used assessment methods. One of the definitions of energy efficiency for the electrolyzer is the ratio of total energy consumption by the electrolyzer to the potential amount of heat released by the combustion of the produced hydrogen. Further information on the theoretical background, experimental setup, results, and interpretation can be found in the thesis study. (Demir, 2018). For the PEC system, energy and exergy efficiencies are defined as follows:

$$\eta_{PEC} = \frac{\mathrm{HHV}_{H_2}\dot{m}_{H_2}}{W_{in}}\ ,\ \psi_{PEC} = 1 - \frac{\sum \dot{E}x_d}{\dot{E}x_{in}} \quad (3)$$

RESULTS AND DISCUSSION

Fig. 2(a) shows the KHP degradation and hydrogen production in the PEC reactor after 40 minutes of operation. 17.6 mg of hydrogen is produced at the end of the photoelectrochemical reaction at 20°C and it increases to 22.6 mg at 60°C. Moreover, the temperature also has a positive effect on the COD removal process. The COD removal efficiency of the system rises from 44% to 87% with the increasing temperature from 20°C to 60°C. Furthermore, the performance of the PEC reactor is also tested in the decolorization aspect. The textile wastewater with 0.0014 M Reactive Black 5 dye is treated in the PEC reactor for 5 hours, and at the end of each one hour, 10 ml of sample treated water is collected and pictured. The highest color change is observed in the first 3 hours then it decolorization process slows down. Fig. 2 (b) shows the change in absorbance values during the 5 hours operation of the PEC reactor. Since the excess iron ions generation occurs in the reactor, which does not react with hydrogen peroxide, a yellowish colored solution is formed (yellow for Fe^{3+} and light green for Fe^{2+}) and the absorbance values are obtained higher than expected. Hence, to see the impact of Fenton type reactions on the wastewater, iron ions are precipitated in higher pH levels with NaOH to form $Fe(OH)_2$. The optical transmittance of the treated sample is increased considerably during the operation time of 5 hours.

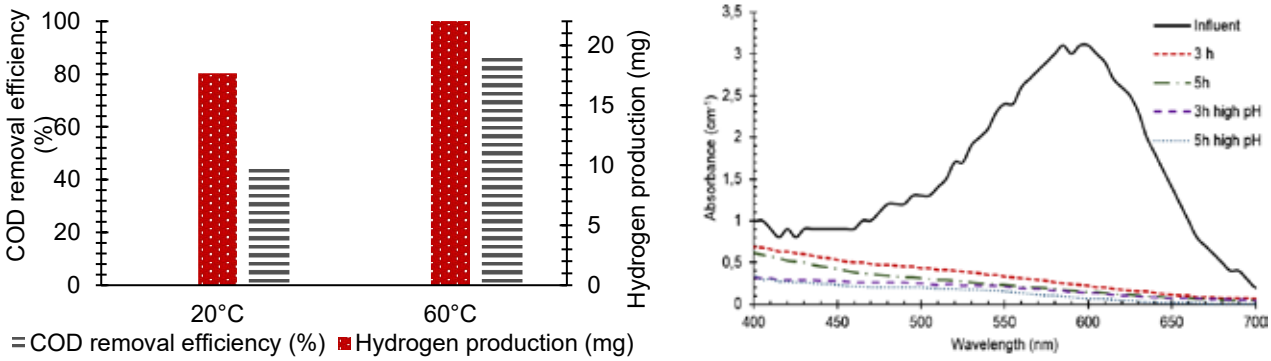

Fig. 2 (a) KHP degradation and hydrogen production in the PEC reactor under different temperatures. (b) Optical absorbance of textile wastewater (RB5 solution) in the PEC reactor during 5 hours of operation.

The overall energy and exergy efficiencies of the PEC system under 40˚C and 1.5 V cell potential are calculated as 81% and 80% respectively. As the solar energy input of the system is too large and the light to hydrogen conversion efficiency is relatively low, any small change in solar irradiance dominates the energy and exergy efficiency definitions. In order to better understand the system performance, solar input of the system is not included in these calculations and modified efficiency definitions results are obtained and presented instead.

CONCLUSIONS

Some concluding remarks are extracted from this study as follows:

- The overall energy and exergy efficiency of the PEC system under 1.5 V of cell potential, 40°C of operating temperature, and 600 W of solar irradiance are calculated as 81% and 80% respectively.
- The maximum hydrogen production rate of the PEC system is obtained as 33.9 mg/h at 2.3 V of cell potential and 60°C operating temperature.
- The COD removal efficiency of the PEC system rises from 44% to 87% with the increasing temperature from 20°C to 60°C.
- The hydrogen production rate of the PEC system rises from 26.7 mg/h to 33.9 mg/h with the increasing temperature from 20°C to 60°C.

IMPROVING CATALYTIC ACTIVITY OF SUPPORTED PRECIOUS METAL CATALYSTS FOR HYDROGEN PRODUCTION BY HYDROTHERMAL CONVERSION PROCESSES

*Sibel Irmak

ABSTRACT

Development of highly active and robust catalysts for hydrothermal conversion of biomass-derived compounds to hydrogen is the most effective way for economically feasible hydrogen production. Precious metal catalysts have been known to be active catalysts for hydrogen production. Since precious metals are expensive these catalysts are widely used in the supported form for recycling.

In the present study, following strategies were applied to increase and improve activity of supported Pt catalysts to be used in hydrothermal conditions for hydrogen production from organic-rich biomass-derived feeds: (i) integrating non-expensive metals into catalyst system, (ii) using different precursors for metals, and (iii) evaluating various carbon supportive materials with enhanced properties. The catalysts were prepared by wet impregnation method that followed by chemical reduction and thermal activation processes.

The results showed that use of different precursors for Pt did not change activity of the catalysts. Co-deposition of W or Ni with Pt showed promising activity. Catalytic performance of the catalyst considerably improved by changing the type of carbons used as support for metal deposition. However, each carbon studied brought its own drawback that indicates there is a need to develop new carbons with unique properties to maximize catalytic activity of the supported metal catalysts.

Keywords: Precious metal supported catalysts, Carbon, Hydrogen, Biomass.

INTRODUCTION

The main challenge for upscaling of hydrothermal conversion technologies for large scale hydrogen gas production is the lack of catalysts that show high activity in hydrothermal conditions. Although research efforts have been made so far significantly improved catalytic activity of supported precious catalysts towards hydrogen [1-2], activity and selectivity of these catalysts are still needed to be improved further for advancing the utility of hydrothermal gasification technologies for hydrogen gas production.

The reason for low activity of the supported precious catalysts in hydrothermal conditions is the deactivation of the catalysts because of following reasons: oxidation of catalyst surface, leaching/sintering of metals from the support or aggregation/poisoning of the metal particles [3]. Following strategies can be applied to improve catalytic activity of the catalysts and lower the deactivation process: ●using a carbon-based catalyst support with enhanced properties for better catalytic action (mechanical strength, high porosity, high surface area, thermal stability, multiple active sites, etc.) [4], ●using different precursors for metals for effective deposition, ●integrating non-expensive metals into precious metal catalyst system to increase resistance of metals to sintering, leaching, poisoning, and carbon deposition [5], and ●doping a heteroatom (e.g., N ad S) into carbon network to improve the stability of deposited metal particles [6]. First three strategies were investigated to improve catalytic performance and stability of the carbon supported Pt catalysts in the present work. The catalysts were evaluated for gasification of simple biomass model compound, glucose, for hydrogen gas production by aqueous-phase reforming (APR) as one of the hydrothermal gasification processes. APR has the potential to produce hydrogen from biomass-derived compounds in aqueous medium under mild reaction conditions (225-265 °C and 2.7-5.4 MPa) that reduces the cost of the procedure [2, 7-9].

MATERIALS AND METHODS

Preparation and characterization of the catalysts: The metal particles were deposited on various carbon supports (graphene, single-walled carbon nanotube and activated carbon in monometallic and bimetallic compositions by wet impregnation. All catalysts were prepared in the total of 8% metal content. Bimetallic catalysts were made of 4% precious metal (Pt) and 4% non-precious metal (W) content. Following precursors were used for preparation of metal nanoparticles: H_2PtCl_6, $PtBr_2$, $PtCl_2$, $NiCl_2$, and $(NH_4)10W_{12}O_{41}$ that are all soluble in water. The metal precursor(s) were dissolved in water and mixed with carbon support at room temperature, magnetically stirred for 30 min and sonicated for 10 min. Then, $NaBH_4$ solution were added drop by drop to reduce the metals on the carbon support.

The solid fraction was heated under flowing H_2 gas at 300°C in a tube furnace. Liquid fraction was kept for determination of undeposited metal contents. Size and distribution of the metal particles were determined by transmission electron microscopy (TEM). X-ray diffraction and BET surface area measurement were also performed to determine important information on structure and physicochemical properties of the catalysts. Actual concentrations of metal nanoparticles deposited on the support were determined by inductively coupled plasma (ICP) using liquid fraction collected after $NaBH_4$ treatment.

Evaluation of the catalysts for hydrogen gas production: Hydrogen gas production activity of the catalysts were evaluated by APR of glucose solution (7.5 g/l). The gasification experiments (APR) were carried out in a Parr 4520 benchtop 600 ml stainless steel reactor equipped with magnetic drive stirrer and a temperature control system. 350 ml glucose solution and 0.1750 g catalyst were placed in the reactor. The air in reactor was purged with argon inert gas before APR. Gasification was performed at 250°C for 1.5 h. After 1.5 h APR process, the reactor was quickly cooled down to room temperature using an ice-water bath. This step took several minutes. Then, the gas mixture produced was collected into a gas burette filled with water to determine the volume of the gas mixture produced.

Analysis of gaseous products: Gas products were characterized using a gas chromatograph with thermal conductivity detector (TCD) (Thermo Scientific Trace 1300). Argon was used as carrier gas. The column was Carboxen 1010 plot fused silica capillary (30mx0.53mm). Triplicate gas mixture (250 µl) was injected into GC with 1:3 split injection mode. The GC was programmed at 40°C for 3 min, increased at 20°C/min to 230°C and maintained at this temperature for 10 min. Inlet and detector temperature were 230°C and filament was at 360°C. The column flow and reference flow were 40 ml/min and 5 ml/min, respectively. The standard gas mixture was composed of acetylene, ethylene, ethane, methane, carbon monoxide, carbon dioxide and hydrogen.

RESULTS AND DISCUSSION

Evaluation of different carbon materials as catalyst supports for platinum metal particles: Catalytic performance of single-walled carbon nanotube (CNT), graphene and activated carbon supports were compared. Despite graphene supported Pt catalyst produced least volume gas mixture, the composition of the hydrogen in this mixture were the highest and not diluted with other gases in the same extent as in other catalysts (Table 1).

Table 1. APR of glucose using different carbon supported Pt catalysts

Carbon support	Gas mixture produced (ml)		Gas Composition (ml)[1,2]		
		H_2	CO_2	CO	CH_4+ C_2H_2
CNT-single walled	568 ±13	298 ±14	215 ±12	29.6 ±1.3	25.4 ±3.7
Graphene	373 ±15	322 ±19	19.9 ±2.5	30.6 ±3.1	n.d.
Activated carbon	594 ±10	308 ±10	255 ±12	25 ±6.1	10.4 ±5.1

[1] The calculation made using ideal gas equation: n_{total}=PV/RT. P=1 atm, T=300 K, V= volume of gas mixture produced. $n_{hydrogen}$ = n_{total} * hydrogen composition/100. [2] n.d. not detected

Production of lower gas mixture in graphene support is attributed to extensive stacking between graphene layers. Van der Waals interactions between surfaces lead to graphene sheets to stack on top of each other and surface area between graphene layers becomes inaccessible. This reduces number of active sites in the catalyst structure. If stacking the graphene layers could be lowered in some extent, the activity would considerable increased.

Evaluation of different Pt precursors: H_2PtCl_6, $PtBr_2$ and $PtCl_2$ precursors were deposited on graphene support at the same conditions. Although the size of Pt particles deposited on graphene support were different, the catalytic activities of the catalysts were similar (Fig. 1). The sizes and distributions of Pt particles on graphene were relatively small with uniform and narrow dispersion in $PtCl_2$ compared to the catalysts prepared with other precursors. The presence of different halogens (Cl and Br) in different quantity in the precursors might affect the morphology of the Pt nanoparticles [10].

Integrating non-expensive metals into Pt metal catalyst: The metal particles were deposited on graphene in monometallic (Pt and W) and bimetallic compositions (Pt-W). The particle size of the metal particles became larger when the catalysts were prepared in bimetallic composition. Integrating non-precious metal, W particles into Pt particles on graphene support created a positive synergy and the catalytic performance of the catalyst significantly enhanced (Fig. 2).

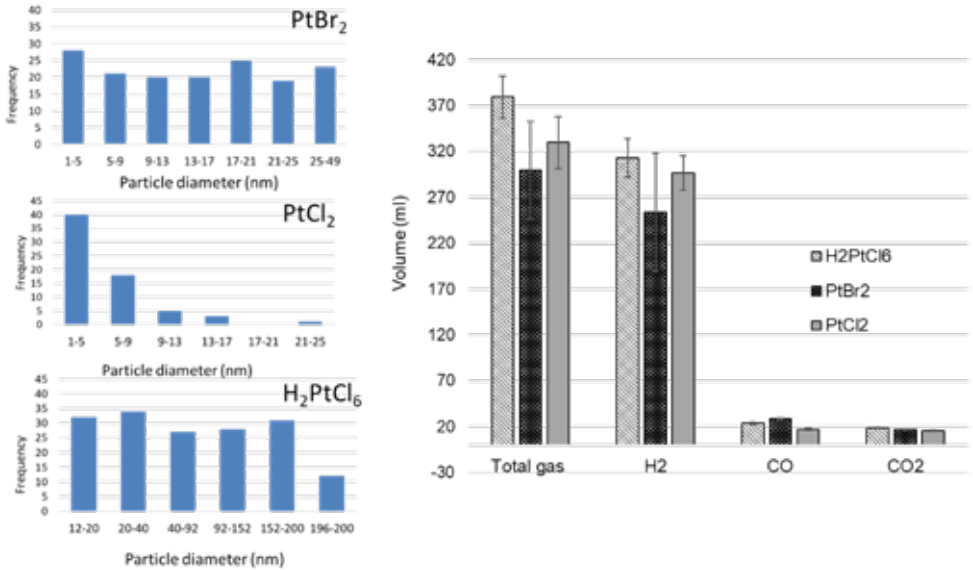

Figure 1. Particle size distributions of the catalysts prepared with different platinum precursors and gasification performance of the catalysts.

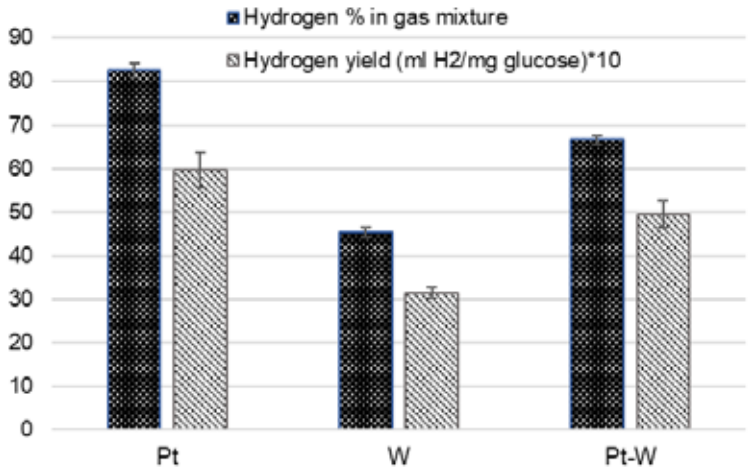

Figure 2. Comparison of gasification performance of the graphene supported Pt catalysts with W catalysts.

CONCLUSIONS

Graphene showed promising catalytic performance as catalyst support for hydrogen gas production. However, extensive stacking between graphene layers should be reduced to improve activity further by increasing surface area. This can be done by partial oxidation of the graphene layers by various treatments. Co-deposition of non-expensive W and low quantity of Pt on modified graphene support could result in highly active and robust catalysts.

THERMODYNAMIC ANALYSIS OF BIOGAS-TO-SYNGAS CONVERSION WITH DRY OXIDATIVE REFORMING AND CH_4 RECYCLING USING ASPEN HYSYS

*Pali Rosha and *Hussameldin Ibrahim*

ABSTRACT

Syngas synthesis from biogas through the dry oxidative reforming route was studied using an Aspen HYSYS simulator. This study dealt with the biogas-to-syngas conversion process's feasibility; initially, the simulation outcomes concerning O_2 effects in dry oxidative reforming, followed by their parametric optimization w.r.t. temperature and O_2/CH_4 ratio, were studied. The simulation outcomes of reported work revealed that the CH_4 conversion influenced primarily by O_2 injecting, particularly at lower temperature range. At all temperatures, CO_2 conversion was found to be less in dry oxidative reforming when compared to dry reforming, but the conversion rate improved at 0.20 O_2/CH_4 ratio. Further, the CH_4 recycling loop showed positive effects in CH_4 conversion and CO_2 emission reduction. For model validation, the simulated outcomes were compared with the previous experimental study in biogas reforming was carried out using pure nickel nanoparticles. Overall, the study infers that the dry oxidative reforming integrated with CH_4 recycling can be an enviro-friendly route for syngas production.

Keywords: Biogas, hydrogen, CH_4 recycling, Hydrocarbon reforming, Aspen HYSYS.

INTRODUCTION

Fossil fuels are a more significant threat to energy security since they are finite in quantity; however, once the Earth's oil is depleted, there will be no energy security without green energy technologies. Moreover, the environment is being severely affected by the excessive use of non-renewable energy resources, such as petrol, diesel, coal, and natural gas. In this regard, focusing on renewable energy resources, various researchers have contributed to produce biomass-derived renewable (biodiesel, biogas, hydrogen, syngas, etc.) fuels [1]. Various techniques currently produce syngas; likewise, catalytic reforming, pyrolysis, and gasification using different feedstocks [2]. In addition, all these techniques above require a vast amount of energy during operation and emit carbon dioxide (CO_2), contributing to climate change.

Syngas as a gaseous fuel is that form of energy source, which isn't gift naturally. The catalytic reforming strategies presently available consist of steam reforming, dry reforming, and partial oxidation. Dry reforming, which makes use of CH_4 and CO_2 as reactants, is an effective approach to make use of greenhouse gases. This approach usually needs excessive energy because of its endothermicity, proscribing its suitability to put in force industrially [3]. Moreover, the catalyst deactivation has additionally emerged as extreme difficulty in dry reforming reactions; thus, to boom reforming catalysts' operational balance, various oxide supports, and promoters had been efficiently investigated with the aid of using diverse researchers [4]. A detailed literature survey reviewed Pakhare et al. stated that non-noble catalysts provide better catalytic activity; however, higher coke formation makes it unsuitable for long-time stability [5]. Thus, to lessen energy input and coke formation on the catalyst in the dry reforming process, one such technique, i.e., dry oxidative reforming, has been proposed by various researchers [1,6]. Dry oxidative reforming utilizes CH_4 and CO_2 as reactants, as well as O_2 as an oxidant to limit catalyst carbon deposition and initiate exothermic reactions.

Few experimental studies are available in open platforms investigating the influence of O_2 addition in terms of reactant (CH_4 and CO_2) conversion and product (H_2 and CO) yields [7, 8]. However, the literature lacks a simulation study that needs to be done for better process understanding and optimizing the parametric conditions. The thermodynamic-based simulation studies are necessary as they provide a footprint to predict performance parameters required for reactor design. In the presented work, the injecting O_2 together with CH_4 and CO_2 into the Gibbs reforming reactor has been completed to get advantages of the reaction exothermicity in the dry reforming. Emphasis was given to the CH_4 recycling loop in the simulation flowsheet and the effect of O_2 addition in dry reforming reactions. Findings of a few reported studies have been referenced inside the text for result validation.

MATERIALS AND METHODS

Aspen HYSYS software was employed as a process simulator, and for optimization purposes, the Peng-Robinson fluid package was used. The assumptions considered were: (1) Biogas with 0.6 CH_4 and 0.4 CO_2 content, and oxidant O_2 in the range between 0-0.20 as for CH_4 volumetrically; (2) Calorific value of CH_4 is 55.5 MJ/kg; (3) Reforming reaction runs were at 1 bar and temperature (range: 450-700°C); (4) 0.1 bar pressure drop in the Gibbs reactor, heater, and cooler; (5) Purely thermodynamic-based study, thus, no catalyst-related aspects taken into account. A

detailed process layout is shown in Fig.1. It incorporates a mixer (M), heater (H), Gibbs reactor, cooler (C), compressor (CR), and component splitter (CS). The streamlines of CH_4 and CO_2 were initially mixed through a mixture; then, O_2 was added by varying O_2/CH4 ratio. All reactant streamlines were passed into the mixture before the heater. Subsequently, this high-temperature stream was fed into the Gibbs reactor to get a syngas product stream. The cooler was used to reduce the enhanced temperature of CH_4 (unreacted); following this, and the unreacted CH_4 is ready for reuse.

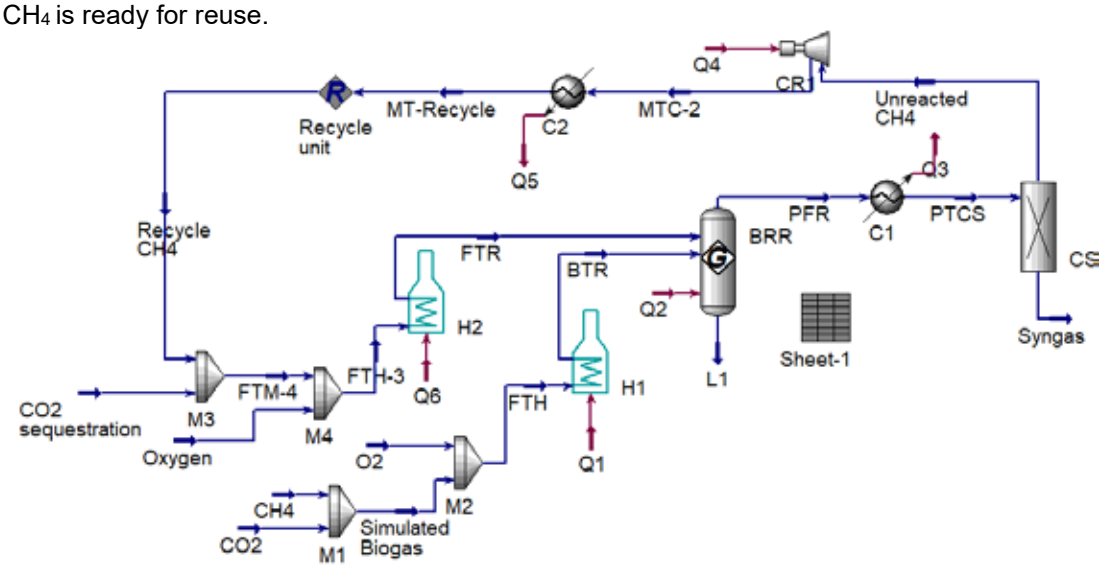

Fig. 1. Process flow diagram for syngas production

RESULTS AND DISCUSSION

EFFECT OF O_2 ADDITION

Table 1 depicts the O_2 effects in terms of reactant (CH_4 and CO_2) conversions, H_2 production, and product (H_2/CO) ratio. Results indicated that as the temperature increases from 450 to 700°C, the reactant conversion enhances. At 450°C, in dry reforming, the maximum CH_4 conversion attained was 6.5%; after that, at 500, 550, 600, 650, and 700°C of temperature, the conversion values were 12.3, 21.2, 32.9, 45.7, and 56.2%, respectively. This enhancement in conversion values was due to increased reaction temperature, which shifts reaction equilibrium to product (H_2 and CO) side [9]. After adding O_2, an improved CH_4 conversion was noticed, stating that the O_2 affects positively on the conversion rate. Contrary, it was also observed that CO_2 conversion reduced in dry oxidative reforming than dry reforming. This statement is consistent with the reported study, which mentioned that exothermic reactions are more dominated at lower temperatures [10]. On the other side, in dry oxidative reforming, the H_2 production and H_2/CO ratio followed an upward trend at all temperature ranges when compared to dry reforming. Further, upon comparing the potential of temperature and O_2 to enlarge H_2 production, it was identified that the lower temperature of 500°C utilized O_2 co-feeding more effectively than all other temperatures.

Table 1. Simulation outcomes summary w.r.t. A=CH_4 conversions; B=CH_4 conversion; C=H_2 production; D=H_2/CO ratio

	O_2/CH_4 =0				**O_2/CH_4 =0.10**				**O_2/CH_4 =0.15**				**O_2/CH_4 =0.20**			
Temp. (ºC)	A	B	C	D	A	B	C	D	A	B	C	D	A	B	C	D
450	6.5	15.5	0.06	0.55	11.6	1.2	0.08	1.13	14.3	-4.7	0.10	1.45	14.3	-4.7	0.10	1.45
500	12.4	27.1	0.11	0.63	17.7	12.4	0.15	0.96	20.6	5.8	0.17	1.14	20.6	5.8	0.17	1.14
550	21.2	42.7	0.21	0.71	27.3	28.6	0.26	0.92	30.4	22.0	0.28	1.03	30.4	22.0	0.28	1.03
600	33.0	60.8	0.35	0.79	40.2	48.2	0.41	0.95	43.7	42.0	0.44	1.02	43.7	42.0	0.44	1.02
650	45.7	77.8	0.51	0.87	54.6	67.5	0.59	0.99	58.6	62.0	0.63	1.05	58.6	62.0	0.63	1.05
700	56.3	90.1	0.65	0.94	67.6	82.5	0.77	1.04	72.3	78.0	0.81	1.09	72.3	78.0	0.81	1.09

EFFECT OF CH_4 RECYCLING

Table 2 presents the CH_4 recycling effects on CH_4 conversion and H_2 production. As discussed previously, the reactant conversion and product yield values increase or decrease owing to the increment and decrement in

conversion values. Further, the reuse of unreacted CH_4 showed positive CH_4 conversion and H_2 production effects. Specifically, at 500°C, the CH_4 conversion was 21.7%; after using the recycling loop, 38.6% of CH_4 conversion value and 0.308 kg mole/h of H_2 production rate were observed. It is clear from the simulation outcomes that reusing unreacted CH_4 enhances CH_4 conversion and H_2 formation.

Table 2. Simulation outcomes summary regarding CH_4 recycling in terms of CH_4 conversions and H_2 production

Temp. (ºC)	CH_4 conversion (%)		H_2 production (Kg mol/h)	
	without recycling	with recycling	without recycling	with recycling
450	15.4	33.8	0.10	0.25
500	21.7	38.7	0.17	0.31
550	31.6	46.4	0.29	0.41
600	45.0	56.9	0.45	0.54
650	60.2	68.8	0.64	0.71
700	74.0	79.6	0.82	0.87

CONCLUSIONS

It is concluded that CH_4 conversion is primarily influenced by O_2 addition, particularly at lower temperatures. However, CO_2 conversion was lower in dry oxidative reforming over all temperature ranges compared to dry reforming. Moreover, the CH_4 recycling showed positive effects on the reactant conversion values. In summary, the simulated study indicates that the dry oxidative reforming process was found to be an eco-friendly route for renewable syngas production. It is also recommended that a detailed experimental study be required to incorporate recycling units better to understand the process in terms of industrial implementation.

ABSTRACT

Fluidized bed gasification is considered one of the most well-known methods in the thermochemical conversion route for renewable fuel production. Several experimental studies were reported in the open literature on downdraft gasification using different biomass feedstocks. In this study, an initiative was made to assess the feasibility of co-gasifying algae-plastic waste mixtures using an Aspen Plus simulator. Simulation results demonstrated that the algae-plastic waste co-gasification enhances H_2 content in the gaseous product distribution. The effect of gasifier temperature is more prominent in energy-efficient product formation; moreover, plastic loading enhanced H_2 production to a greater extent. At the same time, CO_2 formation increased due to more carbon conversion after improving O_2 content in the gasifier. Hence, the findings can produce energy-efficient renewable fuel that simultaneously addresses the waste disposal concern. Also, the study can serve as a guideline for future experimental studies.

Keywords: Co-gasification, Algae, Plastic waste, Hydrogen, Aspen plus.

INTRODUCTION

Currently, a significant portion of the world's energy demands is fulfilled by fossil (coal, oil, and natural gas) fuels. Furthermore, the overuse of fossil fuels as energy sources causes destructive environmental impacts, i.e., acid rain, global warming, natural resource depletion, air pollutants, and so on [1]. In this context, the biomass-to-energy sector is growing worldwide, as biomass waste is already a surprisingly large energy source [2]. Biomass wastes are predominantly municipal solid wastes, agricultural residues, wood, and so on, being investigated worldwide as a potential renewable energy resource [3]. Moreover, microalgae-based renewable fuels provide substantial opportunities to satisfy the worldwide energy requirement, offering zero-carbon solutions and permitting CO_2 mitigation from the open environment [4]. Contrary, the increased worldwide energy demand led to increased waste disposal issues. Generally, plastic wastes are hard to process because of their heterogeneity, quality, and composition [5].

Literature reveals that gasification is the most prominent biomass-to-energy conversion process, offering higher efficiency with minor environmental effects [6, 7]. The produced gaseous effluent comprises H_2, CO, CO_2, and CH_4, while syngas (H_2 and CO) are readily processable to produce green chemicals and/or fuels [8]. Syngas formed via gasification offers lower calorific value, which limits its applicability in terms of power generation [9]. It is expected that the syngas heating value can be improved with the co-gasifying approach, such as algae-plastic waste co-gasification [10]. H_2 is counted as an energy-efficient alternative fuel, energy carrier, and vector; it has the highest calorific value (119.9 MJ/kg) when compared to other fuels [3]. H_2 is likewise probable to contribute almost 34% of the total renewable energy supply of 69% by 2050 [11]. In addition, the usage of blended biomass might also additionally increase H_2 proportion in the product stream of gasifier; as extensive quantity of literature mentioned that the H_2-enriched feedstock may be an H_2 donor to the H_2 low biomass [12, 13].

In the reported study, the main focus is to examine H_2 production by co-gasification route using algae and plastic waste mixture as a feedstock. Concerning novelty, this study seems to be the first study of its kind that presents a simulation for H_2-enriched gaseous fuel production through co-gasification algae-plastic waste mixture using Aspen plus simulator that have not been reported yet elsewhere. The use of computer simulation yields a better understanding of the overall system and is a handy tool in support of design. It is anticipated that the model will help understand the general process's behavior without undertaking laborious, high-cost involved time-consuming experiments. Aspen Plus is essential software for chemical process design and can be used to simulate the gasification systems of solid feedstocks [24, 25]. Han et al. [25] worked on the gasification reduction zone with a chemical restricted equilibrium model to offer the overall performance statistics of the incorporated biomass to the liquid system. The version became efficiently proven with experimental statistics of downdraft gasification, with high-quality accuracy on principle bio-syngas compositions. Tavares et al. [26] said that steam (gasifying agent) improves H_2 content and improved gaseous product calorific value when compared with air. This simulation takes a look at investigating the feasibility of co-gasifying algae and plastic waste combinations using Aspen Plus simulation software.

MATERIALS AND METHODS

Aspen PLUS software was employed as a process simulator, and for optimization purposes, the PR-BM fluid package was used. In this simulation model, the assumptions considered were: (1) Feedstock feed rate was 100 kg/h at 30°C and 1 bar; (2) Steady-state process; (3) Major volatile components are H_2, CO, CO_2, H_2O, and CH_4; (4) Ash as an inert material. The process performance was assessed w.r.t. LHV (lower heating value), CCE (carbon conversion efficiency), and ER (equivalence ratio). Fig.1 shows the complete layout of the process flowsheet. Initially, algae-based biomass stream was passed through the dryer to reduce moisture content. Then, a splitter block was employed to separate dry (DTS) feed and moisture. The ash was separated from the mixed (MTC) stream using a cyclone block, and, after that, the volatile matter was fed to the partial oxidation block followed by a gasification block.

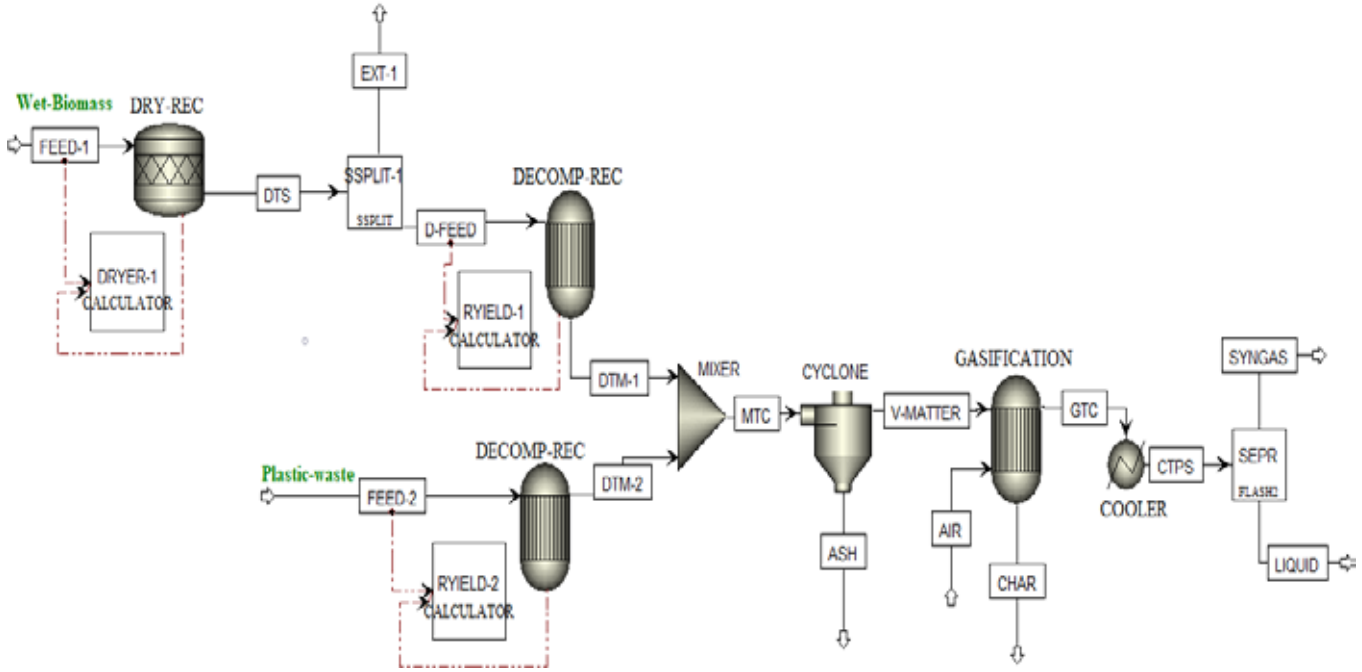

Fig. 1. Process flow diagram for H_2-enrcihed gaseous fuel production

RESULTS AND DISCUSSION

TEMPERATURE EFFECTS ON SYNGAS COMPOSITION, LOWER HEATING VALUE, AND CARBON CONVERSION EFFICIENCY

Table 1 presents the gaseous product distribution w.r.t. H_2, CO, CO_2, and CH_4 at temperatures between 550 and 900°C. Results revealed that the H_2 proportion increases with rising temperature from 550 to 900°C, whereas CO_2 content was found to be decreased w.r.t temperature. It was observed that the lower heating value and carbon conversion efficiency improved with a rise in temperature up to 850°C and, after that, been constant at higher temperatures (>850°C). These improved values enhance H_2 and CO production at the given temperature range. Simulation results demonstrated that the rise in equivalence ratio showed adverse effects w.r.t. H_2 and CO content in the product effluent.

Table 1. Simulation outcomes summary w.r.t. product distribution, lower heating value, and carbon conversion efficiency

Temp. (°C)	H_2 (%)	CO (%)	CO_2 (%)	CH_4 (%)	Lowe heating value (MJ/Nm^3)	Carbon conversion efficiency (%)
550	18.70	6.05	15.90	2.79	3.78	37.29

H_2 ENRICHMENT USING CO-GASIFYING TECHNIQUE

Table 2 highlights the effect of temperature and composition of feedstock on product distribution and lower heating value. The higher temperature favours H_2 production at all algae-plastic waste mixed feedstocks. In the co-gasification process, the thermal energy provided to the plastic waste is larger than the covalent bond strength energy; thus, the bond breakage occurs, and the plastic waste decomposes, which may include mostly H_2. The presence of plastic results in H_2 enrichment, along with decrement in CO and CO_2 using co-gasification.

Table 2. Simulation results w.r.t. product distribution and lower heating value by varying plastic waste content from 0 to 10%

Temp. (°C)	H_2 (%)			CO (%)			CH_4 (%)			CO_2 (%)			Lower heating value (MJ/Nm^3)		
	0	5	10	0	5	10	0	5	10	0	5	10	0	5	10

CONCLUSIONS

It is concluded that gasifier temperature plays an important role in energy-enriched product formation; however, higher equivalence ratio not showing noteworthy effects. An elevated temperature at optimal equivalence ratios facilitates gasification reactions, casing large tar cracking. Moreover, carbon conversion efficiency enhanced in the initial phase because of the synergy of temperature and air oxidant. In the co-gasification process, simulation results revealed that the feedstock composition varies the product distribution. The findings can produce energy-efficient renewable fuel through a co-gasification route that simultaneously addresses the waste disposal issue. Also, the study can serve as a guideline for future experimental studies.

ABSTRACT

A one-dimensional simplified heterogeneous reactor model is used to simulate both steam methane reforming and dry methane reforming (i.e., using methane and carbon dioxide) under hydrogen sulfide poisoning conditions – a key challenge to this method of hydrogen production. The proposed simulation utilizes the Temkin sulfur adsorption isotherm of Alstrup et al. [1] and a Maxted-type catalyst activity expression. The reactor model is solved using the finite volume method, and the complete simulation is written and optimized in MATLAB. The simulation is validated against the numerical results of Rout & Jakobsen [2] and the experimental data of Koningen & Sjörström [3]. It was found that the deactivation order for methane reforming, based on the results of Koningen & Sjörström, was $n = 1$ versus the order of $n = 3$ proposed by Rostrup-Nielsen [4]. Discussion is provided concerning differences in expected deactivation orders observed both in this study and in other investigations, and potential influences of sulfur coverage isotherms on estimated deactivation order.

Keywords: Catalyst deactivation, Sulfur poisoning, Hydrogen, Methane reforming, Reactor simulation

INTRODUCTION

It is well-understood that greenhouse gases are contributing to climate change, instigating unfavorable environmental changes and threatening natural disasters. One potential solution is the utilization of steam-methane reforming along with dry methane reforming (utilizing carbon dioxide instead of steam) for use in hydrogen, fuels, and chemical production. Both steam methane reforming and dry methane reforming have been well studied and thoroughly modeled in literature [5]. However, reforming catalyst sulfur poisoning is not frequently explored, with only a sparse collection of reactor modeling studies being available [6].

Methane reforming is generally described by the following stoichiometric equations:

$$\mathrm{CH_4 + 2H_2O \rightleftharpoons 4H_2 + CO_2} \quad (1)$$

$$\mathrm{CH_4 + H_2O \rightleftharpoons 3H_2 + CO} \quad (2)$$

$$\mathrm{CO + H_2O \rightleftharpoons H_2 + CO_2} \quad (3)$$

With methane dry reforming (being a combination of equations 2 and 3) expressed as:

$$\mathrm{CH_4 + CO_2 \rightleftharpoons 2H_2 + 2CO} \quad (4)$$

Catalyst sulfur coverage can be calculated as the ratio of the mass of sulfur adsorbed versus the empirically-determined catalyst sulfur capacity (representing the total mass of sulfur adsorbed at 100% surface coverage) [7]:

$$\theta_{\mathrm{S}} = \frac{w_{\mathrm{S}} M_{\mathrm{H_2S}}}{S_{\mathrm{p}} \rho_{\mathrm{p}}} \quad (5)$$

Of particular importance is the model for saturated sulfur coverage. A simplification of the adsorption isotherm presented by Alstrup et al. [1] is given by Rostrup-Nielsen [4]:

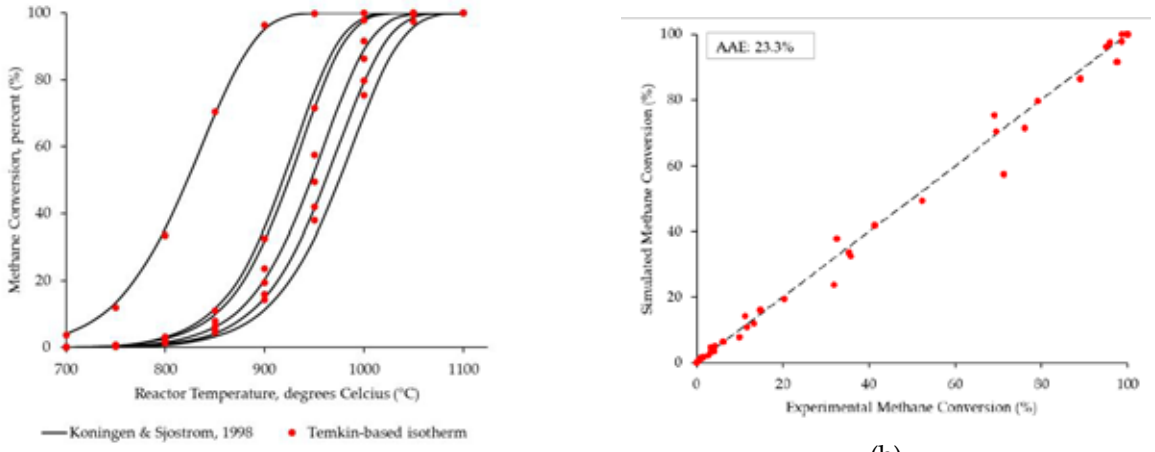
$$1 - \theta_{\mathrm{s}} = 0.293 \exp\left(-\frac{4300}{T}\right)\left(\frac{P_{\mathrm{H_2S}}}{P_{\mathrm{H_2}}}\right)^{-0.3} \quad (6)$$

Lastly, translation of sulfur coverage to residual catalyst activity is given by Rostrup-Nielsen [4], based on a Maxted-type representation of catalyst activity under poisoning conditions [8]:

$$r_{\mathrm{A}} = r'_{\mathrm{A}} * (1 - \alpha\beta\theta_{\mathrm{s}})^{n} \quad (7)$$

In this expression, α represents the number of adsorbed sulfur atoms per nickel atom at surface saturation while β represents the number of nickel atoms deactivated per adsorbed sulfur atom. With $\alpha = 0.5$ and $\beta = 2.0$, the catalyst's nickel active surface area coverage is taken as proportionate to the sulfur coverage of the catalyst.

MODELING & SIMULATION



A simplified heterogeneous reactor model is developed following the approach outlined by Rout & Jakobsen [2], but instead using a finite volume framework programmed in MATLAB. Utilizing the reaction rate expressions of Xu & Froment [9], validation of the reactor modeling program was done against the numerical results of Rout & Jakobsen [2], finding good agreement with respect to temperature profile and methane conversion.

Assessment of the experimental data presented by Koningen & Sjörström [3] requires first that the data be shown to satisfy a *quasi-uniform poisoning* condition. This condition identifies when the catalyst particle is small enough to assume that internal sulfur coverage gradients are negligible, and that the computed sulfur coverage at the catalyst surface is essentially the same as what is found throughout the catalyst particle. Taking the catalyst pellet center sulfur concentration to be 90% that of the pellet surface concentration at saturation (to evaluate a worst-case scenario), saturation time was found to be 0.2 seconds – implying that catalyst pellet poisoning was quasi-uniform. This, along with broad agreement with other kinetic criteria [10], provided sufficient justification to proceed with the use of a simplified heterogeneous approach. The expression for quasi-uniform poisoning saturation time is given as:

$$t_{\mathrm{sat,D}} = N_{\mathrm{D}}/N_{\mathrm{S,sat}} = \left(D_{\mathrm{eff}}\frac{\left(C_{\mathrm{H_2S,s}} - C_{\mathrm{H_2S,c}}\right)}{r_{\mathrm{p}}}\right)\Big/\left(\frac{S_{\mathrm{p}}\rho_{\mathrm{p}}}{M_{\mathrm{H_2S}}}\right) \tag{8}$$

RESULTS AND DISCUSSION

Simulated methane conversion compared well against Koningen & Sjörström [3], having an average absolute error of 23.3% - with underprediction of methane conversion observed at lower H_2S concentrations and overprediction observed at higher concentrations (see Figure 1). Notably, these results are only possible for a deactivation order of $n = 1$, versus the order of $n = 3$ presented by Rostrup-Nielsen [4]. However, methanation studies have suggested deactivation orders ranging from 1 to 2 [11, 12], to as high as 4.3 [13]. It is also worth considering the impact of different models for sulfur coverage on modeling residual catalyst activity at high H_2S concentrations. For example, utilizing the chemisorption isotherm presented by Wise et al. [14], which predicts lower sulfur coverage than Alstrup et al. [1], may result in a predicted order of deactivation of $n = 2$.

(a) (b)

Figure 1: Direct comparison of simulated versus reference methane conversions from Koningen & Sjörström [3] (a), and overall parity plot between simulated versus reference methane conversions. Data based on H_2S feed concentrations of 0 ppm, 25 ppm, 50 ppm, 100 ppm, 200 ppm, and 300 ppm, respectively.

CONCLUSIONS

The principal conclusions of this study are:

- A simplified heterogeneous fixed-bed reactor model was developed and validated to simulate the influence of hydrogen sulfide poisoning for methane steam and dry reforming. A quasi-uniform poisoning criteria (along with conventional criteria to verify kinetic control of methane conversion) was applied to verify it was appropriate to simulate the data of Koningen & Sjoström [3] using this approach.
- Assuming an order of deactivation of $n = 1$, good agreement was obtained between simulated and literature values for methane conversion under H_2S poisoning. An average absolute error of 23.3% was observed, with underprediction at lower H_2S feed concentrations and overprediction at higher concentrations.

- While the order of deactivation differs from what is directly presented for steam-methane reforming, it is inline with similar studies conducted for methanation. Further, variations in what is used to predict sulfur chemisorption may also significantly affect what is predicted for the order of deactivation.
- It is recommended that additional experimental work be completed to permit modeling of both sulfur chemisorption and residual activity for methane reforming catalysts, particularly at lower temperature operation (i.e., below 800°C) where they are most vulnerable to poisoning. It would also be interesting to see how such studies compare with sulfur poisoning studies conducted for other syngas processes.

ABSTRACT

The kinetics for crude glycerol autothermal reforming over 5% Ni/CeZrCa catalyst were studied using previous experimental work. An overall power law model was developed for autothermal crude glycerol reforming, with a frequency factor of 4.3×10^{10} (mol/min)/g_{cat}, an activation energy of 8.78×10^{4} kJ/mol, and orders of reaction for crude glycerol, water, and oxygen of 1.04, 0.54, and 1.78, respectively. The power law model featured an average absolute error (AAE) of 5.8%. Additionally, mechanistic models describing autothermal crude glycerol reforming were also developed for three primary sub-reactions: steam reforming of crude glycerol, total oxidation of crude glycerol, and carbon dioxide methanation. An Eley-Rideal (ER) type expression best described steam reforming of crude glycerol, featuring an AAE of 9.7%. A Langmuir Hinshelwood Hougen Watson (LHHW) type expression best described total oxidation, presenting an AAE of 14.6%. Lastly, carbon dioxide methanation was best represented by an ER type expression, featuring an AAE of 5.8%.

Keywords: Glycerol, Hydrogen, Kinetics, Reactor modeling, Autothermal reforming

INTRODUCTION

Net-zero emission fuels production, representing one of three key pillars (along with net-zero emission electricity and hydrogen production) to addressing greenhouse gas emissions, offers a fast route to decarbonizing otherwise difficult to manage use cases like commercial aviation, mechanised agriculture, and heavy construction. In the latter two cases, diesel fuel may be substitute with biodiesel – a fuel produced by the transesterification of animal fats and plant-based oils to produce fatty acid ethyl esters (FAEEs). However, glycerol ($C_3H_8O_3$) is produced as an unwanted and low-value co-product of transesterification. What is proposed as part of this study's overall program is the conversion of co-product glycerol into synthesis gas via autothermal crude glycerol reforming, where a supply of hydrogen can be generated for use in downstream biodiesel upgrading processes like hydrodeoxygenation.

A number of other investigators have considered glycerol reforming [1-3], but – to our present awareness – there does not seem to be a mechanistic analysis of the reforming of crude glycerol. Accordingly, kinetic data generated through the experimental work of Ghani et al. [4] was used to derive mechanistic rate expressions for the autothermal reforming of crude glycerol over 5% Ni/CeZrCa catalyst.

MATERIALS AND METHODS

Briefly, the experimental data of Ghani et al. [4] was derived for a representative crude glycerol mixture comprising of pure glycerol, methanol, potassium palmitate (i.e., soap), oleic acid (i.e., free fatty acid), and sodium and potassium chloride (i.e., ashes). Integral reactor tests were conducted under conditions ranging between 773 to 923 K, 0.05 to 0.20 oxygen-to-carbon ratio, 1.6 to 3.6 steam-to-carbon ratio, and space velocities between 12.71 and 158.23 g_{cat}.min/mol_C. Integral reactor tests were conducted to determine the rate of reaction under each condition. While a rudimentary power law model was developed, it remains desirable to propose and scrutinize mechanically postulated rate expressions in order to gain insights concerning the potential reaction steps involved in autothermal crude glycerol reforming. Following an approach similar to that of Liu & Lawal [3], the autothermal reforming of crude glycerol was subdivided into three (3) independent reactions: glycerol steam reforming, glycerol oxidation, and CO2 methanation.

Overall Autothermal Reforming Reaction	$C_{2.5}H_7O_2 + 0.7H_2O + 0.65O_2 \rightarrow 2CO_2 + 0.5CH_4 + 3.2H_2$	(4)
Glycerol Steam Reforming	$0.8C_{2.5}H_7O_2 + 2.4H_2O \rightarrow 2CO_2 + 5.2H_2$	(5)
Glycerol Oxidation	$0.2C_3H_8O_3 + 0.65O_2 \rightarrow 0.5CO_2 + 0.7H_2O$	(6)
CO_2 Methanation	$0.5CO_2 + 2H_2 \leftrightarrow 0.5CH_4 + H_2O$	(7)

For the sake of simplicity, crude glycerol was written out as pure glycerol in both the derived mechanistic rate expression as well as for the reversible and irreversible power law rate expressions.

Glycerol steam reforming was found to best match an Eley-Rideal type mechanism describing molecular adsorption of glycerol to the catalyst, followed by dissociation to ethylene glycol and formaldehyde, which then undergo reaction with gas-phase steam to produce carbon dioxide and water. In the case of total oxidation of glycerol, an LHHW mechanism featuring the molecular adsorption and surface oxidation of glycerol was found to be successful. Lastly, in the case of CO_2 methanation, it was found that an Eley-Rideal mechanism describing the methanation of surface-adsorbed carbon dioxide by hydrogen provided the best performance. The mechanisms are described in Table 1 below, and in the rate expressions that follow.

Table 1. Summary of successful glycerol reforming mechanisms

Glycerol Steam Reforming	Glycerol Total Oxidation	CO_2 Methanation
$0.8C_3H_8O_3 + S \leftrightarrow 0.8C_3H_8O_3$	$0.2C_3H_8O_3 + S \leftrightarrow 0.2C_3H_8O_3.S$	$0.5CO_2 + S \rightarrow 0.5CO_2.S$
$C_3H_8O_3.S \leftrightarrow C_2H_6O_2.S + CH_2O.S$	$0.65O_2 + S \leftrightarrow 1.3O.S$	$2H_2 + S \rightarrow 2H_2.S$
$C_2H_6O_2.S + H_2O \leftrightarrow 1.5CO_2 + 4.2H_2 + S$	$0.2C_3H_8O_3.S + 1.3O.S \leftrightarrow 0.5CO_2.S + 0.7H_2O.S$	$0.5CO_2.S + 2H_2 \rightarrow CH_3OH.S$
$CH_2O.S + 0.2H_2O \leftrightarrow 0.5CO_2 + H_2 + S$	$0.2C_3H_8O_3.S + 1.3O.S \leftrightarrow CH_2O_2.S + S$	$CH_3OH.S \rightarrow 0.5CH_4 + H_2O + S$
	$CH_2O_2.S \leftrightarrow 0.5CO_2.S + 0.7H_2O$	
	$0.5CO_2.S \leftrightarrow 0.5CO_2 + S$	

Rate Expression for Glycerol Steam Reforming

$$r_4 = k_0 e^{-\left(\frac{E_a}{RT}\right)} \times \left[\frac{\left(\frac{[A]^{0.8}[B]^{2.4}}{[E]^{1.5}[F]^{4.2}} - \frac{[F][E]^{0.5}}{K_{p(eq)}}\right)}{\left(1 + K_1[A]^{0.8} + \frac{K_W[A]^{0.8}[B]^{2.2}}{[E]^{1.5}[F]^{4.2}} + \frac{K_C[E]^{1.5}[F]^{4.2}}{[B]^{2.2}}\right)}\right] \quad (8)$$

Rate Expression for Glycerol Total Oxidation

$$r_2 = k_0 e^{-\left(\frac{E_a}{RT}\right)} \times \left[\frac{\left([A]^{0.2} - \frac{[E]^{0.5}[B]^{0.7}}{K_{p(eq)}[C]^{0.65}}\right)}{\left(1 + K_3[C]^{0.65} + K_6[E]^{0.5}[B]^{0.7} + K_B[E]^{0.5} + \frac{K_w[E]^{0.5}[B]^{0.7}}{[C]^{0.65}}\right)}\right] \quad (9)$$

Rate Expression for CO_2 Methanation

$$r_1 = k_0 e^{-\left(\frac{E_a}{RT}\right)} \times \left[\frac{\left([E]^{0.5} - \frac{[D]^{0.5}[B]}{K_{p(eq)}[F]}\right)}{\left(1 + K_{3(ads)}[D]^{0.5}[B] + \frac{K_{1(ads)}[D]^{0.5}[B]}{([F]^2)}\right)}\right] \quad (10)$$

RESULTS AND DISCUSSION

The models described here were the most successful in predicting the rate of each respective reaction. The glycerol steam reforming model featured an average absolute error (AAE) of 9.7%, with total oxidation having an AAE of 14.6% and carbon dioxide methanation presenting an AAE of 5.8%. Further, these models were also successfully tested against thermodynamic scrutiny criteria [5].

Power law rate expressions, in addition to the mechanistic expressions, were derived for each of the three reactions and compared favourably against other results found in literature. Activation energy in glycerol steam reforming was 89.1 kJ/mol, versus 103.4 kJ/mol [6] and 43.4 kJ/mol [7] for nickel-ceria catalyst, and 63.3 kJ/mol [2] for cobalt-nickel-alumina catalyst. Further, activation energies for the total oxidation and CO_2 methanation reactions were calculated to be 88.8 kJ/mol and 88.6 kJ/mol, respectively, versus the predicted 116.4 kJ/mol and 87.8 kJ/mol activation energies [8] predicted for each respective reaction over lanthanum oxide catalyst using methane.

CONCLUSIONS

The main findings of this study are as follows:

- The intrinsic kinetics of crude glycerol autothermal reforming (ATR) was studied over Ni/CeZrCa catalyst at conditions of 773 – 923 K at atmospheric pressure, steam-to-carbon ratio of 2.6, and oxygen to carbon ratio of 0.125. The intrinsic kinetic data provided by Ghani et al. [4] was not limited by heat or mass transfer, and

conditions were assumed to be far from equilibrium. The kinetics were studied following a power law approach as well as by proposing a number of kinetic mechanisms following the LHHW and Eley-Rideal frameworks.

- For steam reforming, it was found that the Eley-Rideal models best described the reaction rate, with ER 4 ultimately being chosen as the preferred model following thermodynamic scrutiny, possessing an AAE of 9.7%. This model reflected a rate-limiting reaction between adsorbed intermediate and steam.
- The most suitable model for total oxidation was found to be the power law model. Generally, LHHW-based mechanistic rate expressions performed better than those based on an Eley-Rideal style mechanism. The mechanistic model considering the molecular adsorption of crude glycerol was found to be the best mechanistic description, with an AAE of 14.6%.
- Lastly, the CO_2 methanation reaction was best described by an Eley-Rideal type mechanism considering the adsorption of carbon dioxide, presenting an AAE of 5.8%.

ABSTRACT

The production of hydrogen from various feedstock involves the catalyzation of various reactions for the generation of the desired product. Experimental studies provide an understanding of the reaction mechanism and the nature of the reactants and products of the reaction. Computational studies involving DFT provide even greater insights into these reactions. The pyrolysis of methane over various catalysts requires an efficient means of screening catalysts for the reaction. The reaction is an endothermic reaction that is associated with a high demand for energy to drive the reaction. A process associated with a reduced demand for energy and increased yield of hydrogen will make the pyrolysis reaction more efficient and more industrially applicable. A combination of DFT and ML provides a means of establishing catalytic descriptor-based predictions for the reaction. The prediction of the relaxation energies of doped group 10, 11 and 12 transition elements from their initial structures with the adsorbate ions at the different stages of the reactions provides a predictable path for the calculation of the Turnover Frequency of the reactions, suggesting the preferred catalyst for the reaction. This study seeks to establish a model for predicting catalytic activity in methane pyrolysis reactions at various operational conditions.

INTRODUCTION

Global demand for energy continues to increase, and hydrogen becomes a promising fuel to power our industrial machines [1]. Hydrogen can be produced by water electrolysis, thermochemical and biological methods. Among these, the biological process can be the most favourable because it requires less energy. The method of electrolysis of water requires a lot of energy and hence cannot be a viable alternative. Notwithstanding, it is often used when hydrogen is required in a highly pure form. Steam reforming, a type of thermochemical method, is often used to produce hydrogen and steam reforming of methane is most commonly done. Steam–methane reforming (SMR) is the current industrial method of choice for hydrogen production. However, the SMR process still suffers disadvantages from reactant properties and thermodynamics conditions of the reaction, which include insufficient catalytic activity, low long-term stability of reactant (methane), high production cost and high energy consumption, mostly due to the handling of large amounts of CO_2 co-produced [2].

With the growing need for hydrogen production, and the need to adopt a process that is sustainable and environmentally friendly, it becomes necessary to upgrade some of the existing industrial processes used for hydrogen production for effective management of raw materials such as methane while adopting technologies that are environmentally sustainable. Furthermore, catalysts with higher activity and stability necessary to control the reaction routes and also efficient reaction conditions such as temperature, pressure, feeding rate, type of reactor etc., have to be improved upon for efficient hydrogen production [2][3].

The pyrolysis of methane over molten metals provides an opportunity for carbon dioxide-free hydrogen production while co-producing solid carbon that has several industrial applications.

MATERIALS AND METHODS

This work involves ab initio investigation of molten metals as catalysts for the heterogeneous catalysis of hydrogen production via methane pyrolysis. It has been reported that metals that are active catalysts for methane (Ni, Pt, Pd, Cu, Ag, Au), when dissolved in Bi, an inactive low–melting temperature, produce stable molten metal alloy catalysts for pyrolysis of methane into hydrogen and carbon [4][5].

$$CH_{4\,(g)} \rightarrow 2H_{2\,(g)} + C_{(s)} \qquad \Delta H^0 = 75\,\frac{\text{kJ}}{\text{mol}} \qquad (1)$$

Experimental reports indicate the deactivation of solid catalysts, while the insoluble carbon would float to the surface in molten alloy systems in the reactor[4]. Hence the aim of this work is to simulate the structural and chemical properties of molten alloy systems of varying concentrations of active and inactive metals using ab initio molecular dynamics (MD) code of Car-Parrinello (CP) implemented in Quantum Espresso.
The specific objectives being carried out in the study include:

- Determine the kinetic and wavefunction cutoffs for the separate metal and metal alloy systems.
- Perform variable cell relaxation for separate active (Ni, Pt, Pd), inactive (In, Ga, Sn and Pb) and molten metal alloy systems containing different concentrations.
- Determination of density of states (DOS), projected DOS, D-band etc., to characterize the metal systems.
- Calculate the pair distribution functions, the local concentrations, and Bader charges for the constituent metal atoms as one approaches the surface of the liquid.
- Calculate the activation parameters for the dissociative adsorption of methane using a nudged elastic band (NEB)
- Calculate the adsorption energies of the adsorbate on the catalyst surface.
- Correlation of parameters such as concentrations with turn over frequency (TOF)
- Simulate the effect of temperature and pressure on the molten catalyst systems for the pyrolysis of methane.
- Predict catalytic performance and optimum operating conditions using machine learning models

PHOTOCATALYTIC GLYCEROL REFORMING ON GOLD - COPPER NANO METALLIC TiO_2

[1*] *Ramazan Yıldırım,* [1] *Pınar Özdemir*
[1]Department of Chemical Engineering, Boğaziçi University, 34342, Istanbul, Turkey

*Corresponding author e-mail: yildirra@boun.edu.tr

ABSTRACT

The photocatalytic reforming of glycerol was studied on gold-copper (Au-Cu) loaded titanium dioxide (TiO_2) photocatalyst with the aim of utilizing glycerol, which is the main by-product of biodiesel production, to produce hydrogen using solar energy. 0.2 wt. % Au, 1 wt.% Cu as well as 0.2% Au and 0.8 wt.% Cu containing photocatalysts were tested. The monometallic and bimetallic photocatalysts were synthesized by deposition precipitation with urea (DPU) and sequential deposition precipitation with urea (S-DPU) respectively and calcined in air at 400°C for 4h. Then the photocatalysts were tested in a photoreactor, equipped with 300 W xenon lamp, at ambient condition using 20 wt.% aqueous glycerol mixture. 0.2 wt.% Au loaded on TiO_2 produced H_2 with 1085 µmol/h.gcat production rate, which is comparable to that of 1 wt.% platinum (Pt) loaded on TiO_2. Then, it was concluded that Au/TiO_2 could be a more economical alternative for Pt considering that it produced the same results even thought its loading was five times lower.

Keywords: Glycerol, Au/TiO_2, Hydrogen production, Photocatalysis, Photocatalytic reforming

INTRODUCTION

The increasing world energy demand, which is supplied by fossil fuels, creates new challenges like global warming and climate change due to the emission of greenhouse gases; these challenges initiated worldwide search to find alternative and sustainable energy production processes from the renewable natural resources such as biomass, sun, wind, geothermal reservoirs, and tidal waves [1, 2]. The glycerol, as the main by-product of biodiesel production (10% of total yield) [3], can be also used as an alternative source for hydrogen production via photocatalytic process, and increase the feasibility of biodiesel production from renewable biomass. Additionally, some valuable products of glycerol such as dihydroxyacetone, glyceraldehyde, glyceric acid, hydroxypyruvic acid, and glycolic acid, which are used in food, cosmetics, and pharmaceutical industries, can be also produced more feasibly via the photocatalytic reforming [3, 4]. This way, the glycerol can be utilized in a simpler and more economical process that run under ambient conditions, than the high energy consuming conventional ways like stream reforming, fermentation, and esterification [4-6].

In literature, photocatalytic glycerol reforming has been conducted on especially TiO_2 nanopowder with precious or non-precious metals such as platinum (Pt), palladium (Pd), gold (Au), ruthenium (Ru) or copper (Cu), nickel (Ni), zinc (Zn) so as to get higher H_2 yield [4, 6]. Even though the mostly used monometallic photocatalyst Pt/TiO_2 is the most active, it suffers form O_2 and CO poisoning and more expensive than alternative ones like Au or Cu loaded TiO_2 [4, 7]. In this regard, Au and Cu were used as a mono and bimetallic catalyst on TiO_2 due to their nearest working function values and plasmonic effects under visible light condition to reduce the cost, prevent the oxygen and carbon monoxide poisoning and enhance H_2 production.

EXPERIMENTAL

1 wt.% Cu/TiO_2 and 0.2 wt.% Au/TiO_2, monometallic catalysts were prepared using DPU. 1.1 10^{-3} M aqueous solution of $CuCl_2$ (or $HAuCl_4.3H_2O$) in distillated water were added into 5 g of TiO_2 and 100 mL distillated water mixture. After stirring $CuCl_2$ (or $HAuCl_4.3H_2O$) solution with TiO_2 in 100 mL distillated water, 0.42 M urea aqueous solution was added into the suspension and stirred for four hours at 70°C in order to decompose urea and rise pH to 7-8 interval. Then, the catalyst samples were washed, centrifuged three times, dried overnight at 100°C and finally calcined at 400°C for 4 hours in air [8, 9]. The bimetallic 0.2 wt.% Au-0.8 wt.% Cu/TiO_2, on the other hand, were prepared using S-DPU methods. First the copper was deposited on TiO_2 as previously explained DPU procedure above. Then the catalyst sample was centrifuge, dried and calcined at 400°C for 4 hours in air. After that, all steps were repeated for Au deposition on Cu/TiO_2. Both DPU and S-DPU methods were conducted in dark condition to prevent the effect of light on gold and copper particles [10, 11]. For comparison, 1 wt.% Pt on TiO_2 was also prepared via incipient-to-wetness impregnation of tetraammineplatinum(II)nitrate and calcined in air at 400°C for 4h.

H_2 production from glycerol were conducted in a semi batch photocatalytic reaction system in which argon (Ar) was used as inert-carrier gas with the flow rate of 30 mL/min. 1.0 g_{cat}/L was suspended in 500 mL reaction solution (20 wt.% glycerol and 80 wt.% distillated water). The photoreactor was irradiated by Luzchem 300 W Xe lamp. Determination of H_2 production rate was carried out via a gas chromatograph system.

RESULTS AND DISCUSSION

Au/TiO_2 which was the best performed catalysts was characterized by SEM to investigate distribution and size of gold nanoparticles on TiO_2. In SEM images, the shiny and spherical gold nanoparticles were 40-50 nm size clusters. There can be also smaller gold particles on TiO_2, however they could not be visible in the range of SEM. Although there are some agglomerations of gold in only certain areas, the samples generally have well distributed and large number of gold nanoparticles.

The reflectance – wavelength values of each catalyst were measured using UV-VIS spectroscopy by Kubelka-Munk method to calculate direct band-gap energy; the band gap of samples (about 2.97 eV) was quite close to TiO_2 indicating that Au, Cu or Au-Cu loading on TiO_2 did not have any effect on band gap.

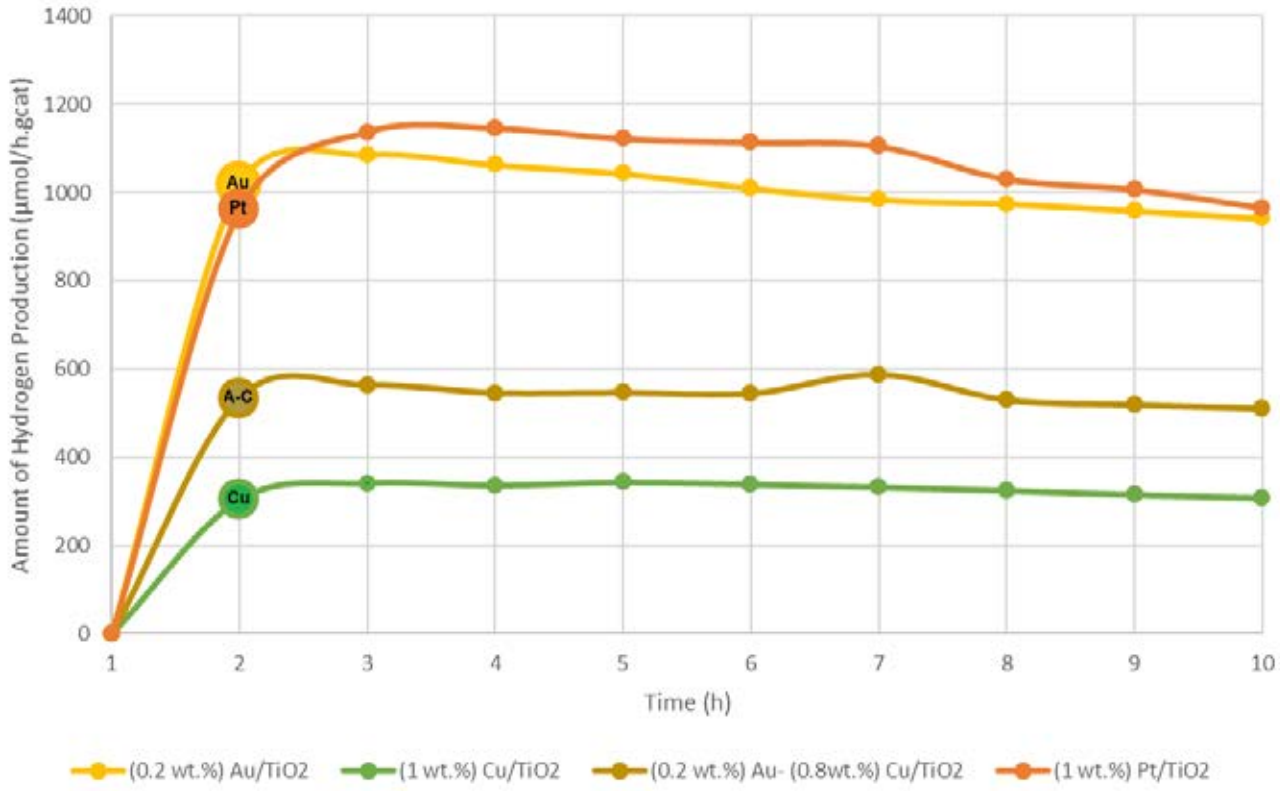

Figure 1. H_2 production rate of (0.2 wt.%) Au, (1 wt.%) Cu and (0.2 wt.%) Au-(0.8 wt.%) Cu loaded TiO_2 catalysts

It can be easily seen from Figure 1 that 0.2 wt.% Au/TiO_2 is active as much as 1 wt.% Pt/TiO_2 for H_2 production with the maximum of 1085 µmol/h.gcat. Having almost the same level of H_2 production in two catalysts, even though Au loading is five times lower than Pt, may be attributed to the plasmonic effects of gold nanoparticle on H_2 evolution [12]; this may increase the feasibility of using Au considering that Pt is more expensive and more sensitive to O_2 and CO [4, 7]. As Figure 1 also indicates, Cu/TiO_2 has the lowest level of H_2 production while Au-Cu containing bimetallic catalyst, tested under same ambient condition with Au/TiO_2 and Cu/TiO_2, performed in between only Au or Cu containing catalysts with the maximum H_2 production of 587 µmol/h.gcat. Since the copper is much cheaper than Au and Pt, it may be considered as a potential catalyst even though the H_2 production rate on this metal in glycerol reforming.

CONCLUSIONS

In this study, photocatalytic glycerol reforming under ambient condition was examined on Au, Cu and $Au-Cu/TiO_2$ catalysts. Glycerol, the main by-product of biodiesel, was utilized as a raw material here instead of sacrificial agent. 0.2 wt.% Au/TiO_2 has the best performance with the maximum 1085 µmol/h.gcat hydrogen production rate which is almost the same with the production rate of 1 wt.% Pt/TiO_2. This makes Au/TiO_2 as a suitable candidate in terms of both cost and catalyst performance for the glycerol photocatalytic reforming. Although 1 wt.% Cu/TiO_2 and 0.2 wt.% Au-0.8 wt.% Cu/TiO_2 give lower hydrogen production rates, the performance is still considerably high such that Cu can be also considered as an alternative catalyst for this purpose.

ABSTRACT

Hydrogen is considered one of the most promising solutions for renewable energy storage and decoupling generation from demand for large-scale implementation in the near future. The copper-chlorine (Cu-Cl) cycle for clean hydrogen production is known to be the most feasible thermochemical cycle due to its low energy requirements. Nonetheless, there are difficulties in scaling up and enhancing the efficiency of the Cu-Cl cycle for its commercialization. One of the most challenging sections to design is the thermolysis reactor in which the decomposition of copper oxychloride ($CuO.CuCl_2$) into molten CuCl(l) and O_2(g) occurs at approximately 530 °C. To address this challenge, this study presents a novel design concept for the thermolysis reactor in a 4-step Cu-Cl cycle with the principal objective of improving the temperature distribution on the reactant side. The results of the flow and heat transfer analysis of the reactant side in the heat exchanger showed a decrease of 61% in temperature standard deviation in the upward direction, which shows an improved temperature distribution.

Keywords: Thermochemical Cu-Cl cycle for hydrogen production, Continuous thermolysis reactor, Molten salt heat exchanger, Solar salt.

INTRODUCTION

Decoupling the generation from the demand is a well-known solution to address the challenges involved with uncertainty and fluctuations in implementing renewable sources. Hydrogen is one of the most reviewed mediums to carry on the decoupling. The thermochemical Cu-Cl cycle for hydrogen production is mentioned to be the most promising method in more than 200 thermochemical cycles studies by McQuillan et al. [1] due to its comparably low heat requirement. Wang et al. [2] investigated the Cu-Cl cycle in terms of heat quantity, heat grade, thermal efficiency, engineering challenges, and hydrogen production cost, and concluded that its overall efficiency is between 37 and 54% by having the lowest temperature requirement among all cycles, similar cost, and it has the ability to line up with a variety of low-temperature sources with lower technical challenges. There are three main variations of the Cu-Cl cycle, 3-step, 4-step, and 5-step [3], which are sharing the main components of electrolysis, thermolysis, and hydrolysis reactors [2]. Based on a comparison done by Ishaq and Dincer [1], the 4-step cycle has the highest energy and exergy efficiencies of 41.9, and 75.7, respectively. However, the thermolysis reactor is mentioned to be the most critical component in the cycle as it has the highest maximum heat requirement of 194.5 kW, a required temperature of 450-530°C, and a maximum exergy destruction rate with a value of 112.2 kW [3], [4]. Furthermore, transporting corrosive products with such a high temperature is a challenging task. Wajda and Gabriel [5] asserted that the Cl_2(g) controls the decomposition of $CuO.CuCl_2$, and represented a design for the thermolysis reactor to scale up the total cycle for a pilot industrial site. Using CuCl(s) as the reactant, they showed that their reactor with dual electrical heaters can decompose 2 kg of CuCl between 3.5-4 hours. Daggupati et al. [6] found that the release of O_2(g) begins at 380°C and speeds up considerably at temperatures higher than 500°C. Naterer et al. [7] suggested that by generating a reduced pressure inside the reactor, the $CuO.CuCl_2$ decomposition is spontaneous at 480°C, despite the difficulty in controlling the reaction. It is suggested that in the temperature range of 500-530°C the decomposition is spontaneous and below 500°C the reverse reactions will occur. Abdulrahman [8] investigated the thermal scale-up analysis of a multiphase continuous stirred tank (CSTR) that is heated by a half jacket as the thermolysis reactor. In another study by Abdulrahman [9] a heat transfer analysis for a scale-up thermolysis reactor with an internal helical heating tube was investigated. They concluded that the molten CuCl acts as a better heating fluid compared to helium gas and using an internal heating tube is more effective than a half-pipe jacket in transferring heat. Despite all of these efforts in paving the way for commercializing the Cu-Cl cycle, previous reactor designs showed the generation of unwanted substances such as CuCl(g) and Cl_2(g) due to non-uniform distribution of temperature in the reactant which resulted in forming condensed CuCl(s) crystalline and caused blocking and clogging of the reactor tubes [5]. This abstract represents the pathway to design a novel thermolysis reactor that aims to address the following challenges:

- The significant temperature gradient between the surface and bottom of the reactant due to the proximity of the electrical heaters to the bottom caused the temperature to increase over 600°C near the bottom.
- The insufficient temperature on the surface of the reactant for the adequate decomposition of the salt.

- Crystalline formation with a thickness of up to 4 mm inside the reactor is caused by high CuCl vapor pressure.
- Scale-up difficulties due to using batch reactors and problems related to handling the materials.
- Trapping and condensation of oxygen vapor before exiting the molten salt upper surface.
- Production of intermediate chemicals in the reactor.

A primary CFD study of the involved heat exchanger inside the reactor is presented to show to the feasibility of the design.

DESIGN APPROACH AND METHODOLOGY

Temperature variation inside the reactant is crucial in achieving the desired reaction since at temperatures over 450°C, $CuCl_2$ starts to decompose into CuCl(s) and Cl_2(g) [3]. The generated Cl_2(g) reacts with the CuO over 450°C and the generation of O_2 will speed up between 500-530°C.After 550°C, CuCl(l) is vaporized and condensed on the cooler walls and tubes. It can block the outflow of materials, generates partial pressure of oxygen inside the reactor, and negatively effect the heat transfer and thermal performance of the reactor [5]. Consequently, temperature margins, are considered as the main constraints for this design. The proposed reactor consists of three main components: a screw pump and junctions, heat exchanger chamber, and molten salt chamber. Key features of the proposed reactor along with their reasoning are presented in Table 1. Fig. 1 shows the reactor design concept.

Table 1. Key features of the reactor and their reasoning.

Feature	Reasoning
Upward flow of materials	The density of the involved materials in the reaction is ranked as $\rho_{O_2} < \rho_{CuCl} < \rho_{CuO.CuCl_2}$[2]. To prevent the contamination of the O_2(g) in the molten bath, assist its extraction, and have a controllable continuous flow of material, the reactant is pushed in the upward direction. This scheme, along with the next features, enables the effective handling of solid, liquid, and gaseous phases.
Heating temperature increases upward	Considering the density difference, the molten salt is on top of the solid reactant. Therefore, to decrease the thermal resistance, temperature increases as the particles flow upward. In this way, the molten bath is developed at the top of the overall volume of reactant, where the temperature is higher. Generation of O_2(g) increases at higher temperatures which are located at the top surface. This further facilitates the removal of the O_2(g) with minimum traveling through the molten bath.
Screw pump for material handling	To enable a controllable continuous delivery, reaction, removal, and flow of solid material into the reactor, a horizontal screw pump is used. It also provides a seamless flow of material that prevents the product heel between the working cycles.
Oxygen removal port	The oxygen removal port is located at the top of the heat exchanger chamber where the O_2(g) is generated. This prevents sudden surge in O_2(g) partial pressure due to the proximity of the port to the location that the majority of O_2(g) is produced.
Use of conjugate heat transfer by implementing a cross flow heat exchanger	$Cl_2(g)$ and $CuO(s)$ are extremely reactive. Hence, the only available direct heating technique can be provided by inert gases, which are found to be ineffective [11]. Therefore, conjugate heat transfer is used by introducing circuits of bended pips that form a cross-flow heat exchanger inside the reactor. Solar salt is considered as the heating fluid. Thermal resistance is minimized by increasing the heat exchanger aspect ratio and injecting the reactants as near as possible to heating interfaces.
Variable height gate for molten CuCl removal	To control the speed and completeness of the reaction a variable height gate is used to connect the heat exchanger chamber to the molten salt chamber. This gate is used to change the residence time of the molten salt in the heat exchanger chamber.
Molten salt chamber	Molten salt overflows the gate after the required residence time. The molten salt chamber provides a vertical flow of reactant to feed the next step in the cycle which is the heat recovery from the CuCl molten salt.
Nitrogen injection and removal ports	To have a complete reaction and avoid unwanted substances, inside the reactor should be free of any gaseous that can react with the reactant and products. Therefore, N_2(g) is injected into the reactor to purge the remaining gaseous inside.

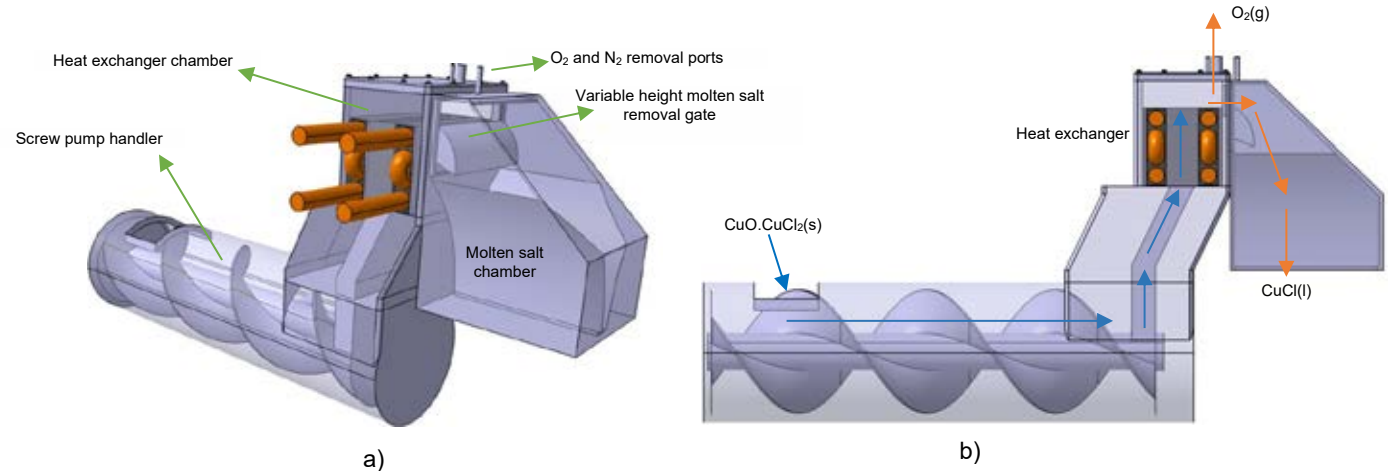

Fig. 1. a) Components of the reactor; b) flow of material inside the reactor.

RESULTS AND DISCUSSION

Fig. 1a shows the reactor and Fig. 1b shows the reactant and products as they move upward in the reactor. A CFD analysis of the heat exchanger has been conducted to assess the temperature distribution of the reactant inside the reactor. It is assumed that reactant will enter the heat exchanger chamber with 430°C and $CuO.CuCl_2$(s) is substituted by CuCl in the numerical model due to its unknown thermal conductivity and dynamic viscosity. Fig. 2 shows the temperature contours inside the reactant. The temperature standard deviation is a measure to show the dispersion which is 58.27°C at the heat exchanger entrance, 35.14 at the middle section, and decreases to 22.49°C at the heat exchanger outlet. This shows an improvement of 61% in temperature distribution along the channel. To further improve the temperature distribution, a study should be performed to improve the heat exchanger design inside the reactor.

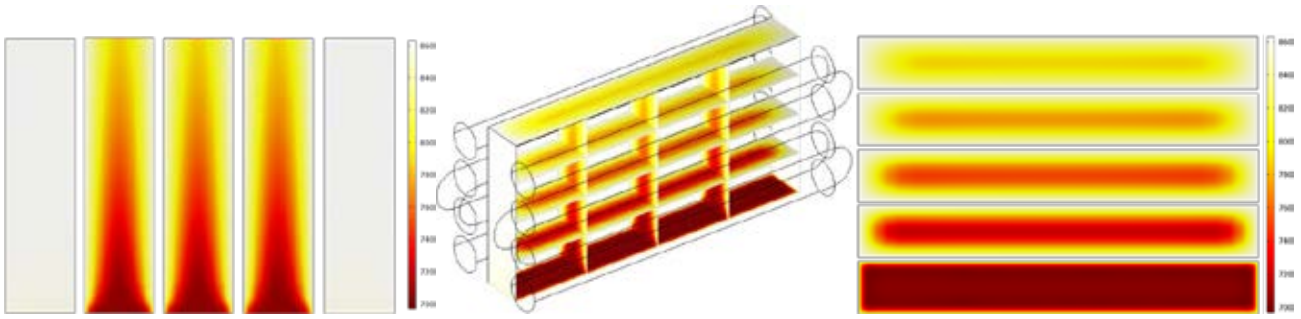

Fig. 2. Temperature distribution of the reactant inside the heat exchanger

CONCLUSIONS

The thermolysis reactor is one of the most critical components of the CuCl cycle and addressing its challenges helps the scale-up process of the CuCl cycle, substantially. With the proposed design, the main objective to improve the temperature distribution inside the reactant was achieved. To do so, an upward flow of reactant was considered, which is powered by a screw pump, and the heating is provided at the heat exchanger by using a circuit of solar salt as the heating fluid. This combination enables the easy removal of O_2(g) and CuCl(l) as well as providing the highest temperature at the top section of the heat exchanger which results in optimum heating of the reactant and avoiding the generation of unwanted substances. A numerical model was developed for the involved heat exchanger to assess the temperature distribution inside the reactant channel. It was shown that the temperature standard deviation decreases by 61% in the upward direction, from 58.27°C to 22.49°C. To further assess the feasibility of this design, separate studies should be done on designing an optimum heat exchanger and assessing the dynamic of other components of the reactor.

ABSTRACT

The conversion of Hydrogen Sulfide into H_2 and Sulfur ($H_2S \rightarrow H_2 + S$) is beneficial from both environmental and energy perspectives. The two-step thermochemical decomposition of H_2S is considered one of the most promising technologies for Hydrogen production. This work investigates the chemical kinetics of the two-step thermochemical decomposition of H_2S using Nickel Sulfide and studies the key parameters that affect the overall cycling process and H_2S conversion efficiency. Gas-phase and surface-phase kinetics of the two-step thermochemical decomposition of H_2S models were developed in CHEMKIN software. The formulated model results were found to be consistent with the experimental results.

Keywords: Solar thermochemical cycle, H_2S splitting, Hydrogen, Nickel sulfide

INTRODUCTION

Most oil and gas reservoirs in the United Arab Emirates (UAE) are sour, enriched with a high amount of hydrogen sulfide (H_2S) and sulfur species. H_2S is a highly hazardous gas that has serious poisoning effects on industrial processes or human health if exposed at concentrations above 100 ppm. The conventional approach to dispose of this noxious gas is the Claus process, which is not an economically viable method due to the high cost of the chemical process that results in the formation of SO_2, a further environmental containment. H_2S production is expected to increase due to the discovery of sour gas reservoirs and heavy oil refining.

Various strategies for converting H_2S into Hydrogen and Sulfur have been investigated in literature through a variety of technologies. These involve thermal decomposition, thermochemical, electrochemical, and photochemical methods. Owing to the thermodynamic limitations of H_2S dissociation by thermal decomposition reactions, extensive research has been investigating more practical methods for generating higher H_2 equilibrium concentrations at lower temperatures. Higher conversion efficiencies at lower temperatures were found to be achieved using closed-loop thermochemical decomposition cycles. This involves breaking up the overall reaction into a sequence of kinetically favorable reactions with at least one separation step to fully decompose the H_2S into H_2. Kiuchi et al. in [1], demonstrated splitting the H_2S dissociation into two intensive steps; First, sulfiding of a metal or metal sulfide by H_2S to liberate the hydrogen and then calcining the higher metal or metal sulfide to decompose into sulfur and the original metal or metal sulfide.

$$M_xS_y + zH_2S \rightarrow M_xS_{y+z} + zH_2 \quad (1)$$

$$M_xS_{y+z} \rightarrow M_xS_y + zS \quad (2)$$

The main objective of this research work is to develop multistep chemical kinetics of the two-step Thermochemical decomposition of H_2S using Nickel Sulfide. The kinetic model was simulated to examine the key parameters that affect the overall cycling process and H_2S conversion efficiency, including temperature, residence time, catalyst time stability, and the behavior of adsorbed species on active catalyst sites during sulfurization/ regeneration transient steps.

MATERIALS AND METHODS

The kinetic model was developed using CHEMKIN® software to investigate the kinetics of the gas-phase of species that might interact during the chemical reaction without a catalyst. Similar to the gas-phase kinetic model, surface-phase kinetic was also simulated in CHEMKIN® software to understand the kinetics of hydrogen sulfide on Nickel surface. Both model simulations include the inlet gases, a CSTR reactor, and an outlet source.

RESULTS AND DISCUSSION

The kinetics of the H_2S splitting gas-phase chemical reaction was developed using CHEMKIN® software. The validity of the kinetic model was compared with two experimental studies obtained by Binoist in [2] and Hawboldt et al. in [3].

Figure 1 represents the comparison between the developed gas-phase kinetic model and the experimental result of Hawboldt et al. and Bionoist.

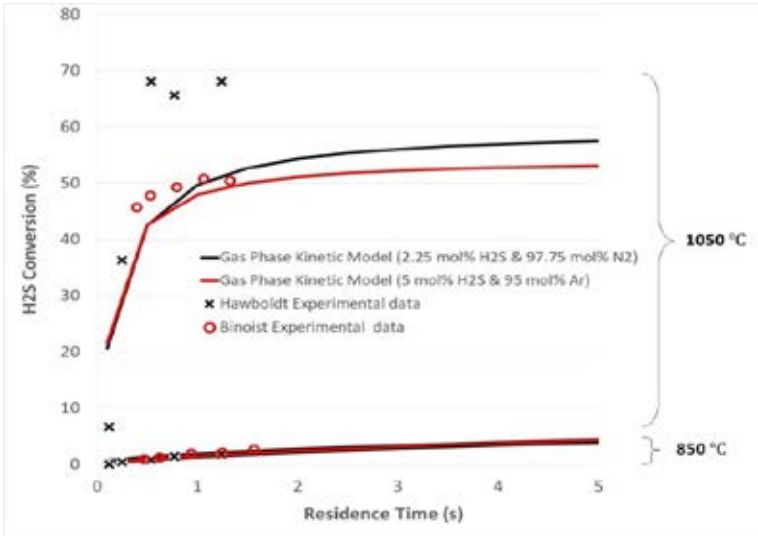

Figure 1. Comparison between the experimental result of Hawboldt et al. (H_2S: 2.25 mole%, N_2: 97.75 mol%) & Binoist (H_2S: 5 mole%, N_2: 95 mol%) with the Gas Phase Kinetic model.

Figure 1 clearly demonstrates that the model reasonably well predicts the gas-phase kinetic behavior for the system without catalysts. It can be noted that the H_2S conversion increases with both the residence time and temperature. The H_2S conversion at 5 s residence time were 4% and ~55% at 850°C and 1050°C, respectively. However, the gas-phase H_2S conversion is kinetically not significant below 850°C.

To understand the kinetics of hydrogen sulfide on Nickel sites, a surface-phase kinetics model was also developed and simulated in CHEMKIN® software using a transient solver. The experimental results obtained by Osasuyi in [4] were used as a benchmark in validating the model competence. Figure 2 reflects this comparison at three different temperatures of 150°C, 300°C, and 500°C. As shown, at 150°C, the H_2S decomposition reaction is hardly successful due to the reaction kinetics and mass transfer limitations accompanying the heterogeneous reaction with Ni_3S_2. Moreover, from 300 to 500°C temperature levels, the total H_2S conversion is displayed at an early stage of the reaction for a very short-lived period.

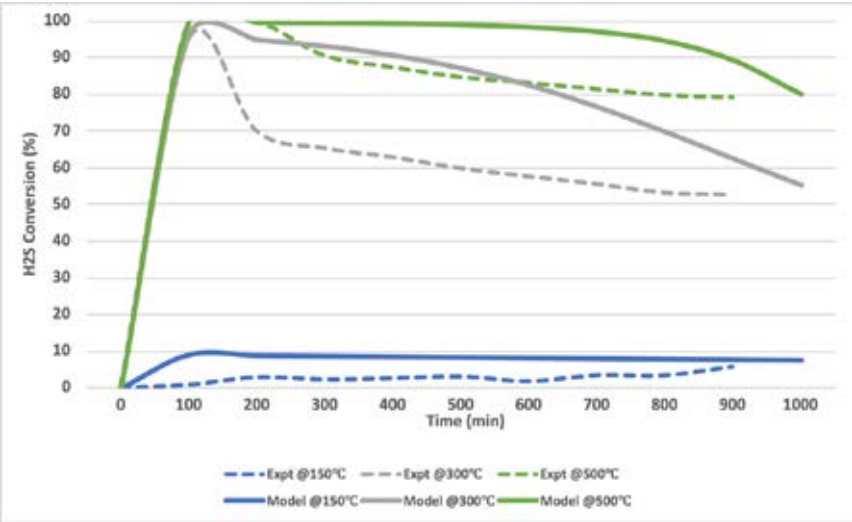

Figure 2. Osasuyi experimental results vs. Surface Phase Kinetic Model results

The deviation between the kinetic model from experimental results is because the surface phase kinetic model considers the sulfur formation as a single site attachment on Nickel sites, whereas in reality, there could be additional complex reaction routes like the formation of S_2-S_8, which is not considered in the model but encountered by the experimental results.

The predictive capability of the model is further explored by analyzing the site fraction of H_2, higher and lower Nickel Sulfides, and Sulfur at a temperature range of 150 to 800°C.

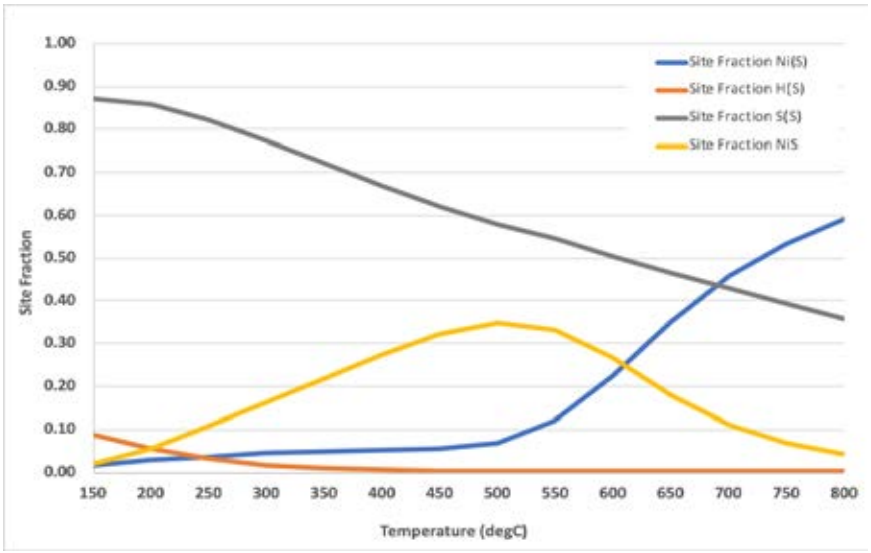

Figure 3. Site fraction of H(S), lower and higher Nickel Sulfide Ni(S) & NiS, and Sulfur S(S) at a temperature range of 150 to 800°C

Figure 3 represents the steady-state solutions of site fractions and clearly explains the H_2S decomposition behavior on the Nickel surface as temperature increases from 150°C to 800°C. As temperature progresses, the sulfur atoms on the Nickel surface desorbs, freeing up vacant positions on the Nickel surface for H_2S adsorption. As the reaction proceeds and more sulfur atoms are desorbed, a bulk transformation of the Nickel Sulfide to a higher stable Sulfide state eventually occurs. This sulfidation phenomenon is exothermic in nature; however, this takes place up around 500°C, while the regeneration step can happen at a higher temperature above 700°C.

CONCLUSIONS

The gas phase and surface phase kinetics of the two-step thermochemical decomposition of H_2S was simulated in CHEMKIN software. The predictive capability of the model was explored by using the experimental data obtained by Binoisit in [2], Hawboldt in [3] and Osasuyi in [4]. The formulated model results were found to be consistent with the experimental results. However, the model can be further developed by encountering additional complex reaction routes like the formation of S_2-S_8. The model will be used to select suitable reactor type and design parameters that is the key aspect for developing and optimizing the chemical process system.

APPLYING ARTIFICIAL INTELLIGENCE ON STEAM GASIFICATION OF WASTE PLASTIC TO GENERATE HYDROGEN

[1] Serap Özmen, [1] Peter T. Clough*

ABSTRACT

Global warming is a major environmental threat, and the demand of renewable energy sources has been increased significantly. Hydrogen has been proposed as a key future energy carrier for the low carbon energy systems owing to its cleanliness and high-energy yield. Meanwhile another significant global threat is plastic pollution and waste plastic management is a major concern in many countries. Consequently, hydrogen production from waste plastic has become one of the most demanding research topics. One of the most promising techniques to produce hydrogen from waste plastic is gasification. However, there is a lack of understanding for the plastic gasification process since the plastic samples are mostly used as a side feedstock with biomass and coal for the gasification studies. In this study, Artificial Neural Network (ANN) modelling will be employed to provide insights of plastic gasification process. Different types of plastics will be gasified under different reaction conditions within a lab scale fluidized bed reactor and the data will be collected to train the ANN model with the data collected from literature. Thus, the impact of the input materials on the hydrogen production will be investigated.

Keywords: Plastic gasification, Hydrogen production, Artificial neural network, Process modelling, Waste to hydrogen

INTRODUCTION

Plastic pollution and waste management have been identified crucial challenges to tackle in recent years as the global production of plastic increases. One of the cornerstones to deal with this problem is the thermal conversion of the plastic waste via gasification through which, syngas is produced as a main product. Among the species found in syngas, hydrogen is the most desirable fraction since it has been found as the key energy carrier since it has the highest energy content per unit mass among all fuels [1,2]. Meanwhile to enhance this process for the production of syngas with high H_2/CO ratios, steam is commonly chosen as the gasifying agent, promoting the reforming and water-gas shift reactions [3].

Various modelling methods have been commonly used for the gasification processes such as kinetic modelling, black box modelling and computational fluid dynamics (CFD) modelling. However, ANN modelling has gained popularity in the applications related to renewable energy systems since it does not contain any energy or mass equations unlike the traditional mathematical models. ANN modelling approach is a generic nonlinear regression model which learns the mapping from the input data onto the output with high prediction accuracy. Currently, ANN modelling is widely used for process simulation, pattern recognition and signal processing and it is the most popular and reliable computation technique in the chemical engineering applications due to its accuracy, precision time and low cost [4].

Several other methods such as pyrolysis and in-line and dry reforming have been practiced for the production of hydrogen as well among which gasification plays an advantageous role due to its flexibility in the usage of plastics with alternative composition or blended with other feedstocks. Many research studies have co-blended plastics with biomass and coal, which are the most common feedstocks for gasification processes, in order to increase the hydrogen concentration in the syngas [5]. Consequently, there is a lack of understanding on the relationships between the inputs and outputs to and from a reactor for the gasification of waste plastics. The aim of this research is to investigate the artificial intelligence prediction of the characteristics of catalytic steam gasification for waste plastic within a fluidised bed reactor for hydrogen production. This will provide insights into the operation of gasifiers and contributes to the knowledge on the impacts of input materials on the yield of hydrogen.

METHODOLOGY

The primary work package included the chemical characterisation of the plastic materials and the design, setup and operation of a lab-scale fluidised bed system suitable for catalytic steam gasification. Following this, the application of ANN for the prediction of the concentration of H_2 in the syngas is assessed. These predictions will be based on the literature data and the experimental data collected from steam gasification of various types of plastics under different conditions such as reaction temperature, flow rate of plastics, catalyst/plastic ratio, steam/plastic ratio.

Reactor design

For the experimental study, a lab-scale fluidised bed reactor system was designed, procured, and installed. The system includes a fluidised bed reactor, a radiation heating system (to control the temperature of the reaction), mass flow controllers (to control the gas and steam flow rates to the system), a data logger for the thermocouples (to read the temperature at different locations in the system), tar collection bottles and a gas analyser (to define the gas concentrations which are H_2, CO_2, CO and O_2 in the syngas). Also, a software called Agilent VEE was employed to control the process and collect the data outputs. The process flow diagram of the system and an image of the system can be seen in Fig. 1.

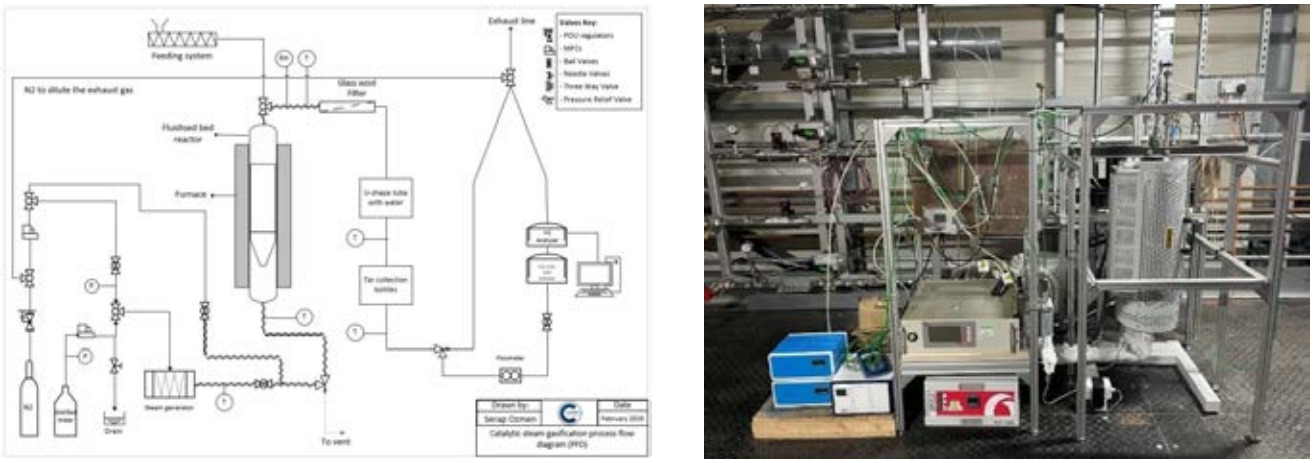

Fig. 1. Process flow diagram of the system (left), An image of the rig setup for plastic gasification experiments (right)

Furthermore, to overcome the difficulties of the feeding of the plastic samples into the reactor, a novel solid feeding system was designed. A linear actuator was employed to control the feeding rate of the plastic samples into the reactor.

Characterisation of plastic samples

The instruments which will be employed to determine the characteristics of the plastic samples and gas products are:

- Thermogravimetric analysis (TGA) for proximate analysis
- Gas Chromatography/ Mass Spectroscopy (GC/MS) to identify the different substances within the plastic samples
- Calorimetry (Bomb calorimeter) (CV) to measure low heating value of plastic samples
- Brunauer, Emmett and Teller (BET) to measure the surface area of materials and to explain the physical adsorption of gas molecules on a solid surface
- Barrett-Joyner-Halenda (BJH) to calculate the pore size distributions and volume of pores

ANN modelling

A prediction model was created on MATLAB trained with data collected from literature until the experimental data collection was completed. The data were analysed and pre-processed to make them suitable for the model. The independent variables such as the type and characteristics of the plastic and reaction conditions such as temperature, catalyst type, catalyst/plastic ratio, steam/plastic ratio, etc. will be called 'input data' while the dependent variable which is hydrogen volume concentration in the syngas will be called 'output data'. To analyse the data, Pearson's correlation coefficients (PCC) and distance correlation coefficients (DCC) were calculated. Feed-Forward Neural Network (FFNN) was employed with different model structures (number of layers and hidden layers) and different training functions to find the best model according to the different performance functions. To validate the model, different datasets collected from literature was used as an unseen data.

RESULTS AND DISCUSSION

For the initial steam gasification experiments, 0.1g of Polypropylene (PP) was used as a feedstock and 12 g of sand was used as a bed material without any catalyst. The test was run at 850 °C with 60% of steam and 40 % of Nitrogen as carrier gas with 25.79 ml/s total gas flow rate. The results show that 0.0026 mol CO, 0.0011 mol CO_2 and 0.0569 mol H_2 was produced with 82% hydrogen conversion. Once the novel feeding system will be added to the system, the amount of plastic used in the tests will be increased significantly.

In terms of ANN modelling, the structure of the model and the training algorithm was defined based on the performance of the model by using mean square error and regression results. Highlighted in Table 1, Levenberg-Marquardt algorithm (TRAINLM) is the best training algorithm for the model with the existing data. It can also be seen that there is no major difference with the results of single- or two-layers structure. Although there are limited data to train the model (as the data collected from the literature), the performance results of the model are quite promising.

Table 1. Performance results of the prediction model based on different training algorithms and different structure of the network

	Single layer		**Two layers**	
Training algorithm	MSE	Regression	MSE	Regression
TRAINLM	0.002	0.986	0.001	0.988
TRAINBFG	0.002	0.979	0.003	0.974
TRAINRP	0.003	0.976	0.003	0.978
TRAINGDA	0.011	0.904	0.005	0.963

Moreover, the Regression Learner app within MATLAB was employed to compare the performances of different machine learning algorithms. While the best algorithm is Gaussian Process Regression (R squared: 0.72), ANN still has a better performance.

CONCLUSIONS

The thermochemical degradation processes to convert waste plastic into fuels are promising methods not only it helps to decrease the dependence on fossil fuels but also it helps to mitigate the plastic pollution and plastic waste management. In this research ANN modeling will be used to contribute to the knowledge on the relationship between the input materials (type of plastic, reaction temperature, steam/plastic ratio, catalyst/plastic ratio, etc.) and the hydrogen yield within the steam gasification process.

ABSTRACT

This work is about the collaboration between Purdue University (Purdue) and University of Engineering & Technology (UTEC). Both are educational institutions located in the USA and Peru, respectively. This work presents the results of the implementation of a Collaborative Online International Learning (COIL) Program. Students from different engineering careers and cultures participated in the development of a COIL Project on the hydrogen production by water splitting using high temperature heat from a concentrating solar plant. Students formed working groups to carry out the different research activities. It was found that the objective of the COIL Project were achieved in a short period of time, evidencing the academic growth of the students and, at the same time, students gained international experience.

Keywords: Collaborative Online International Learning (COIL) Program, Transformative pedagogy, Green hydrogen.

INTRODUCTION

The short experience in international collaboration activities of a university may represent a barrier in its academic growth. Currently, online international intercultural collaborative programs could contribute to solving this problem. This work presents the results about the experience of students from different disciplines, culture, and nationality around the development of the COIL Project "Hydrogen production by water splitting using thermochemical cycles powered by Solar Concentration Power Plant for a mining industry in Peru". These students belong to Purdue (USA) and UTEC (Peru). The main goal of this work is to show the results of the implementation of a COIL Program to facilitate the transformative pedagogy [1–3] for students from Purdue and UTEC through the development of an academic project.

METHODOLOGY

The implementation of the COIL Program took into account the following activities: (a) videoconference meetings with the participation of students and professors from Purdue and UTEC universities; with the support of the zoom platform and computer applications (powerpoint, google drive, Homer Pro, System Advisor Model and Aspen Plus), (b) formation of working groups with students from different interdisciplinary careers, and (c) research in charge of the different working groups on the production of green hydrogen using thermochemical cycles supported by concentrating solar plants for a mining industry in Peru.

RESULTS

The results of the COIL approach in the development of the project "Hydrogen production by water splitting using thermochemical cycles powered by Solar Concentration Power Plant for a mining industry in Peru" include: (i) calculation of the hydrogen consumption of the truck fleet of transportation of material from the mining industry, (ii) sizing of the hydrogen production plant through water fractionation supported by a concentrating solar plan, and (iii) sizing of the concentrating solar plant.

CONCLUSIONS

Conclusions of the implementation of the COIL program are the following:

- The COIL program presents great potential for the exchange of knowledge and experiences in an international and intercultural framework, in addition to knowing different teaching methodologies, and expanding the network of contacts with students from other countries.

- The objectives of the COIL Project were achieved in a relatively short time thanks to the synergy of the effort of the work teams working in cellular mode,
- The disparity of the effort and intellectual contribution of each student from work teams was evidenced. For the next edition of the COIL Program, we recommend that the participants could be chosen through a selection process, where the candidate must have interest in COIL-Project' subject, while demonstrating a solvent time management and predisposition to work in independent groups,
- Good results were achieved without the need to travel.

ABSTRACT

The basic engineering of a hydrogen production plant has been developed. In this work, the results of the technical and economic assessment of a green hydrogen production plant with renewable energy in Peru, is presented. The hydrogen production plant employs a water splitting technology based on thermochemical cycles [1-2] powered by a concentrating solar plant and a photovoltaic power plant. This plant includes a hydrogen storage and hydrogen transportation systems to replace diesel fuel (1,15 millions of liters per year) by hydrogen within a truck fleet from a mining company in Peru.

Keywords: Green hydrogen, Green mining, Concentrating solar plant, Replacement of diesel by hydrogen, Renewable energy, Sulfur-iodine thermochemical cycle.

INTRODUCTION

Based on the demand of a Peruvian mining company, we estimated a consumption of 1,15 million liters of diesel per year, which represents an emission of 2 870 tons (CO_2). In this work, the deployment of a hydrogen production plant is proposed to replace the diesel fuel consumed by the mining trucks fleet.

The hydrogen production plant employs a water splitting technology based on thermochemical cycles [1 -2] powered by a concentrating solar plant and a photovoltaic power plant. A concentrating solar plant meets the demand for high temperature heat to the thermochemical cycles and the photovoltaic power plant provides electricity to the different hydrogen compression processes for the hydrogen storage and transport systems.

In this work, the results of a technical and economic assessment of a green hydrogen production plant with renewable energy in Peru are presented.

METHODOLOGY

The following activities were carried out:

- Identify the mining truck model that consumes the most diesel fuel.
- Characterization of the hydrogen demand of the mining trucks fleet.
- Sizing of the hydrogen storage system.
- Analysis and simulation of the thermochemical process.
- Sizing of the solar concentrating thermal plant.
- Sizing of the photovoltaic power plant.
- Technical and economic assessment of the hydrogen production plant.

RESULTS

The technical and economic assessment of a green hydrogen production plant with renewable energy in Peru has the following results:

- The hydrogen demand accounted for 3,02 tons/day for the 14 mining trucks.
- It could be necessary the deployment of a green hydrogen production plant for 3,02 tons/day (running 6

hours per day) to replace the diesel fuel (1,15 million of liters per year). The CAPEX of the project is about 4,3 million dollars.

- An 8,4 MW_{th} concentrating solar plant was designed
- A 6,47 MW_e photovoltaic solar power plant was designed

CONCLUSIONS

It is concluded that:

- It is technically feasible to use hybrid solar concentrating and photovoltaic plants to produce hydrogen by thermochemical water splitting technique at a large scale, supplying green hydrogen on-demand.
- The SI (sulfur-iodine) reaction process uses two operation modalities: discontinuous operation based on solar energy availability and continuous operation. The discontinuous section working for about 6 h/day, includes mainly the SO3 decomposition at 850°C and storage of the produced SO2. While the other modality comprises the rest of the process working 24h/day.
- The costs of the main and auxiliary equipment of the plant were estimated and the results show that this project is not economically feasible. This suggests that some adjusts should be made on the plant's design to process and transport it efficiently.
- The implementation of a green hydrogen plant could decarbonize the mining company's operation in around 2870 tons of CO2 per year.

ACKNOWLEDGEMENT

We appreciate the support of Purdue's Office of Globalization and UTEC's Office of Internationalization.

PHOTOELECTROCHEMICAL WATER SPLITTING: SHORT REVIEW ON CURRENT DENSITY AND STABILITY OF PHOTOELECTRODES

[1] Dinko Brezak, [1] Doria Marciuš, [1] Ankica Kovač*
[1] University of Zagreb, Faculty of Mechanical Engineering and Naval Architecture, Zagreb Croatia

*Corresponding author e-mail: dinko.brezak@fsb.hr

ABSTRACT

Direct conversion of water to hydrogen via solar energy encounters multiple obstacles in practical operation - the most important ones being low current density and short-term stability. If photoelectrochemical water splitting is expected to ever compete with a solar panel system in tandem with electrolyzers, it is necessary to develop photoelectrodes with higher current densities using certain nanostructures and a combination of materials that meet a wide range of requirements. The limited stability of photoelectrodes becomes more pronounced with the rise of their efficiency and in photoelectrochemical water splitting is one of the biggest challenges hindering the commercialization of this technology. For this reason, it is of utmost importance to find materials that could fulfill both aforementioned requirements to bring the photoelectrochemical water splitting to the level of competitiveness. This review seeks to provide insight into what has been researched so far, as well as to propose the perspective future directions for the technology development regarding mentioned drawbacks.

Keywords: Photoelectrodes, Photoelectrolysis, Efficiency, Stability

INTRODUCTION

Environmental change, greenhouse gas pollution and depletion of fossil fuel supplies have motivated the scientific community to explore alternative ways of energy production and usage. Hydrogen as a carrier and reservoir of energy has proven to be a potential solution for the energy transition to renewable energy sources. When combusted, it creates only water as a by-product, which makes it safe for the environment. Hydrogen can be produced in multiple ways, of which one of the most desirable ways is water electrolysis. Combining solar panels and electrolyzers enables renewable energy production without emitting harmful gas emissions. The photoelectrochemical (PEC) method of splitting water (WS) simplifies things even more by 'inserting solar panels' into the electrolyzer. This reduces the construction complexity and allows direct hydrogen production from solar energy without the intermediate conversion of solar energy into electricity [1].

A material that can both utilize solar energy and enable a chemical reaction of water decomposition has many requirements to fulfill, which generally necessitates compromise and optimization [2]. Some of the demands for photoelectrode material are bandgap, bandgap limits, absorption of broad solar spectra, high efficiency, long life cycle, low electron-hole recombination, nontoxicity, stability in acidic and alkali environment, low-cost and earth-abundant. As some of the mentioned requirements are mutually opposed, multilayer structures are used, where every layer assuages a certain aspect [3]. The aim of this research is to investigate perspective photoelectrodes that placate the most mentioned requirements with an emphasis on higher current densities and stability as ultimately, these two parameters are crucial for the commercialization of this technology.

PHOTOELECTRODE MATERIALS

Titanium dioxide (TiO_2) is the first material used for PEC WS and thanks to its one-dimensional structure is still one of the most promising materials for photoelectrodes. The main drawbacks are wide band gap (3 eV) which causes poor solar light utilization, and easy recombination of charge carriers, holes and electrons. To improve the active catalytic area, modification of surface morphology is essential. Band structure modification is required to reduce photogenerated charge recombination and surface sensitization is for improving light absorption. Tubular morphology improves TiO_2 photocatalytic ability, but it doesn't solve the wide band gap. The most common methods for synthesizing TiO_2 nanotubes (NT) are a hydrothermal method, template and electrochemical anodization method, latter being most prominent as it ensures highly oriented NTs. Tubular morphology improves TiO_2 photocatalytic ability, but it doesn't solve the wide band gap. Reducing the bandgap is accomplished through element doping and by self-doping of Ti^{3+}. With TiO_2 color changes, bandgap can be reduced from 3eV to 1eV [4].

By forming heterojunctions with various materials, electron hole recombination can be reduced. Homojunction interfaces are beneficial for the charge carrier separation due to similar characteristics on two sides of homojunction. TiO_2 has two typical photoactive phases, anatase and rutile, and by combining these two phases and creating homojunction we achieve fewer recombination centers for charge carriers [5]. Co-doping with anions and modification with different nanoparticles (NP) result in broadening the absorption region for visible light and the reduction of band gap energy [6]. Oka et al. [7] investigated π-conjugated polymer as a pure organic semiconductor film, polythiophene,

characterized with a crystalline polymer well filled with grain morphology. It is prepared with a facile polymerization method and achieves decent current density and high durability. Photoanodes based on zinc oxide (ZnO) as a transitional metal oxide have strong stability, excellent electron mobility and convenient conduction band position [8]. Yu et al. [9] studied organic semiconductors that are ideal for PEC WS for their superior charge transfer characteristics, easy sustainability of energy levels and low production costs. They reported stable organic semiconductor photoanodes with a high performance consisting of n-type non-fullerene, which is passivated with nickel foils, p-type polymers, layered double hydroxide and gallium indium (GaIn) eutectic as model materials [9]. In [10] researchers studied photoanodes based on alloy containing elements from groups III and V in the periodic table (III-V). These photoelectrodes spatially and functionally decouple the light harvesting from the electrolysis part of the device and that reduces the cost, liquidates parasitic light absorption and enhances the stability without compromising efficiency. The monolithically combined PEC cell was produced by an epitaxial lift-off method and inversely grown InGaP/GaAs transfer to a robust Ni-substrate. The resultant photoanode exhibits stability of over 150 hours and solar-to-hydrogen (STH) efficiency of 9% [10]. Another promising candidate for a photoanode material is hematite (α-Fe_2O_3). Its main disadvantage is difficult charge recombination suppression but has high efficiency. Thick hematite films constructed by highly ordered and attached hematite mesocrystals (MC) and the formation of plenteous interfacial oxygen vacancies delivers high current densities, great collection efficiencies and charge separation, short depletion widths, and a large fraction of depleted regions in hierarchical structures [11]. He et al. [12] developed highly efficient photoelectrode by sandwiching photothermal cobalt (II, III) oxide (Co_3O_4) layer between an electrocatalysts sheet FeOOH/NiOOH and a$BiVO_4$ photoanode film. Deposited Co_3O_4 layer shows excellent photothermal effect in the near-infrared region and raises the photoanode temperature in situ, leading to improved charge transfer, expanded light absorption and fast water oxidation kinetics [12].

PHOTOELECTRODE COMPARISON AND DISCUSSION

In Table 1. Comparison of different photoelectrodes and their characteristicsTable 1, previously mentioned photoanode characteristics are summarized with their current densities, stability, preparation method and applied bias voltage.

Table 1. Comparison of different photoelectrodes and their characteristics including stability and current density

Photoanode	Electrolyte	Bias	Reference electrode	Stability	Current density	Preparation method	Ref.
TiO_2-NT/NiS	Na_2S and Na_2SO_4	0 V_{RHE}	Ag/AgCl	Over 30 min.	7.68 mA/cm^2	Electrochemical anodization	[4]
TiO_2-R/A	Na_2SO_4	0.6 V_{SCE}	Saturated calomel electrode	Over 2 hours	1.7 mA/cm^2	Hydrothermal	[5]
C, N-TiO2/NiS/CdS/ZnS	Na_2S and Na_2SO_3	0 V_{RHE}	Ag/AgCl	Over 30 min.	18.79 m A/cm^2	Anodization	[6]
TiO_2-Bi_2Se_3	Na_2S and Na_2SO_3	1.23 V_{RHE}	Ag/AgCl	Over 6 hours	1.76 mA/cm^2	Hydrothermal	[13]
Polythiophene	NaOH	0 V_{RHE}	Ti mesh	Over 12 hours	0.75 mA/cm^2	Facile polymerization	[7]
Cross-linked ZnO/CdS/BiOI	-	1.1 V_{RHE}	Ag/AgCl	Over 2 hours	9.12 mA/cm^2	Solvothermal	[8]
Organic semiconductor LDH/Ni/eu@nfOP	-	1.23 V_{RHE}	Ag/AgCl	Over 10 hours	15.1 mA/cm^2	Passivation	[9]
Inverted tandem InGaP/GaAs	KOH	0 V_{SCE}	Saturated calomel electrode	Over 150 hours	11.7 mA/cm^2	Epitaxial lift-off	[10]
Ti-Fe_2O_3 MCs	NaOH	1.23 V_{RHE}	Ag/AgCl	-	3 mA/cm^2	Solvothermal and spin coating	[11]
NiOOH/FeOOH/ Co_3O_4/$BiVO_4$	KPi	1.23 V_{RHE}	Ag/AgCl	Over 4 hours	6.34 mA/cm^2	Deposition	[12]

TiO_2-rutile/anatase (R/A) photoanode is prepared by in situ growth method. Mismatched heterojunction interfaces are mostly full of defects that affects electron-hole recombination. TiO_2-R/A homojunction on the other hand has extreme band bending and improved surface area, which consequently improves transmission and charge separation [5]. Mollavali et al. [6] achieved the highest photocurrent of 18.79 mA/cm^2 in the presence of sacrificial agent/electrolyte (Na_2S and Na_2SO_3). A stable photo response was possessed by multi-metal chalcogenide (CD) heterojunction, and it acts as an electron reservoir that traps photogenerated electrons and separates electron-hole pairs. In [13] TiO_2 metal oxide photoelectrode was sensitized with semiconductor Bi_2Se_3 that has a narrow band gap which improves light response and generates transport of charge carriers. A 3D cross linked heterostructure

ZnO/CdS/BiOI NR arrays has been prepared by solvothermal strategy. Photoanode achieves a high photo conversion efficiency of 3.49% and long-term stability over 6000 seconds [8].

CONCLUSIONS

Investigated photoelectrodes by various researchers so far showed a promising but challenging future for PEC technology. The greatest achieved stability of photoelectrode (150 hours) is still nowhere near the time (10,000 hours) needed to justify commercialization and mass production. Another obstacle is low current density, as present maximum measured current density with the presence of sacrificial agents amounts to 18.8 mA/cm^2 as shown in Table 1. For comparison, photovoltaic panels achieve around 45 mA/cm^2 current density and have a lifespan of around 25 years (200,000 hours). For that reason, to make PEC technology competitive with photovoltaic-electrolyzer (PV-E) tandem devices, more research should be conducted and one of the possible potential directions could be in utilizing perovskite structures who showed excellent photoactive properties.

THERMODYNAMIC ANALYSIS OF BIOGAS-TO-METHANOL CONVERSION WITH CH_4 RECYCLING USING ASPEN HYSYS

*Pali Rosha, * Hussameldin Ibrahim*
Clean Energy Technologies Research Institute, Process Systems Engineering, Faculty of Engineering and Applied Science, University of Regina, 3737 Wascana Parkway, Regina, SK, Canada

ABSTRACT

The methanol synthesis from syngas derived through dry reforming of biogas was studied using an Aspen HYSYS simulator. Studies revealed that hydrocarbon reforming is a practical approach to produce energy-efficient renewable fuels. In this simulation study, an initiative was made to utilize biogas for renewable methanol production using Aspen HYSYS simulator. In the biogas dry reforming process, it was observed that the reactant (CH_4 and CO_2) conversions are largely favoured at elevated temperature (900°C) and ambient pressure (1 bar). Moreover, at optimal parametric conditions, i.e., 200°C (temperature) and 100 bar (pressure), the methanol production rate of 24.7 kg/h was assessed. However, the variation in syngas product distribution was observed w.r.t. temperature and pressure in the water gas shift reactor. Hence, based on the above observations, it can be stated that the biogas-to-methanol process is eco-friendlier, and might be used to mitigate greenhouse gases.

Keywords: Biogas, Syngas, CH_4 recycling, Renewable methanol, Aspen HYSYS.

INTRODUCTION

The conversion of biomass-to-renewable fuels is currently growing worldwide, as biomass waste is already a surprisingly large energy source [1]. The worldwide scientific fraternity has explored various renewable (biodiesel, biogas, hydrogen, syngas, and so forth) fuels using technological approaches [2]. It is worth mentioning that today's research mainly focuses on bio-energy to replace existing conventional fuels. Various hydrocarbon (dry reforming, steam reforming, partial oxidation) reforming routes have been investigated successfully in the last couple of decades for syngas production. Dry reforming is the only one, which consumes two major greenhouse (CH_4 and CO_2) gases; moreover, CH_4 and CO_2 are the main constituents of biogas.

Lately, researcher attention has shifted to bio-methanol production using renewable biogas as a feedstock [3, 4]. In this context, strategies that join biogas and syngas to produce value-added chemicals and/or fuels have recently attained prominence. Syngas, mainly composed of H_2 and CO, serve as essential sources of bio-methanol. At present, methanol comes from conventional fuels using reforming routes; interestingly, literature states that other carbon sources, consisting of CO_2 and biomass, could be effectively utilized for bio-methanol production [5]. In this context, producing syngas from biogas may gain researcher attention. Few scattered simulation studies exist in an open platform on methanol synthesis, likewise, with tri-reforming to optimize the parametric conditions of the overall process [6, 7].

Considering this, it is a right time to utilize biogas for methanol production using dry reforming process. Moreover, for a complete understanding of the biogas-to-methanol conversion process, a detailed simulation study needs to be done first. The use of computer simulation yields a better experience of the overall system and is a handy tool supporting design. This Aspen Hysys-based simulation study seems to be the first study that presents a bio-methanol simulation via dry reforming of biogas. It is anticipated that the model will help understand the general process's behavior without undertaking laborious, high-cost involved time-consuming experiments.

MATERIALS AND METHODS

An Aspen HYSYS simulation software was employed as a process simulator, and for optimization purposes, the Peng-Robinson fluid package was chosen. The assumptions considered were: (1) Simulated (0.6 CH_4 and 0.4 CO_2) biogas was fed at 30°C and 1 bar; (2) The 0.1 bar of pressure drop is assumed in heaters and coolers; (3) A thermodynamic-based study, hence, no catalyst-related aspects are consideration; (4) Impurity-free biogas. A detailed process layout w.r.t. biogas-to-methanol conversion process is shown in Fig.1. The biogas (clean) was initially entered into the pre-heater (H1) at 1.1 bar and 30ºC. The H1 was used to increase the temperature of the biogas stream in the temperature between 700 and 1000ºC. The produced high-temperature stream was then passed into the Gibbs reactor for conducting reforming reactions. The unreacted CH_4 was compressed in the compressor (CR1), and the temperature of unreacted CH_4 was reduced to 30ºC using a cooler (C2). The FTH-2 stream was fed to the heater (H_2) followed by FTR into the Gibbs reactor. The water gas shift reactor product stream was fed to the

component splitter (CS-2); following this, the syngas (STM-5) and H_2 (HTM-5) coming from the prior processes were sent to the mixture (M4) to make H_2/CO ratio suitable for the methanol synthesis process.

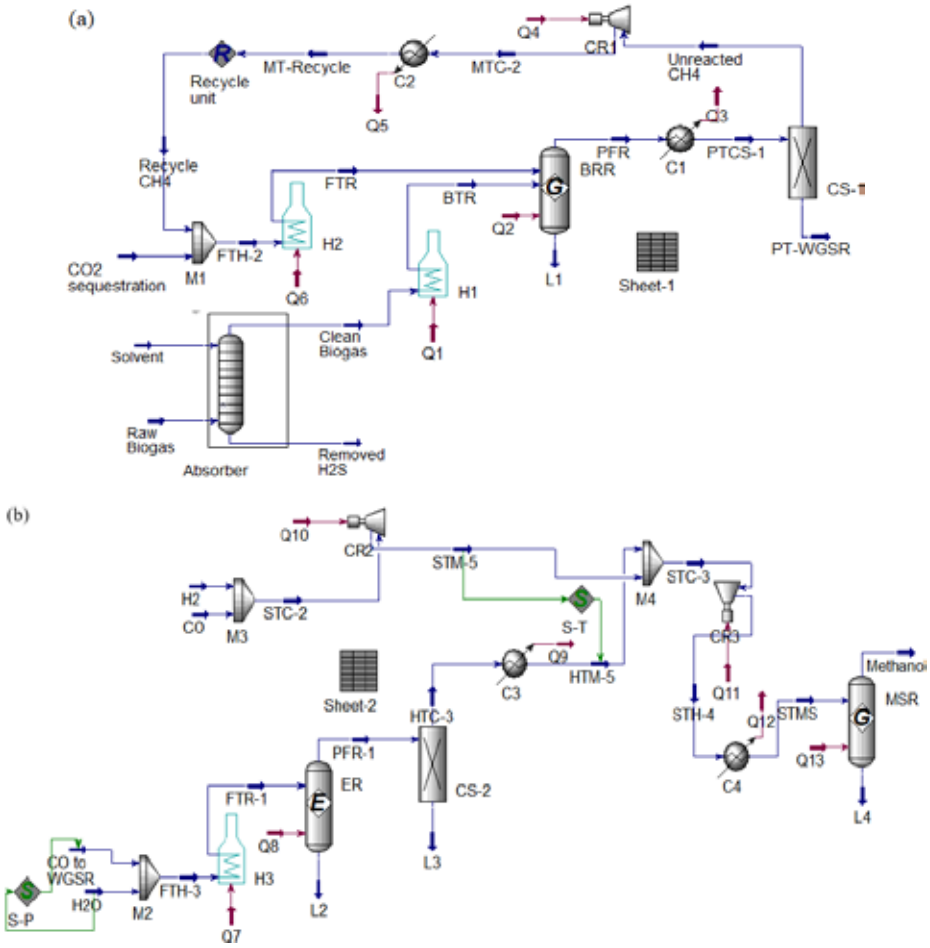

Fig. 1. Schematic layout of biogas-to-methanol conversion unit (a) Biogas dry reforming; (b) Methanol production

RESULTS AND DISCUSSION

EFFECT OF RECYCLING OF UNREACTED CH_4

Table 1 depicts the unreacted CH_4 effects in terms of CH_4 conversions and H_2 production at different temperatures. Results demonstrated that conversion of CH_4 and productivity of H_2 increase with increasing temperatures (700 to 1000°C). It was attributed to the dry reforming endothermicity, which shifts reaction equilibrium towards the product side [8]. After that, recycling of unreacted CH_4 showed positive effects in terms of CH_4 conversion and H_2 productivity. However, at elevated temperatures (>900°C), the recycling loop showed a negligible influence due to higher CH_4 conversion when compared to the lower temperature. Table 2 depicts the results of water gas shift reactions in terms of reactor conversion and product (H_2/CO) ratio. Results showed that the reactor conversion and H_2/CO ratio decrease with increasing temperature (150 to 400°C). It was due to the exothermicity of the water gas shift reaction, resulting in more favorable at lower temperatures [9].

Table 1. Simulation result summary of biogas dry reforming w.r.t. CH_4 conversion and H_2 production

Temp. (°C)	CH_4 conversion (%)		H_2 production (Kg/h)	
	Without recycling	With recycling	Without recycling	With recycling
700	56.3	90.2	1.32	2.34
750	62.6	84.9	1.49	2.39
800	65.3	84.0	1.57	2.42
850	66.2	83.6	1.60	2.42
900	66.5	83.5	1.61	2.42
950	66.6	83.5	1.61	2.43
1000	66.6	83.6	1.61	2.43

METHANOL SYNTHESIS

Table 3 highlights the results of the methanol production at different temperatures and pressure. Results showed that lower reactor temperature and high-pressure offer maximize methanol production rates. Since methanol production reaction is exothermic; thus, according to the Le Chatelier-Braun effect, the temperature must be maintained as low as possible to obtain maximum methanol yield [10]. Simulation results indicated that a minimum reactor temperature of 200°C and pressure of 100 bar should be needed to get the maximum methanol proportion rate.

Table 2. Results of waste gas shift reactor in terms of conversion and product ratio

Temp. (°C)	CH_4 conversion (%)	H_2/CO ratio
150	96.65	1.983
200	94.07	1.97
250	90.74	1.954
300	86.85	1.934
350	82.62	1.913
400	78.26	1.891

Table 3. Methanol production by varying temperature and pressure in kg/h

Temp. (°C)	80 bar	85 bar	90 bar	95 bar	100 bar
200	24.49	24.56	24.62	24.67	24.71
225	21.91	22.27	22.61	22.95	23.31
250	18.84	19.31	19.75	20.15	20.53
275	14.76	15.35	15.91	16.43	16.92
300	10.17	10.80	11.41	11.99	12.54

CONCLUSIONS

The study reveals that biogas-to-methanol conversion might be a sustainable solution to meet worldwide energy demands. It was noticed that CH_4 and CO_2 conversions are more favorable at elevated temperature (900°C) in the dry reforming of biogas. Meanwhile, a 0.585 kg mole/h rate of methanol was achieved at parametric conditions of 200°C and 30 bar. However, the variation in syngas composition was observed regarding temperature and pressure in the water gas shift reactor. Hence, it can be stated that the biogas-to-methanol conversion process could be utilized to mitigate greenhouse gases.

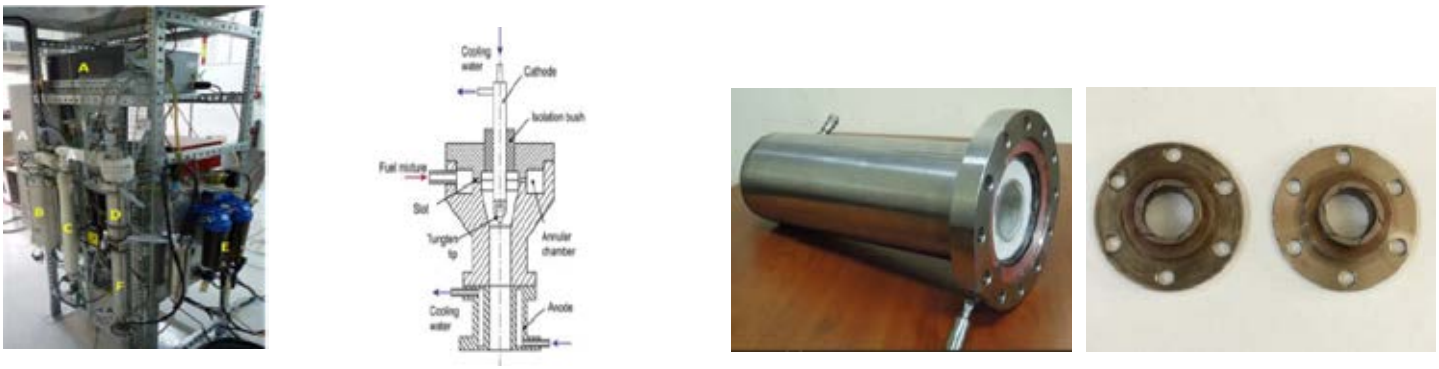
ABSTRACT

The wide use of internal combustion engines significantly affects the environment, human health, and global warming due to their exhausts, while spark ignition engine is considered as one of the main pollution sources globally. Therefore, in order to create a clean environment, achieve higher efficiency, and comply with strict regulations aimed at protecting the globe, many methods have been used to enhance SI engine performance and reduce emissions. Possible solution for emission reduction is the use of alternative fuels such hydrus ethanol or synthesis gas under lean conditions. In this study, a developed design of plasma fuel reformer was used to enhance generation of hydrogen-rich synthesis gas mixing with gasoline. Four modifications of the anode design, two modifications of the swirl ring, and two cathode materials were tested to decide the most efficient configuration of the plasma torch assembly in terms of syngas (or hydrogen) yield. The experimental results revealed that the anode design with smooth funnel shape of the gas inlet anode 1 in ring 1 at air:fuel flow rate of 30:5 was the most effective in terms of hydrogen concentrations in the reformate syngas, by about 46% increment comparing to plasmatron old design.

Keywords: plasma, fuel reforming, syngas production, plasma torch

INTRODUCTION



One way in the technology to reduce pollutant emissions from internal combustion engines (ICs) is to reform hydrocarbon fuels. This technology involves reacting engine fuel with oxygen and/or water as an oxidizer. So that the final product after the reaction is a synthetic gas consisting of a mixture of hydrogen (H2) and carbon monoxide (CO). In-vehicle fuel reform systems can significantly reduce nitrogen oxide (NOx) and emissions for a combustion engine when hydrogen-rich synthetic gas is added to the internal combustion unit [1-6]. Synthetic gas from fuel reforming technology can also be used as a fuel cell source for automotive applications, such as auxiliary power units (APUs) for heavy vehicles and marine transportation [7-10]. Hydrocarbon fuel reform applications use plasma technology as a heat source through reaction. The plasmatron, consisting of a cathode and anode, produces a plasma torch. First, the plasmatron heats the mixtures, which are fuel, air, and gaseous vapor, to high temperatures due to the high energy density produced by the plasma. Second, the ionization and reaction of the components of the gas mixture to produce hydrogen-rich synthesis gas [11]. This study is concerned with the development of plasma-assisted fuel reform for internal combustion engines to reduce emissions. Early studies [12 -16] have shown the production of hydrogen-rich syngas and the reduction of NOx emissions when fueling engines with syngas mixtures. In this study, we investigated the effect of changes in the shape of the anode, cathode material, and plasmatron inlet flow characteristics on the performance of the fuel reforming process. The optimum configuration of the plasmatron with the highest hydrogen yield was identified and used for further operation [12-13]

MATERIALS AND METHODS

The plasma system developed and tested in the experimental series was part of a fuel re-former used in conjunction with a spark ignition (SI) engine test system. The purpose of the reformer is the production of hydrogen-rich syngas as an admixture to hydrocarbon fuels to feed the SI engine. Fuel reformation occurs in a controlled mixture of air, gasoline vapor and steam at atmospheric pressure. The interaction between the constituents of the fuel mixture is initiated by energy of the plasma arc inside the discharge chamber; then, the fuel reforming proceeds to completion when the components exit the discharge tubular reactor. Fig 1a depicts the fuel reforming system employed in this work.

The swirling ring is shown in Fig 1c. Fig 1d shows a picture of the quartz-lined post-discharge reactor with thermal insulation, which was made of mineral wool, water-cooled, and a shell and flange made of stainless steel. In the experimental series, the hydrogen content in the reformate syngas was the main indicator of successful modification of the plasma system. The hydrogen content was measured during each modification of the plasma system configuration. Additionally, the voltage and power output were evaluated during these modifications. The plasma system modifications were the anode geometry, the emitting material of the cathode, and the swirling ring geometry. Four anodes with various

dimensions and cross sections were made and then used as modifications. All anodes were made of low-carbon steel, type AISI 1020. Differences in dimensions consisted of variations in the gas channel diameter. Differences in cross sections consisted of stepped or straight pattern variations of the gas channel. These variations are shown in Fig 2a. The anodes were replaced in sequence within the dis-charge chamber to compare the resulting plasma system performance.Two copper cathodes with different emitting materials of the insert tip were prepared as modifications. The first emitting tip was made of hafnium metal of 99.8% purity. The second tip was made of lanthanated tungsten alloy, as shown in Fig 2b.

(c) The swirling rings of the discharge chamber. (d) Quartz-lined post-discharge reactor with water-cooled shell and flange.

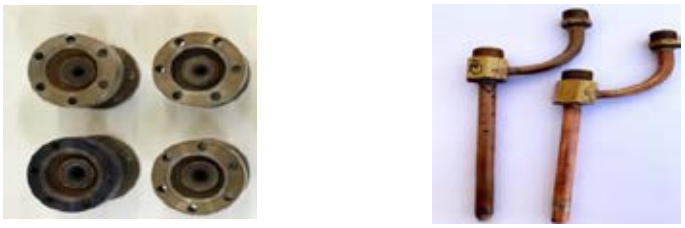

Fig 2. (a) Four anodes with various dimensions and cross sections. (b) Two copper cathodes with different emitting materials.

RESULTS AND DISCUSSION

Two series of comparative tests were performed using a hafnium metal cathode tip and an EWLa2 alloy tip. The individual test series consisted of three consecutive reforming runs with air-fuel ratios of 30: 5, 27: 4.5 and 24: 4 g / min, each lasting 15 minutes. Steady-state discharge voltages were determined during testing at 500 mA DC in the range of 3.6 to 3.7 kV for both types of cathode chips. lanthanated tungsten alloy cathode tips were much preferred for the reformer over those made of hafnium metal. Further experiments were performed in this regard using EWL a2 alloy chips. Four series of tests were performed on different dimensions of the anode under the two vortex ring conditions of the Ring 1 and Ring 2 designs. Experimental results for anode 1 using rings 1 and 2 are shown in Fig 5a and 5b. Initially, the system was in steady state for the first few minutes when the fuel-air mixture began to form in the reactor. Steady-state discharge voltages were set to approximately 4kV and 500mA DC using the anode in the first and second experiments. Syngas production began in the first 15 minutes and the experiment was performed at 24: 4 g / min with a constant air-fuel ratio of 6. The ratio for the next 15 minutes was 27 / 4.5 g / min and the ratio for the last 15 minutes was 30/5 g / min. The highest proportion of syngas in both experiments was H_2 compared to CO and CO_2. For Ring 2, hydrogen reached 21%. In the case of ring 1, it reached 24% due to the difference in the dimensions of the vortex ring. Ring 1 design has a depth width of 0.5 x 1 mm. At 6%, CO_2 share represents the lowest share of syngas. From the start to the end of all experiments with Ring 2, CO_2 was almost completely reduced compared to Ring 1 under 6% conditions. In particular, the increased pressure when the system was closed increased the voltage discharge at the end of the experiment.

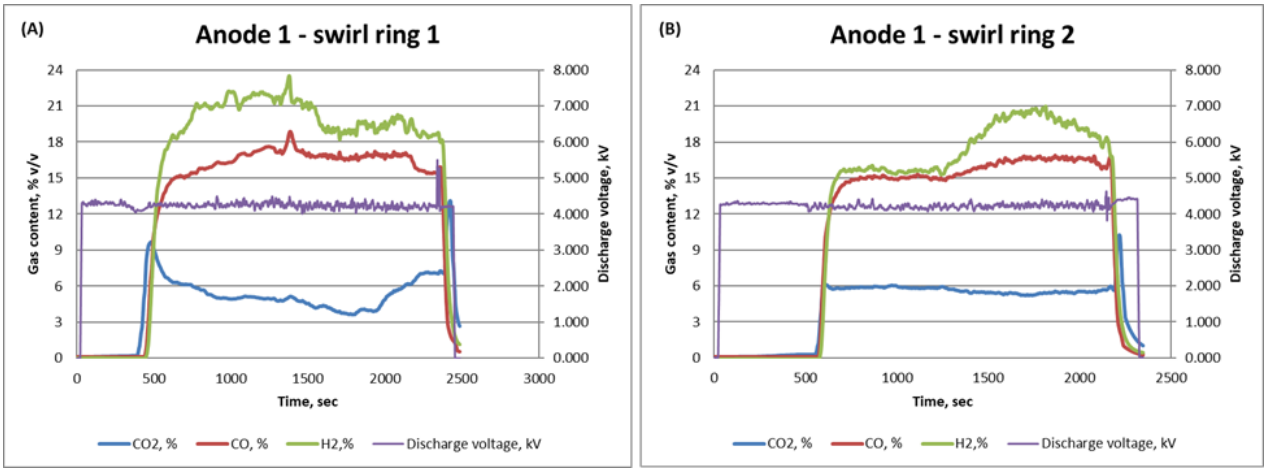

Fig 5. Comparison between ring 1 and ring 2 with anode 1.

CONCLUSIONS

The aim of this study is to investigate the increase in hydrogen-rich syngas produced by plasma reformer system and its effect on nitrogen oxides emissions and fuel consumption in internal combustion engines. An improved plasmatron design carried out consisting of four anode, two swirling rings and two cathode (hafnium metal and Lanthanated) to study the effect on producing hydrogen-rich synthetic gas. It was found that the highest hydrogen percentage in the synthetic gas is 24% (comparing to 13% with old plasmatron design) at anode 1, swirling ring 1 and the best type for cathode is Lanthanated tungsten material due to more resistance to corrosion during the fuel reforming process.

ABSTRACT

Hydrogen production via steam reforming of ethanol reaction was investigated over nickel impregnated commercial mesoporous carbon catalyst (10Ni-MC) in conventionally and microwave heated reactor systems. The characterization results of the catalyst revealed that according to UIPAC classification, nickel impregnated mesoporous carbon showed Type IV isotherm with H2 hysteresis. Highly stable product distributions for steam reforming of ethanol were obtained with the 10Ni-MC catalyst. With an increase in the reaction temperature, the hydrogen yield and the hydrogen concentration were increased in both reactor systems. Higher hydrogen yield and higher concentration of hydrogen were observed in the microwave heated reactor system compared to the conventionally heated reactor system.

Keywords: Hydrogen, Ethanol steam reforming, Microwave heating, Mesoporous Carbon, Nickel

INTRODUCTION

The need for clean and renewable energy sources or carriers has been growing due to the necessity of sustainable and environmentally friendly energy. Hydrogen, a non-toxic, clean, and renewable energy carrier can be considered a potential energy carrier. Ethanol produced from the fermentation of wastes such as corn cobs and sugar beets is one of the most promising sustainable resources for the on-board production of hydrogen via steam reforming reaction. The steam reforming of ethanol involves two main reactions: the steam reforming of ethanol (SRE) and water gas shift reactions (WGSR).

$$C_2H_5OH + H_2O \leftrightarrow 2CO + 4H_2 \qquad \text{(SRE)}$$

$$CO + H_2O \leftrightarrow CO_2 + H_2 \qquad \text{(WGSR)}$$

A conventionally (CONV) heated reactor system is generally used to heat the catalytic bed in the reaction system. Recently, many researchers have focused on improving a new heating reactor system as a process intensification method for different reactions. Microwave (MW) heating reactor system arises as a new heating method. Moreover, recent research studies have revealed that microwave heated reaction system provides more stable reactor performance, higher yield and conversion, and lower coke formation than the conventionally heated reaction system [1,2].

The selection of the catalyst in the microwave reactor applications is critical. Only if the material has a high dielectric loss tangent value can the catalyst bed be heated by microwave. The high dielectric loss tangent value of carbon-based materials provides high microwave absorption capacity. Moreover, the metal particles are good microwave absorbers due to the shape of the metal crystals on the catalyst surface and pores. Due to the sharper parts and corners of the metal crystals, the catalyst can absorb microwaves quickly. The carbon-based catalyst and these metal particles are the reason of the hot spot formed in the catalyst bed, which enhances the reaction rate, the conversion of reactant, the yield and mole percentage of the desired product.

MATERIALS AND METHODS

Commercial mesoporous carbon (MC) was used as a catalyst support, and 10 % nickel was incorporated into mesoporous carbon using an impregnation method. Activity tests of the 10Ni-MC catalyst for the steam reforming of ethanol reaction were performed ~~by~~ using both microwave heated and conventionally heated reactor systems at 500°C and 600°C under atmospheric pressure with a feed H_2O/C_2H_5OH ratio of 1:1 by volume. Weight hourly space velocity (WHSV) of the reaction gas mixture was 4.8 h^{-1} in all 5-hour activity tests. In all experiments, 0.15 g of catalyst is charged to the reactor. The hydrogen production system has been described in detail in our previous publication [1].

RESULTS AND DISCUSSION

XRD pattern of the 10Ni-MC catalyst revealed the presence of metallic nickel and the characteristic peaks of the carbon. According to IUPAC classification, nickel impregnated mesoporous carbon catalyst showed Type IV

isotherms with H2 hysteresis loops. Its surface area and mean pore diameter values were 241 m^2/g and 10.6 nm, respectively.

In all activity tests, the complete conversion of ethanol was achieved. The comparison of the mole percentages of hydrogen and methane at 500°C at the conventionally heated and microwave heated reactor systems is shown in Figure 1. After reaching the steady-state at 500°C and 600°C in the microwave heated system, a more stable product distribution was achieved than the electrically heated reactor system. The hydrogen yield at 500°C in the CONV heated reactor was 51 %; on the other hand, the hydrogen yield in the MW heated reactor was 78 % for the SRE reaction. Moreover, with an increase in the temperature to 600°C, the hydrogen yield values in the CONV and MW heated reactors increased to 78 % and 86 %, respectively. Higher hydrogen yield was observed in the MW heated reactor at the SRE activity tests at both temperatures.

Moreover, in the microwave heated reactor system at 500°C and 600°C, there was a decrease in the mole percentage of methane. The mole percentage of the hydrogen increased with microwave heating compared to the conventionally heated reactor system (Fig.1). The hot spots on nickel particles are responsible for the increase in the hydrogen yield, the mole percentage of hydrogen, and the decrease in the mole percentage of methane because higher temperatures favor the steam reforming of ethanol reaction and methane reforming reaction.

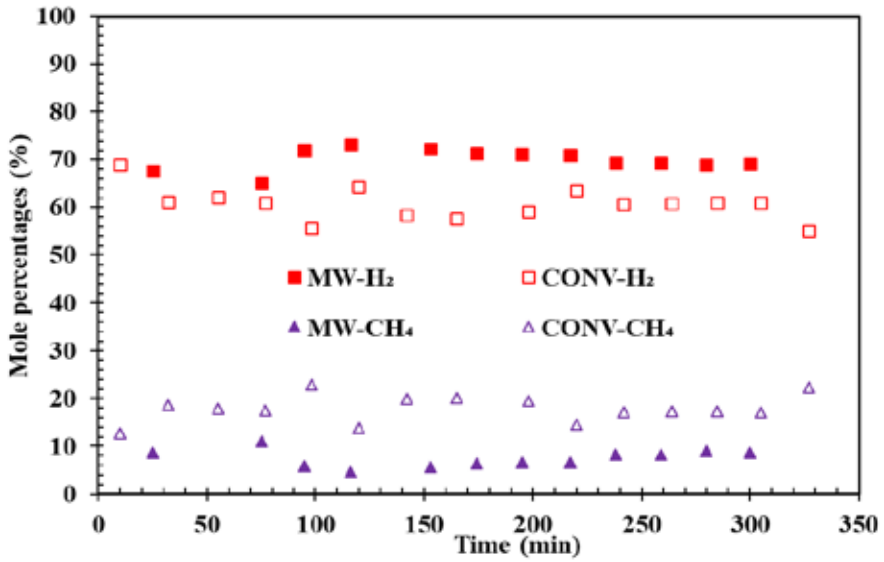

Fig.1 The comparison of H_2 and CH_4 mole percentages in MW and CONV reactors at 500°C

CONCLUSIONS

The activity results in the microwave heated reactor system have shown that highly stable product distributions were obtained in the steam reforming of ethanol reaction. The hydrogen yield and hydrogen mole fraction were increased with an increase in the reaction temperature. Higher hydrogen yield and higher mole fraction of hydrogen were observed in the microwave heated reactor system compared to the conventional heated reactor system. Nickel-loaded mesoporous carbon-supported catalyst gave good catalytic activity in the microwave heated reactor system due to the high microwave absorption capacity of the carbon-supported materials.

ABSTRACT

Hydrogen has emerged as a clean novel energy carrier. Catalytic dehydrogenation of hydrocarbons such as paraffin is a reliable method for hydrogen production. In this study, a radial flow conventional tubular fixed bed reactor is pseudo-dynamically modeled and the operating conditions are optimized using genetic algorithm to maximize olefin and hydrogen production. The model accuracy is validated by industrial data and the model output is optimized using multi-objective genetic algorithm method. Validated model reveals that paraffin conversion and selectivity are enhanced by 3.6% and 0.12% in the optimized process compared to the conventional process, respectively.

Keywords: Heavy paraffin dehydrogenation, Radial flow conventional tubular reactor, Pseudo-Dynamic model, Genetic algorithm

INTRODUCTION

Greenhouse-gas (GHG) emissions and its consequent climate change have raised international concerns [1]. According to 2021 British petroleum's (BP) annual statistical review of world energy [2], global consumption of fossil fuels have risen exponentially from 1965 until 2019. Renewable and clean energy sources are being developed to ensure industrial growth while reducing the hydrocarbon fuel consumption. Hydrogen is a promising and clean energy source [3]. Amidst numerous ways of hydrogen production, catalytic dehydrogenation of hydrocarbons and specifically heavy paraffin is focus of this paper. Dehydrogenation is a chemical process that separates hydrogen from an organic molecule. This process is usually used to convert alkanes to olefins which are much more reactive and therefore precious [4].

Several studies have simulated heavy paraffin dehydrogenation process. Zahedi *et al.* have reported the dynamic model of an industrial dehydrogenation reactor and compared the results with industrial reactor's data [5]. Saeedizad *et al.* studied reversible and irreversible reactions of the overall dehydrogenation of heavy paraffin and the conversion of Paraffin to olefins over deactivating $Pt - Sn - Al_2O_3$ catalyst [6]. They obtained kinetic parameters using non-linear estimation methods and they also showed that the catalyst erosion is even more dependent on temperature than the main reactions. The modeling of a dehydrogenation reactor and optimization by NSGA-II method was represented by Bayat *et al.* and the rate of production as a function of reactor radius was reported [7]. Finally Frantsina *et al.* introduced the results of comparative analysis on three cycles of heavy paraffin in presence of a Pt catalyst in their study [8]. To date there is no published study on dynamic modeling of hydrogen production via dehydrogenation of heavy paraffin in conventional reactors. In this paper, a radial flow conventional tubular fixed bed reactor is pseudo-dynamically modeled and the respective operating conditions are optimized using genetic algorithm to maximize olefin and hydrogen production.

MODEL DESCRIPTION

A pseudo-dynamic mathematical model of a radial flow fixed-bed conventional tubular reactor was prepared. Dominant reactions in dehydrogenation of heavy paraffin are shown in Figure 1(a). Reaction rates and optimized Kinetic parameters were taken from Zahedi *et al.* [5] and Vafajoo *et al.* [9] which are shown in Table 1. Governing equations reported in Table 2 include mass and energy balances, Ergun equation for pressure drop, and catalyst deactivation equation. All balance equations dependent to radius were numerically solved using Backward Euler method. Main assumptions of the model are: (a) all gas mixtures are assumed to be ideal, (b) external reactor wall is assumed to be insulated, (c) gas mixtures move radially inside the reactor therefore radial velocity is variable, (d) there is no mass and heat transfer between catalyst particles, (e) molecular diffusion is ignored compared to bulk flow, and (f) pressure drop only occurs radially. The differential element along the radius of the reactor is shown in Figure 1(b).

Catalyst Deactivation	$t = \frac{1 - a_c^{(1-n-{E_d}/{E_A})}}{k_{d0}(1 - n + {E_d}/{E_A})}$	(14)

RESULTS AND DISCUSSION

Steady-state and pseudo-dynamic simulations have been performed on model and the model is validated by Bistoon petrochemical complex (BPC) LAB plant data [10] with less than 5% error. Olefin production rate along the radius of the reactor in 1st, 10th, 20th and 29th days are compared in Figure 2. Olefin is considered to be the desirable product of process and its yield decreases with time due to the coke formation and subsequent catalyst deactivation process. Radial temperature profile during 29 days of operation is demonstrated in Figure 3. As the overall process of heavy paraffin dehydrogenation is endothermic, temperature decreases along the radius of the reactor but the amount of

this decline in temperature decreases by time due to the catalyst deactivation and subsequent reduction of paraffin conversion.

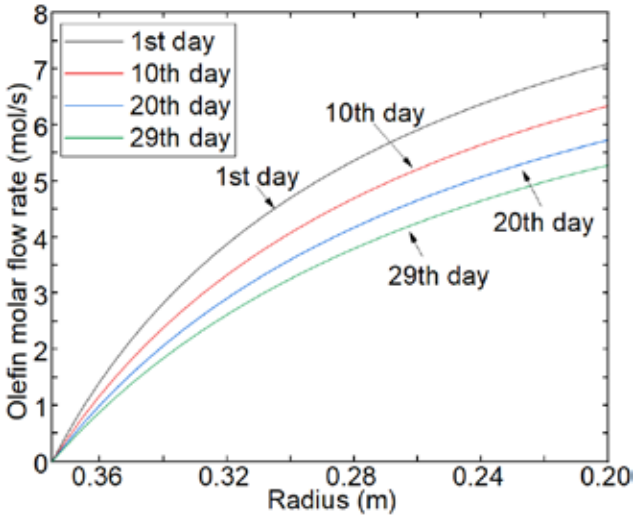

Figure 2. Olefin production rate in designated times

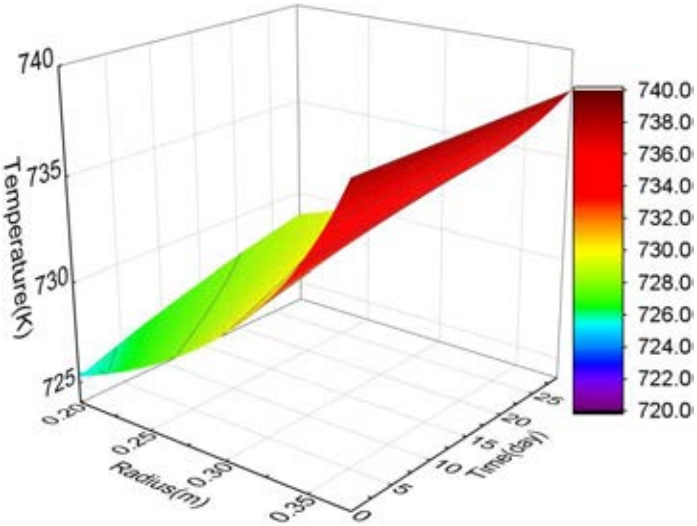

Figure 3. Radial temperature profile for 29 days

CONCLUSIONS

Steady-state and pseudo-dynamic simulations are performed on a pseudo-dynamic mathematical model of a radial flow fixed-bed conventional tubular reactor. Model validation proves the simulation accuracy. A multi-objective optimization is performed using genetic algorithm method to increase yield of the reactor. It is shown that paraffin conversion and selectivity are potentially enhanced by 3.6% and 0.12% in the optimized process compared to the conventional process, respectively.

ABSTRACT

Renewable hydrogen (H_2) carriers such as methanol (MeOH), dimethyl ether (DME), oxymethylene dimethyl ethers (OMEs) and conceivably ammonia (NH_3) can be reformed back into H_2 and are fundamental chemical conversions for the long-term viability of the H_2 economy due to their higher densities and ease of transportability compared to H_2. MeOH is an especially important carrier as it is a simple C1 chemical that can be produced from green solar-PV-generated H_2 and direct-air-captured CO_2 with a current commercially practical solar-to-fuel efficiency of 10% from renewable solar energy. MeOH steam reforming (MSR) in stationary systems next to H_2 fuel-cell filling stations can eliminate the need for on-board mobile reformers and the former systems can be more robust in terms of attaining strict H_2 product specifications and MeOH is a safe, lossless and a compact medium for long-term H_2 storage. Both thermal- and photo-catalysts are viable options for achieving stable, long-term performance of stationary MSR systems.

Keywords: fuel-cell vehicle filling stations, methanol steam reforming, hydrogen transport and storage, stationary reformer, liquid hydrogen carriers

INTRODUCTION

Much research has focused on the MeOH steam reforming (MSR) to produce H_2 and CO_2 with minimal selectivity and yield to carbon monoxide (CO) [1]. CO must remain at low to trace levels to avoid poisoning the noble metal catalysts (platinum (Pt), palladium (Pd) *etc.*) that are applied in fuel-cell stacks. Using H_2 in mobility applications such as fuel-cell vehicles can increase fuel efficiency to 80% or higher, or approximately double the efficiency of state-of-the-art internal combustion and compression ignition engines. H_2 for transport also avoids the shortcomings of Li-ion batteries with the former having superior range and faster filling times for short and long-haul transport. However, auxiliary equipment such as on-board reformers for mobile applications can increase the complexity of the fuel system. Alternatively, we propose reforming liquid hydrogen carriers at stationary installations such as H_2 filling stations so that H_2 can be stored safely and at high density and released as needed for filling fuel-cell vehicles.

The MSR and MeOH decomposition reactions are endothermic (Eq. (1) and (2)) and as such require heat be applied to the system to drive them to completion. Another important reaction is the water-gas shift (WGS) reaction (Eq. (3)) that can be used to generate further H_2 while simultaneously eliminating CO.

$$CH_3OH + H_2O \rightarrow 3H_2 + CO_2 \qquad \Delta H_{298K} = +49.6 \text{ kJ mol}^{-1} \qquad (1)$$

$$CH_3OH \rightarrow 2H_2 + CO \qquad \Delta H_{298K} = +90.6 \text{ kJ mol}^{-1} \qquad (2)$$

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta H_{298K} = -41.3 \text{ kJ mol}^{-1} \qquad (3)$$

The catalysts needed for reforming MeOH are widely known and available [1] and coupling them with a suitable reactor can allow for a proof-of-concept demonstration. A microchannel reactor is one type of prospective MSR reactor that has excellent heat transfer characteristics and suitable flow properties in the catalyst bed to avoid 'hot spots' and 'dead zones', respectively. It also allows for high conversion of feed MeOH and steam being of the plug-flow type. The moderate operating temperature of 200–300°C can be achieved using a hot oil heat transfer fluid and a low operating pressure favours the forward reaction by Le Chatelier's principle.

The gas specifications for fuel-cell operation are provided in ISO 14687-2 [2]. It should be noted that these specifications are conservative and "reflect the priority of automobile OEMs to minimize risks of damaging very expensive pre-commercial fuel cell demonstration vehicles" [3]. Multiple grades of hydrogen may be accommodated in the future.

A system demonstrating this conversion technology must be scalable to prototype and pre-commercial/commercial scales. To achieve this, the following technology criteria ought to be accounted for: cost, safety, selectivity to intended products, H_2 yield, ease of optimization, low operational sensitivity, and relevant capacity.

DISCUSSION OF MEOH VS. NATURAL GAS AS A HYDROGEN SOURCE

There is a two-fold nature to the hydrogen sourcing challenge, there is the need to trade off fuel cell performance and durability against the cost of delivering adequate quality hydrogen to the consumer [3]. MSR is distinguished from steam methane reforming (or SMR) in that it avoids many shortfalls of the latter that and can be made from renewables. Methane can also be sourced from biogas *via* anaerobic digestion although not at the scale needed for the hydrogen economy and is typically used as a fossil fuel.

MSR eliminates sulphur and ammonia that are present in natural gas

MSR avoids all sulphur compounds (such as H_2S etc.) and NH_3 found naturally in natural gas streams. Sulphur's effect on fuel-cells requires it to be maintained at ppb levels. Catalyst poisoning when exposed to sulphur compounds has been found to increase with time of exposure. Like sulphur, NH_3 contamination is cumulative. The effect of CO (discussed more latter) is displaced by H_2S meaning that although the kinetics of CO are faster, H_2S has a higher adsorptive strength and over time suppresses CO adsorption making H_2S worse for the catalyst overall. Detection of sulfur compounds also requires "extremely sensitive analytical equipment and careful monitoring of fuel quality along the entire fuel chain from production to dispensing" [3].

MSR avoids many inert gases present in natural gas

MSR avoids helium and other hydrocarbons contamination and dilution naturally present in natural gas streams. Helium is difficult to detect and can be present at 100s of ppmv in natural gas. A cumulative inert amount of ~300 ppmv is recommended for fuel-cell operation to avoid sensor and stack malfunction. Competing technologies such as SMR and water electrolysis both entrain or produce inert gases. Air is typically entrained during SMR, and water electrolysis can also produce trace amounts of inert O_2, that require to be kept below the threshold.

The MSR process is less complex overall than SMR

An example of a SMR process for hydrogen is shown in Fig. 1. Major differences are that the MSR can be operated at lower reforming temperature of 200–300°C compared to 750°C for SMR. MSR still requires WGS, water separation, and PSA, but can more easily compress liquid MeOH prior to the reforming step than natural gas. A lower WGS step temperature is preferred as the equilibrium yield to CO increases with temperature and as such the MeOH reforming temperature is more compatible with WGS. Moderate pressures of 8–10 atm were modelled as a good target pressure at a steam/carbon ratio (S/C) of 4 for SMR and is expected to be similar for MSR [3].

Removing contaminants and quality of H_2 product gas needed

As mentioned previously, ISO 14687-2 details the H_2 gas specification needed for fuel-cell durability. CO (0.2 ppmv specification) is seen as limiting species to remove, higher removal leads to lower H_2 recovery and lower overall fuel efficiency. Attempting to maintain low CO contamination can affect the H_2 purity as N_2 can 'break-through' in the PSA process if present at high concentrations prior to PSA. Because MSR starts with a liquid MeOH feed it can be designed to avoid any entrained air during the process (as opposed to SMR) and is an advantage of this route. This highlights the challenge of maintaining all inert gases (He, HCs, O_2, water, N_2, Ar etc.) at low to trace levels prior to PSA. CO_2 is easily removed from PSA.

Easing the CO specification will increase the overall efficiency. In an analysis carried out by the DOE assuming relatively high fuels cost ~US$ 7.73 $MMBTU^{-1}$ the CO purification only affects the H_2 cost 4.4% over an order of magnitude change (0.1–100 ppmv CO) [3]. A slightly dated (2015) but still relevant DOE target for hydrogen fuel cost at the station is US$ 1.5 kg_{H2}^{-1}.

INTERESTING CATALYST SYSTEMS

Stage 1: Thermal Catalysts:

Many thermal catalyst systems have been proposed as seen in the following references [1,4]. Typically, a good MeOH synthesis catalyst would also act as a good reforming catalyst under different conditions. However, the traditional copper-based, copper zinc-oxide alumina (CZA) catalyst, used successfully for decades for MeOH synthesis, presents challenges due to its short-term stability under MSR conditions. Catalysts that avoid the dispersed copper phase based on Pd and ZnO have shown improved durability under operating conditions [4].

Another approach that could be explored is to decompose MeOH into CO and H_2 directly on standalone Pd catalyst and shift the CO out of the system in a downstream WGS step. This approach has not been significantly documented in the literature.

Stage 2: Photocatalysts

A ZnO material demonstrates photoactivity for MeOH reforming under dark or thermal-only conditions with MeOH-water vapour and under UV light with MeOH-only and MeOH-water vapour [5]. In unpublished results, direct UV-assisted MeOH decomposition and thermal MSR is not as favoured as UV-light-assisted MSR. The analytical technique UV electron paramagnetic resonance (UV-EPR) confirmed the production of UV induced electrons/defects upon irradiation. The electron reduces the Zn(II) to Zn(I) and light provides photogenerated electron and holes for MSR.

The benefit of using ZnO is that it avoids the metallic Cu or Pd phase of thermal catalysts that tend to sinter due to the hydroxylation of the ZnO phase. By using ZnO alone and allowing it to slowly hydroxylate, it is conceivable that the material could be regenerated in a thermal reconditioning step to remove the water in the structure. Such a technique of operating two reactors in parallel (on online and one regenerating) is used throughout the chemical and petrochemical industries and addresses and simplifies the unavoidable catalyst deactivation typical under MSR conditions.

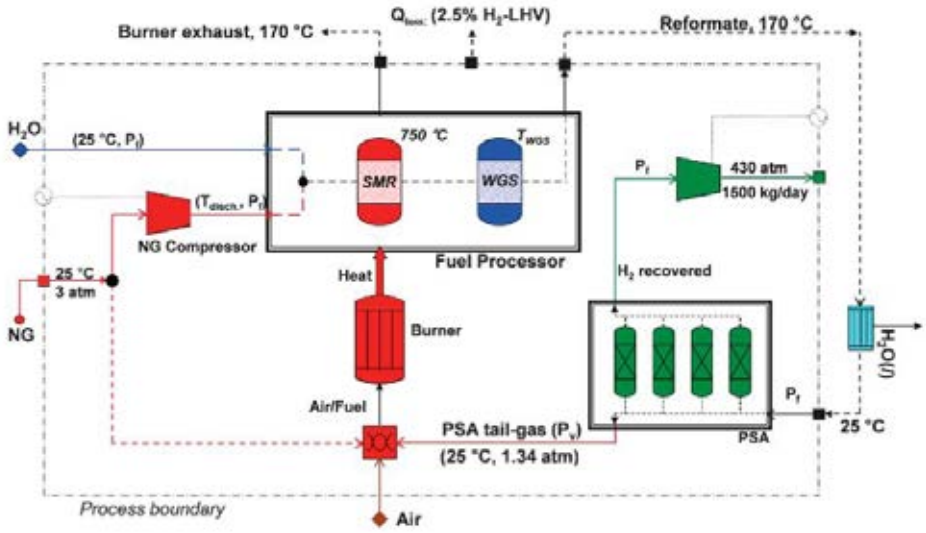

Fig. 1 Example of SMR process and auxiliaries that would be similar to a MeOH-based system [3]

ABSTRACT

The use of thermochemical water-splitting cycles to produce hydrogen gas is considered a promising low-carbon technology if they are powered by solar energy. This work presents an experimental study of a two-stage thermochemical cycle for hydrogen production. It is based on the carbothermic reduction of iron ore (Fe_2O_3) and the re-oxidation of it with steam, being the whole process powered by concentrated solar energy. Samples studied were self-reducing pellets The first stage of the proposed cycle consists in the reduction of hematitic iron oxide into its own metal at temperatures above 1173 K. The second phase of the cycle consists of iron metal oxidation by steam, which produces hydrogen gas. The rate of hydrogen gas production was measured using the gas chromatography methodology. After carbothermic reduction the samples showed a high specific surface area of 35.05 m^2/g measured by the BET method.

Keywords: Hydrogen production, Solar fuels, Carbothermic reduction, Iron oxide (Fe_2O_3), Catastrophic swelling,

INTRODUCTION

The use of renewable energies and renewable materials in industrial processes are the path to a low-carbon society. A well analyzed to hydrogen production process is based on a two-step cycle of metallic oxides, in which the solar thermal energy is used to decompose a metallic oxide into a reduced form of the metal and oxygen gas. Next, the reduced metal is reoxidized with steam, generating hydrogen gas. In this work, it is proposed a two-step thermochemical cycle to produce CO and H_2 based on the carbothermic reduction of self-reducing pellets of iron ore (Fe_2O_3) and charcoal followed by the oxidation of the reduced iron produced in the reduction step by steam.

The metal oxide must react with carbon at relatively low temperatures, ideally under 1273 K, and it should be abundant, recyclable, and available at a low cost. The iron oxide meets those requirements [1-3]. The first step is the carbothermic reduction which is endothermic and produces a CO and CO_2 gas mixture at a higher content of carbon monoxide. The second step is the oxidation of the reduced iron with steam producing a steam and H_2 gas mixture. Iron ore reduction by solid carbon takes place as they are brought in contact and heated above the equilibrium temperature between the oxide and the metal (Eq. 1), and the oxidation step, the reaction is exothermic and the final principal species are hydrogen and iron oxide (Fe_3O_4) (Eq.2).

$$Fe_2O_{3(s)} + 3C_{(s)} \leftrightarrow 2Fe_{(s)} + 3C_{(g)}, \quad (1)$$

$$Fe_3O_{4(s)} + H_2O_{(g)} \leftrightarrow Fe_2O_{3(s)} + H_{2(g)}, \quad (2)$$

The oxidation reaction occurs at temperatures between 823 and 1173 K [4]. These temperatures are lower than those needed in direct decoupling cycles and therefore, the amount of energy supplied to the system is lower. During the first stage of the tested cycle, a porous metal with a high specific surface is formed, which has advantage of a high reaction kinetic rate that makes the second step cycle reaction more efficient.

MATERIALS AND METHODS

A commercial pellet feed with a particle size of less than 0.150 mm was used as the iron ore for the experiments. The charcoal was obtained from a raw rice carbonization process. The carbonization was performed by heating a certain amount of rice to 973 K during 2 hours. The self-reducing pellets were manually pelletized ranging from 1.5 to 2.0 cm in diameter. The reduction step was performed by using an electrical resistance vertical furnace. The sample holder is tied by a nickel-chromium wire connected to an analytical balance. The reduction experiments were performed isothermally at 1223 K in an inert atmosphere established by nitrogen gas flowing during 120 minutes.

The schematic representation for the iron oxidation step is presented in Fig. 1. Steam and nitrogen gas are fed into the reactor cavity at 270 °C. The sponge iron samples are placed in the cavity and the temperature is monitored with a K-type thermocouple.

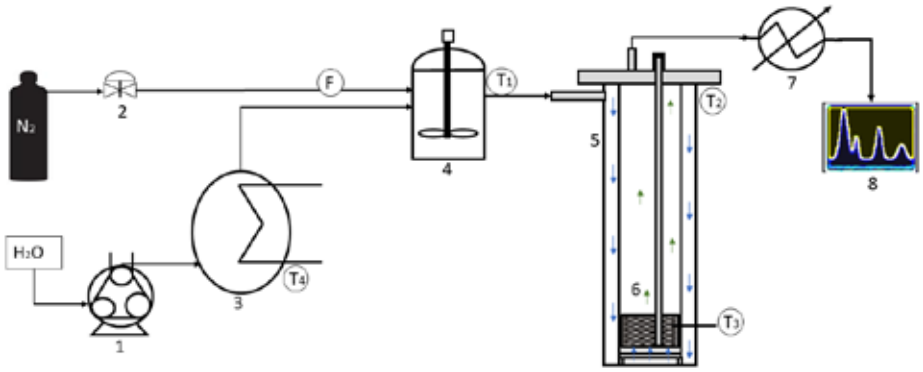

Fig. 1. Schematic diagram of experimental setup used for Oxidation step. 1) peristaltic pump, 2) pressure regulating control valve, 3) water evaporator, 4) Mixer and pre-heater, 5) reactor, 6) iron samples, 7) condenser, 8) as chromatograph.

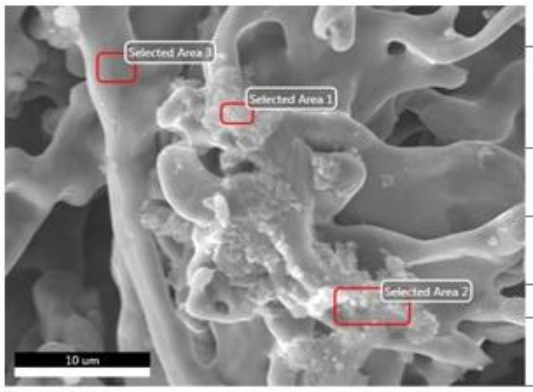
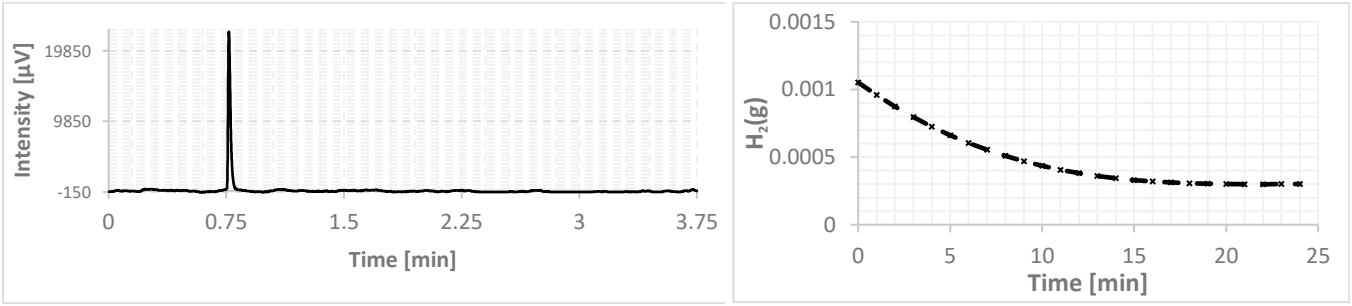
The experiments were performed isothermally at 1023±5K, for 50 minutes. Nitrogen flow (1.5 mL/min) and the steam were injected as shown in Fig. 1. The steam was generated by dripping a controlled amount of water (0.04 mL/s) in a stainless-steel chamber heated by using a electrical resistance plate at 523 K. The reactor output was connected to a gas chromatograph Nexis GC-2030, with split injection of gaseous samples and TCD detector. The products were separated by a carboxen 1010 plot column (30 m), which uses N_2 (99.999%) as the carrier gas. A chromatogram analysis of the gases was carried out at every 3.75 min until finishing the test.



The oxidized samples were characterized by a scanning electron microscopy using a FEI microscope model Inspect f50 equipped with an EDS detector. The phases in the samples were characterized by an X-ray diffraction analysis using a Philips X'PERT MPD equipment. The sample surface area was estimated by nitrogen adsorption isotherms using the BET method, using a Micromeritics equipment, model ASAP 2020.

RESULTS AND DISCUSSION

Carbothermal reduction: After reduction of iron ore and rice charcoal to 1173 K for 120 min, the material had a spongy appearance, with a shape characterized by catastrophic swelling, showing a significant increase in volume. After the treatment, the sample lost 25.85 wt.% of its initial weight. It is observed that the weight loss can be attributed to the output of oxygen from the iron ore that reacts with the fixed carbon contained in the charcoal. Due to the carbonization conditions of rice, there are no losses by volatile material. Which did not need to be taken into account. The mass balance showed a 39.81 wt.% weight loss of the self-reducing pellets. However, for the conditions of temperature and time, the reduction was not complete. As can be seen in Fig. 2, charcoal (C) particles are still detected and the presence of ash in the composition of the analyzed (area 1 and 2).



The sponge iron samples obtained in this work had a specific surface area of 35.05 m^2/g measured by the BET method. This is an exceedingly high value compared to the specific surface area of sponge iron obtained by conventional processes, for which, a typical value of 1 m^2/g of DRI has been reported for Schutze [5] or 16.26 m^2/g reported for Guo [6]. The microstructure of the tested sample was observed in a scanning electron microscopy (SEM), which revealed a structure formed by iron filaments throughout the sample. Nearly all the iron grew from the oxide in the form of whiskers. In the results of X-ray diffraction analysis can be seen that practically all the material was converted to metallic iron during the reduction, with an almost negligible presence of wustite.

Iron Re-Oxidation: In spite of the gas chromatograph being in-line connected to the reactor outlet, gas samples were collected every 3.75 min. Fig.3a) shows the results of one of the analyzes performed with gas chromatography. It can be seen that for a retention time of 0.767 min, a peak associated with gas hydrogen was generated, as expected, only this gas was identified. At the same time that the sample shows a mass gain due to the conversion of iron to magnetite and wustite, the release of hydrogen in its gaseous form also occurs. Fig. 3b) shows that there is a high initial rate of H_2 release, which decelerates rapidly as the oxidation process occurs. There was a high rate of H_2 formation at the beginning of the process, followed by a decreasing rate, thus, 60.27% of the total produced was released during the first 13 min. after the oxidation started. This behavior was explained in greater detail in previous works [7]. In the results of the X-ray diffraction analysis, it can be observed that practically all the material was transformed into Fe_3O_4 during the oxidation, with less presence of FeO and Fe_2O_3.

CONCLUSIONS

This work presents an experimental investigation of a reduction-oxidation thermochemical cycle for the production of hydrogen and carbon monoxide gas (syngas), each at different stages of the cycle. This type of cycle works at lower temperatures than those commonly used, due to the presence of a reductant from biomass such as rice coal. The high iron surface area obtained in this work favored the production of H_2, allowing the possibility for the cycle to be optimized in relation to the time of the iron oxidation step, interrupting the oxidation process as it decelerates.

ABSTRACT

Water splitting via solar energy to generate hydrogen represents a promising energy resource to address the emission and the environmental climate change. Cadmium Sulfide (CdS), with its specific characteristics, attracts significant attention as a promising photocatalyst for water splitting. However, most experimental studies do not provide adequate data to perform kinetic studies and develop kinetic models that are necessary for reactor and process design. Therefore, in this study, the binary photocatalyst CdS-ZnS/Pt was employed for water splitting using simulated solar energy to produce Hydrogen. In addition, it was necessary to design and fabricate a fully automated experimental lab-apparatus (cylindrical reactor with 70 mm ID and 10 mm depth; top-down illumination) to conduct unattended and long-duration experiments while collecting data continuously. At first, the crystallinity of the catalyst, the particle size distribution of the particles, and the band gap of the catalyst were checked given their critical role in the hydrogen evolution rate. The XRD results verified the hexagonal structure (of CdS), the FESEM images showed particles' size from 150 nm to 2 μm, and the solid state UV-Vis yielded a band gap of 2.3 eV. Toward the collection of the kinetic data, various ranges of the catalyst loading, the concentration of the sacrificial reagent, the temperature, and the light intensity were studied. In parallel, the photo-deposition of Pt cocatalyst proved as another critical factor; herein conducted for 30 min under 1-sun intensity. The so far data showed that the optimum hydrogen evolution rate at one-sun is 37 μmol/h or (2507 μmol/g.h) at 50^{O}C and 0.2 M ascorbic acid. At completion, the experimental dataset will be one of the few appropriate ones for kinetic studies' and comprehensive design of photocatalytic reactors.

Keywords: Kinetic data, Experimental, PhotoReactor, Water splitting

INTRODUCTION

Fossil fuels are still the main energy resource around the world causing multiple environmental challenges with many associated with the global warming. Hydrogen, with its high energy content, is considered a promising renewable and sustainable energy source of the future [1]. Different techniques have been proposed for hydrogen production such as photocatalytic, photoelectrochemical, thermal and biological [1, 2, 3]. The advantages of using photochemical and electrochemical over the other techniques is the direct utilization of solar energy with higher yields but at ambient pressure and temperature [4]. Photocatalytic solar energy conversion with high efficiency and at large scale will have a significant impact on the economy, environment and energy [5]. For this reason, one of the most active research topics is on the development of technologies for water splitting using solar energy and a semiconducting catalyst [6, 7, 8]. However, the challenges scaling these technologies are also many [9]. The photochemical techniques depend on photocatalysts' efficiency to drive the chemical changes but also involve multiple physical processes (photon's absorption, electrons production, carrier diffusion and transport, and mass transfer of reactant and products [10]. The main emphasis in the literature is to synthesize innovative materials with ideal conduction band, narrow bandgap, and at low-cost [11, 12]. As an example, CdS with a narrow bandgap (2.4 eV) and negative flat band potential (-0.9 V vs. NHE) is one of the widely used components of photocatalysts [2, 13, 14]. However, the overall hydrogen production depends on the contribution of all parameters affecting the chemical and physical process. Despite that, most of the research focuses on the materials regardless of the need to improve the overall photocatalytic process, including the reactor design as well as the mechanism of the reaction. The lack of comprehensive hydrogen evolution reaction kinetics studies is also prominent in this field. In this work, emphasis is on conducting a thorough experimental campaign on the photocatayitic hydrogen evolution reaction and the effect of external factors on the mechanism and kinetics. The generated data, upon completion, can be used to predict hydrogen rate, as a function of photocatalyst loading, reagent concentration, light intensity, and temperature, and to describe the reactions kinetic model.

MATERIALS AND METHODS

Materials

Cadmium acetate dihydrate (98%) purchased from Aldrich, Sodium Sulfide nonahydrate (98%) acquired from ACROS ORGANICS. Zinc Acetate dihydrate (99%) obtained from Aldrich, Chloroplatinic Acid hydrate (99.99%) obtained from

Merck, PVP from Fluka Analytical (average MW 40,000), Sodium borohydride (98%) purchased from Aldrich, Ascorbic Acid (L+ 99.7%) purchased from BHD. All the chemicals were used without further purification.

Synthesis of Photocatalyst

Cadmium Sulfide was synthesized in our lab by mixing approximately 0.1 M Cadmium Acetate and 0.1 M Sodium Sulfide in 1:1 molar ratio, under continuous stirring for 30 min at room temperature; the yellow precipitate was filtered and washed with deionized water several times; and the product was then subjected to high-temperature treatment at 600 °C under N_2 atmosphere for 3 h.

The CdSZn photocatalyst was synthesized using our reported procedure [2], in more details CdS powder was used in suspension of water under continuous stirring, 0.1 M of Zinc Acetate was added drop wise to produce CdSZnS photocatalyst. 0.2% Pt nanoparticles was used as cocatalyst to produce CdSZnS/Pt photocatalyst.

Hydrogen Evolution Reaction

The synthesized CdSZnS/Pt photocatalyst was transferred to the reactor (Fig. 1) for hydrogen evolution reaction, Ascorbic Acid was used as sacrificial reagents. The water splitting reactions were conducted at different catalyst loading (5-15-20 and 25mg), various concentrations of Ascorbic Acid (0.2-0.3M), different temperatures (40-50-60^{O}C) and light intensities (~500, 1097, 1500 and 2000 W/m^2). The CdSZnS/Pt suspension was kept under stirring while the reactor temperature was controlled by a heat exchanger. The photoreactor was purged with Argon for 30 min before each experiment in order to remove oxygen from the system. The photocatalyst was illuminated (with the ScienceTech UHE16 Solar Simulator using a Xenon-arc lamp) for 30 min for Pt nanoparticles photodeposition at the surface of the catalyst, then the illumination was paused to inject the sacrificial reagent in dark and allow adsorption to reach equilibrium. The hydrogen evolution reaction was carried out under Argon atmosphere (~54 ml/min flow) to prevent the photo-corrosion and dissolution of the photocatalyst. The pressure within the reactor was maintained at around 50 mbar using an back flow pressure controller. The evolved hydrogen gas was continuously monitored using a residual gas analyzer (Hiden Analytical RGA) calibrated before each experiment with a 50 µl pure H_2 bolus injection which corresponds to partial pressures similar to the ones during the experiments. Finally, the photoreactor system was shielded by four opaque acrylic windows to prevent personnel exposure to the UV irradiation.

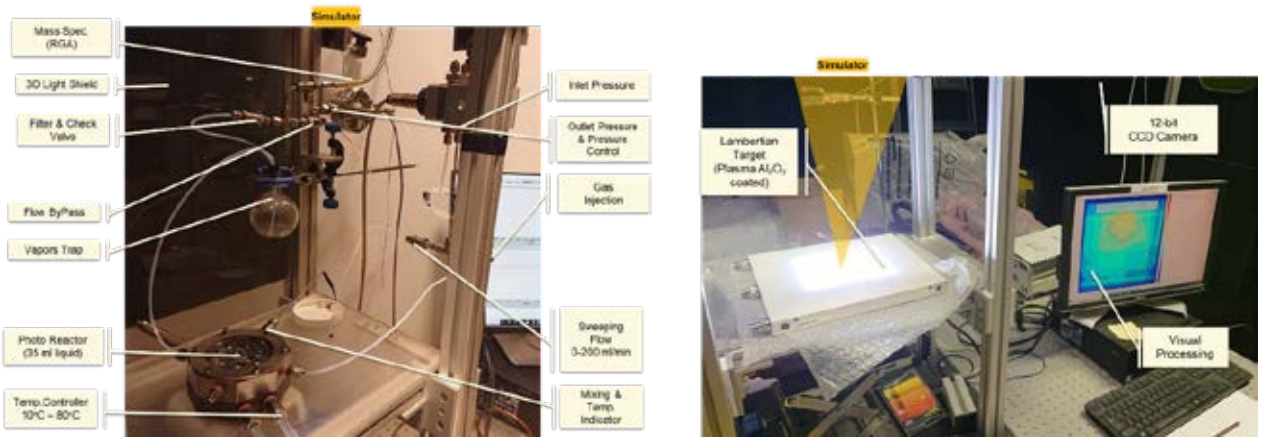

Fig. 1. Photo of the photoreactor system (left) and an example of the light intensity measurement and calibration (right).

PRELIMINARY RESULTS AND DISCUSSION

Effect of Photocatalyst Loading

To study our photoreactor's capacity under specific temperature and light intensity different loadings of photocatalyst suspension were loaded. At 40^{O}C and with 0.2M of Ascorbic Acid, the hydrogen specific evolution rate (µmol/g.h on Table 1) achieved the maximum at 15 mg photocatalyst loading. However, with 0.3M of Ascorbic Acid the optimum photocatalyst loading was at 20 mg. On the other hand, the hydrogen evolution rate (µmol/h) for 0.2M Ascorbic Acid continuously increased for increasing photocatalyst loading from 5 to 25 mg while reached a maximum at 20 mg for 0.3M concentration. In all cases tested so far, the hydrogen production is stable for at least six hours indicating a fair stability of the photocatalyst.

Effect of Temperature

So far, the effect of temperature on hydrogen production was tested at three values 40, 50 and 60^{O}C and only for 0.2M Ascorbic Acid. The hydrogen production showed the highest value at 50^{O}C (2507µmol/g.h) which indicates the significant role of temperature.

Table 1: Hydrogen production at different photoatalyst loadings and ascorbic acid concentrations.

Catalyst. Loading [mg]	Hydrogen Evolution [μmol/g.h] (or [μmol/h]) Ascorbic Acid 0.2M	Ascorbic Acid 0.3M
5	794 (4)	1210 (6)
15	1754 (26)	1565 (24)
20	1508 (30)	1768 (35)
25	1329 (33)	401 (10)

CONCLUSIONS

Numerous parameters are essential for the hydrogen evolution reaction the ones related directly to the semiconducting properties of the photocatalyst that are typically studied in the literature. The interpretation and understanding of these parameters are critical to achieve a sustainable and economically viable photochemical water splitting. In this work we reported the preliminary results of photocatalyst loading and temperature on the hydrogen evolution using a specific chemical system and demonstrated the importance of collecting continuous data and at various conditions. Data that will be used for the development of kinetic models and subsequently for photoreactor design.

ABSTRACT

Hydrogen can be produced as a thermochemical by-product from the reactions involving metals such as Na, Al, And Fe with water in tbe gas or liquid phase. The effectiveness of the splitting of hydrogen from water molecule can be increased using activators or catalysts. The faster chemical reaction rate is demanding to meet the industry needs. The process controlling should be implemented in this reaction, since metal reaction with water is exothermic in nature. In this work, cylindrical aluminum wires are activated using a NaOH solution and hydrogen production rate is studied experimentally as a function of several parameters including temperature and wire diameter. To provide an atomistic insight into our experimental results, first-principles total energy calculations were carried out using density functional theory (DFT). Activation barriers calculated by DFT are compared with experimental results and validate our theoretically proposed reaction mechanism.

Keywords: Hydrogen generation, Aluminum activation, Density functional theory, Clean energy.

INTRODUCTION

The deficit of organic non-sustainable fossil fuels and growing global ecological problems has increased interest in hydrogen technologies with renewable power sources. Safety issues related to hydrogen storage and transportation hamper the effective use of hydrogen in various energy applications. Aluminum is the energy carrier that can be potentially used to produce hydrogen due to its inherent high energy density, pollution-free energy release, lightweight and its recyclable technology. The aluminum could react with oxygen in the water, but it has been prevented by the inert alumina formed on the outer skin. Sarou-Kanian et al [1] studied the low temperature reactivity of aluminum nano-powders with liquid water. Zhuk et al [2] explained the commercial possibility and awareness of the hydrogen production using aluminum and its alloys. They examined the combined cycle of steam turbine (heat engine), electrochemical generator, and air-aluminum fuel cells, with the aluminum-steam combustion as a starting stage. Wang et al [3] reported the aluminum-based hydrogen production methods, their limitations and challenges for commercialization. They explained the Al–water reaction with assistance of alkalis, in neutral conditions, at elevated temperatures, hydrogen production from aluminum–alcohol reactions, and the concept for cogeneration of hydrogen and electrical energy. In this work, we investigate the aluminum activation using NaOH concentration using experiments and DFT model is applied for estimating the activation barriers. The estimated activation energy barrier from the experiment is compared with DFT theoretical results.

METHOD

The cylindrical pure (99.86 %) aluminum wire with a diameter of 0.6 mm is used. The aluminum wire is immersed in a 4M NaOH solution in a typical burette system at three constant temperatures (298 K, 323 K and 343 K) and monitor the volume of the produced H_2 gas until the wires are fully consumed. The temperature of the solution is controlled by a sensor immersed in the solution. The sensitivity of the hydrogen volume evolution measurements is estimated to be +/- 0.2 ml. The initial weight of the aluminum wires is 51.5 mg (+/- 0.001).

In an attempt to understand the mechanism of the hydrolysis reactions, a DFT model of the reactions was constructed. First-principles total energy calculations were carried out within a plane-wave DFT framework using the Vienna Ab Initio Simulation Package (VASP) [4]. Calculation parameters were chosen for describing the quantum mechanics of the system [5]. Long-range attractive van der Waals (vdW) interactions were modeled using the DFT-D3 correction [6,7]. Due to its macroscopic dimensions, the Al wire was modeled by a mildly oxidized Al(111) surface. A reaction mechanism wad proposed that involves the consecutive dissociation of water molecules. Following the determination of the optimized geometric structures of the reactants and products of each step, the activation barriers were calculated using the climbing image variant [8] of the nudged elastic bands (CI-NEB) method [9]. To validate our theoretical model, a simple Arrhenius analysis was performed, and the global activation barrier of the

experimental reactions was estimated. This result was then compared to the activation barrier of the theoretical rate-limiting step.

RESULTS AND DISCUSSION

The experimental reactions for Al hydrolysis in NaOH solutions is commonly represented as follows,

$$2Al + 2NaOH + 6H_2O \rightarrow 2NaAl(OH)_4 + 3H_2 \quad (R1)$$

$$2NaAl(OH)_4 \rightarrow 2NaOH + 2Al(OH)_3 \quad (R2)$$

The resultant H_2 gas evolution is recorded under different experimental conditions for the determination of the optimal conditions. The effect of NaOH concentration and solution temperature are considered in this study, as represented in Figure 1(a). It is noticed that higher temperatures lead to enhance the production rate of the H_2 gas. by comparing the 4H duration of the reaction at 25℃ and 70℃, it requires about 20 minutes for completing the reaction, i.e., the whole wire is consumed. As the surface area of the wire decreases due to reaction in progresses, the hydrogen evolution rate shows a downward trend until the reaction is finished.

We estimate the activation energy barrier (E_a) and hydrogen evolution rate (k) of the experimental reactions using an Arrhenius model. Using the hydrogen evolution rates at the three temperatures as represented, the Arrhenius plot for lnK vs 1/T is drawn from hydrogen evolution rate vs time (Fig. 1(b)). The activation energy is calculated from Arrhenius relation that gives the dependence of the rate constant k for chemical reactions on temperature:

$$ln\ k = ln\ ko + E_a/RT \quad (1)$$

where k is the rate constant at T, E_a is the activation energy, R is the ideal gas constant (8.3145 J/(mol K),T is the temperature, A is the collision frequency factor. E_a can then be calculated from the slope of the plot lnK vs 1/T. The factor n in model influences the deviation from a straight line in the ln(k) vs 1/T plot. The calculated activation energy is 35.06 kJ/mol. In the DFT model, the initially oxidized Al wire is represented by an Al(111) surface linked with three oxygen atoms as seen in Figure 1(a). We design a set of reaction steps that involve the consecutive dissociation of three H_2O molecules, followed by the adsorption of two OH- groups that is captured from the NaOH solution. In the final reaction steps, an $AlOH_4$ group is formed and released into the solution. This mechanism is summarized in Eq. R_3-R_6.

$$2Al + 3O + H_2O \rightarrow Al_2O_2(OH)_2 \quad (R_3)$$
$$Al_2O_2(OH)_2 + H_2O \rightarrow Al2O(OH)_4 \quad (R_4)$$
$$Al_2O(OH)_4 + H_2O \rightarrow Al_2(OH)_6 \quad (R_5)$$
$$Al_2(OH)_6 + 2OH \rightarrow 2Al(OH)_4^- \quad (R_6)$$

The initial, transition and final states of each of the reaction steps and also the calculated activation barriers are illustrated in Figure 1(c). It is seen that the reaction limiting step is R_3 with an activation barrier of 61.75 kJ/mol. Each step has a larger activation barrier than the earlier step that is mainly due to the decreasing accessibility of the central Al atom. In the third step, the H_2O molecule could not form a bond with the vicinity of surface atoms and its dissociation is therefore largely unassisted. The calculated values of activation energy barrier agree well with reported ones [10-12]. The product of the last step is the $AlOH_4$ group, detaches that leaves behind a surface vacancy. Though, the subsequent reactions are taking place around the edges of these craters since they present low coordination sites. These gaps are then expected to further grow as reaction proceeds to form larger crater. This is endorsed from SEM images, as shown in Figure 1(d) of an Al wire immersed in 4M NaOH solution for 30 minutes.

CONCLUSIONS

The activation of aluminum particles in NaOH solutions and their reactions with water are investigated in a joint experimental and theoretical framework. Ab initio activation barriers of a four-step surface reaction mechanism was compared with the experimentally estimated barrier. Given the difficulties associated with determining the actual reactions steps in any experimental setup, the agreement between the experimental and theoretical activation barriers is considered as acceptable. These results validate the proposed reaction mechanism involving the mixture of dissociation of water molecules and direct surface adsorption of free OH^- radicals from the solution. Hence, the optimum combinations exist between the particle size, NaOH concentration and reaction temperature to maximize the hydrogen reaction rate and yield, that will be considered in the future work.

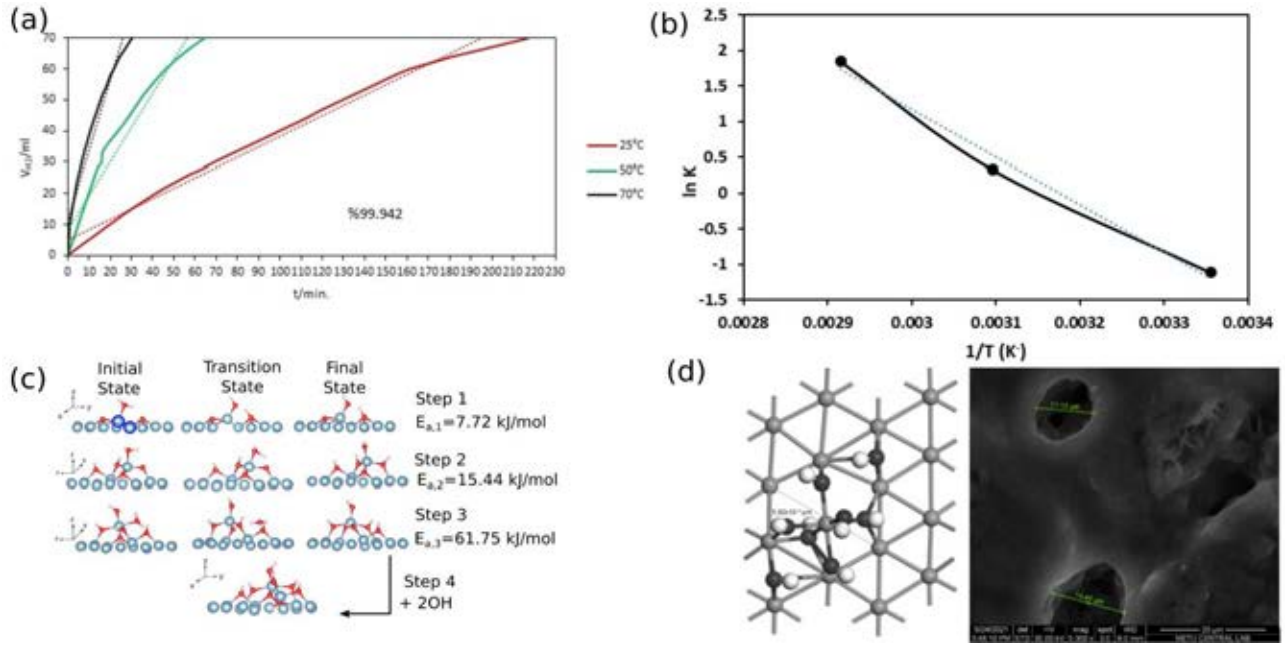

Figure 1: (a) The volume of produced hydrogen for a 99.942 % pure Al wire with an initial diameter of 0.6 mm. Red, green and black curves correspond to reactions taking pace at 25 C, 50 C and 70 C, respectively. The dashed lines are linear fits for better clarity. (b) The Arrhenius plot used to estimate the experimental activation barrier. (c) The DFT model. The top, middle and bottom panels correspond to the first, second and third steps of the reaction that are detailed in Equations R_3-R_6. The bottom panel represents the final system after the final direct adsorption of the 2 OH^- groups. The two Al atoms in the first image circled in blue are the two Al atoms participating in the reactions. Red, white and blue spheres represent oxygen, hydrogen, and aluminum atoms, respectively. The point of view, denoted by the Cartesian axes inserts, is rotated to provide the clearest view. ABSTRACT

The use of H_2 as alternative fuel in the transportation sector is one of the most promising solutions to reduce global warming. Chemical looping hydrogen processes (CLH) allow the production of high purity H_2, suitable for powering PEM fuel cells. This work focuses on the production of pure and renewable H_2 by CLH process using iron as redox material and ethanol as renewable reductant. To scale up the technology, the thermal stability of Fe for repeated redox cycles is a key point and still needs improvement. The addition of structural promoters can be an effective solution. Experiments at 3 different reaction temperatures (675°C-750°C) are conducted to evaluate the effect of the addition of Al_2O_3 and MgO on Fe_xO_y redox performances. The particles' thermal stability is evaluated for 10 redox cycles. The results show that the presence of Al_2O_3 led to a completely deactivation of iron oxides after few cycles at all the conditions due to the formation of Hercynite ($FeAl_2O_4$), which cannot be oxidized by water. However, introducing an air oxidation step in the system (3 steps CLH) makes this material suitable for this application. The addition of MgO guarantees stable H_2 yields at the lowest temperature tested (675°C, E=35%).

Keywords: Hydrogen, Chemical looping, Structural promoters, Water splitting, Iron oxide

INTRODUCTION

Nowadays, H_2 is considered an ideal fuel as its combustion yields only water. However, H_2 does not exist in nature in its molecular form but it is extracted from other compounds such as fossil fuels, water and biomass using different technologies. In order to obtain a totally clean H_2 also the H_2 production should derive form a CO_2-neutral process.

Chemical looping hydrogen processes (CLH) allow the production of pure H_2 by water splitting, exploiting the redox properties of transition metals. The 2 steps CLH process consists by two spatially and temporary separated phases. First, the reduction step, in which the metal oxide is reduced to the metallic form at the expense of the fuel oxidation by the lattice oxygens of the metal oxide into CO_2 and H_2O. Then, in the water oxidation step, in which the reduced metal is oxidized by steam to produce pure H_2 and to restore the metal oxide, which are ready for the subsequent reducing step. The process can also involve a 3-steps configuration, in which the oxidation step with steam is followed by an oxidation step with air. Generally, the 3 steps CLH is adopted to minimize the heating costs of the plant by exploiting the heat released by the oxidation of the metal oxide with air to heat the process units.

The main advantage of the CLH is the feasibility to produce directly pure H_2 able to be fed to Proton Exchange Membrane fuel cells usable in the automotive sector, without any additional purification units. Furthermore, if a renewable fuel and an environmentally safe metal are used, H_2 can be obtained in a completely green way.

The aim of this work is to produce pure and green H_2 by chemical looping technology using Fe-based particles and bioethanol as renewable fuel, making the pure H_2 production stable for a high number of cycles. The carbon formation during the reduction step and the decay of the reactivity of the Fe are the primary limitations of the proposed system. The carbon formation, caused by the utilization of a carbonaceous fuel in the reduction step, is one of the main issues for the development of this process undermining the purity of the hydrogen and the particle reactivity. If the carbon deposition occurs, carbon can react with water during the steam oxidation step producing CO by gasification reaction. For PEMFC applications the concentration of CO must be lower than 10 ppm to avoid the deactivation of the Pt-based catalyst of the cell. Furthermore, a fraction of solid carbon can remain on the particles surface during the cycle contributing to the particle' s deactivation. In author's previous works, a relationship between the amount of ethanol fed in the reduction and the purity of H_2 obtained in oxidation was demonstrated. Specifically, the reduction degree of Fe_xO_y is directly linked to the amount of ethanol fed; the carbon deposition takes place when carbon is not needed for the iron oxide reduction; in fact, avoiding the complete reduction to Fe, the lattice oxygen atoms are able to convert solid carbon into CO and CO_2

To improve the resistance at high temperature of the Fe_xO_y/Fe, Al_2O_3 and MgO are added as promoters (60 wt.% Fe_2O_3- 40 wt.% Al_2O_3, 60 wt.% Fe_2O_3- 40 wt.% MgO). These two materials are widely used in the field of heterogeneous catalysis as support, but they also offer a catalytic activity to many chemical reactions. The samples were already tested by the authors in isothermal cycles (675°C)[1]; the results showed that both MgO and Al_2O_3 actively participate in the process offering their catalytic activity on the ethanol cracking reactions but also reacting with Fe forming spinel structures.

The aim of this work is to evaluate the redox performance of 60Fe40Al (60 wt.% Fe_2O_3- 40 wt.% Al_2O_3) and 60Fe40Mg(60 wt.% Fe_2O_3- 40 wt.% MgO) into a 2 steps CLH process at 3 different temperatures (675°C,700°C and 750°C) in order to find the optimal operative conditions which maximize both the H_2 yields and the stability of the redox material. The experiments are also conducted on pure Fe_2O_3 to better understand the effect of promoter's addition on particle's reactivity. The sample 60Fe40Al is also tested into a 3 steps CLH (reduction-steam oxidation-air oxidation) in order to prevent the formation of the spinel with Fe and make possible the use of this material in the process.

MATERIALS AND METHODS

Fe-based particles synthesis and bench scale plant details.

The Fe-based particles are synthesized by coprecipitation method from the nitrate metals salts and then calcined with air in a muffle furnace at 350°C for 2 h and 900°C for 2 h. The amount of the structural promoter added is constant and equal to 40 wt.%. Tests are conducted in a fixed bed reactor at 3 different reaction temperature (675°C, 700°C, 750°C) maintaining the pressure constant at 1 bar. The fixed bed is constituted by 1 gram of Fe-based particles with particle's diameter of 150 μm < d_p < 300 μm. The bench scale plant is described in detail in the author's previous works[1,2]. The 2 steps CLH tests are conducted feeding alternatively ethanol in the reduction step and water in oxidation with a constant flowrate of 4 mL/h, in the presence of Argon as carrier gas (250 mL/min). In the 3 steps CLH experiments air is also fed to the reactor with a constant flowrate of 500 mL/min.

RESULT AND DISCUSSION

Influence of Al_2O_3 and MgO addition into 2 and 3 steps CLH as a function of temperature (675°C, 700°C, 750°C)

The experiments related to the determination of the optimal amount of ethanol consist into 1 redox cycle in which different amount of ethanol are fed in reduction (5.7-1.9 mmol EtOH/g_{Fe2O3}). The optimal amount is defined as the amount for which no CO is detected in the water oxidation step. This parameter is strongly connected to the accessibility of the iron active sites, to the surface area of the sample and to the kinetics of the reduction reactions at the tested temperatures. For the samples tested in all the temperature range studied the optimal amount of ethanol is equal to 1.9 mmo/g_{Fe2O3}.Table 1.0 summarizes the results obtained with the sample 60Fe40Al at 700°C.

Table 1: Determination of the optimal amount of ethanol fed for the sample 60Fe40Al at 700°C.

Ethanol Fed (mmol/g_{Fe2O3})	H_2 (NL)	CO (NL)
5.7	0.081	0.021
3.8	0.031	0.008
1.9	0.023	0.000

After the determination of the optimal amount of ethanol stability tests (10 redox cycles) are conducted. Figure 1. reports the process efficiency (E) of each sample for 10 consecutive redox cycles at all tested temperatures. E is calculated as the ratio of the amount of H_2 produced during the oxidation step and the maximum amount of H_2 that can be produced by the sample, considering the complete reduction to Fe and the complete oxidation to Fe_3O_4. Looking at the results collected in Figure 1.0, the promoter addition significantly affects the Fe reactivity and stability at each tested temperature[3]. The decrease in H_2 yields during the cycles registered for the sample of pure Fe_2O_3 (Figure1.0 A) confirms the low thermal stability of this material. Increasing the reaction temperature from 675°C to 750°C the deactivation is favored. The addition of MgO is promising: the process efficiency is kept constant to 35% for all the cycles without any significant variations with temperature. The results obtained with the sample 60Fe40Al confirms the issue in coupling Fe/Al into 2 steps CLH. The sample deactivation occurs at each operative conditions tested and at higher temperature it becomes more evident. These results suggest that the hercynite ($FeAl_2O_4$) formation occurs at each temperature and that its production is favored at high temperatures. Figure 1.0 D report the E (%) of the 3 steps CLH experiments with the sample 60Fe40Al.Based on the results obtained the introduction of an air step in the process seems to be the only way to use this material for H_2 production by water splitting. In this case the process efficiencies are constant for 10 consecutive redox cycles. In fact, according to literature results, $FeAl_2O_4$ can be oxidized and converted to Fe_2O_3 and Al_2O_3 only by air [4].

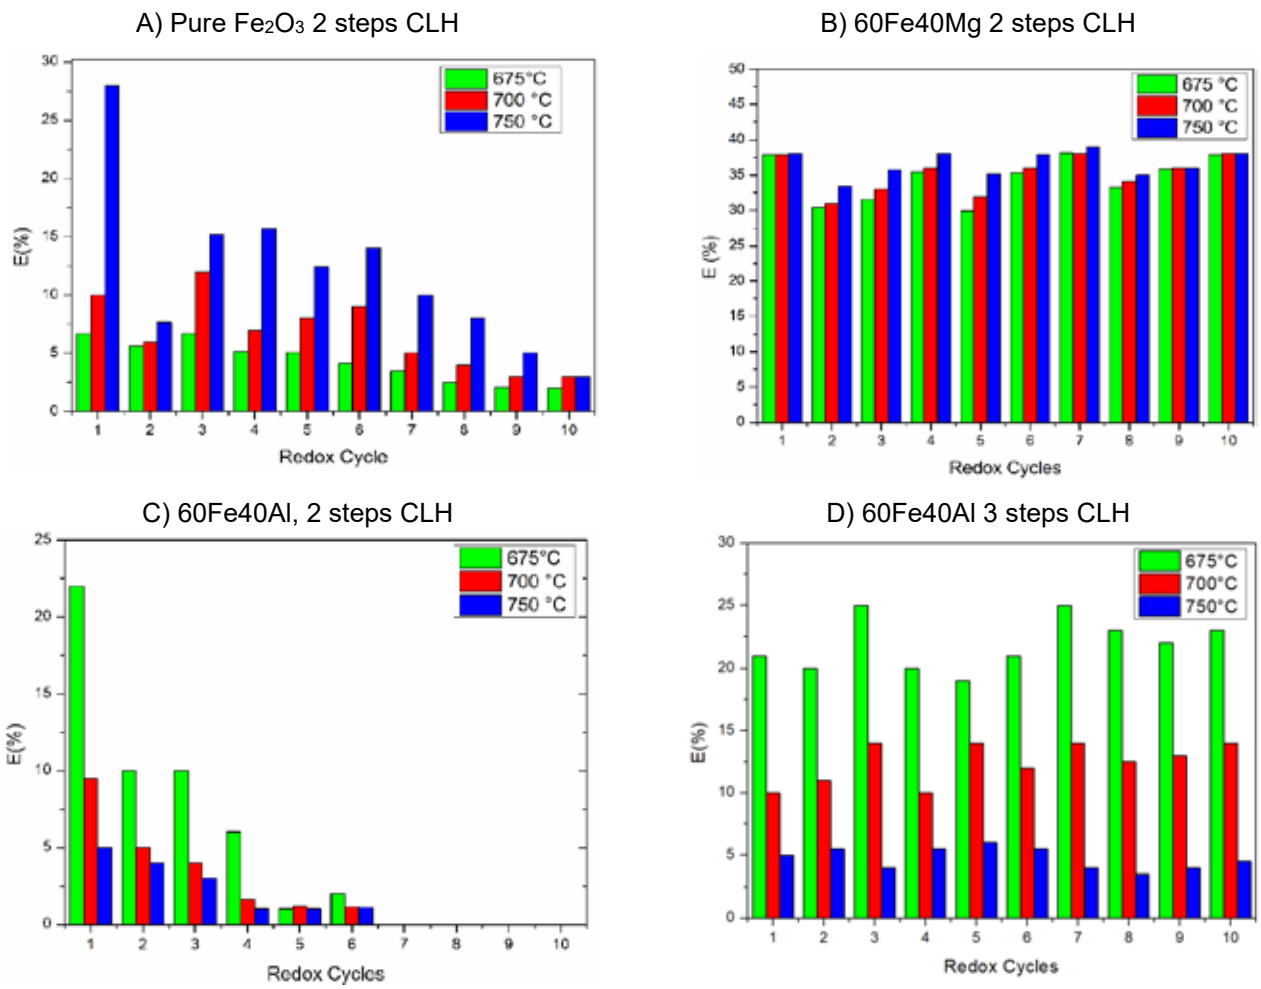

Figure 1: Process Efficiency for 10 consecutives redox cycles, 2 steps CLH: A) Fe_2O_3, B) 60Fe40Mg, C) 60Fe40Al. Process Efficiency for 10 consecutive redox cycles, 3 steps CLH: D) 60Fe40Al.

CONCLUSIONS

The directly production of pure and green H_2 by CLH process is studied focusing the attention on the effect of adding Al_2O_3 and MgO in the redox cycle of iron. The redox activity is evaluated at 3 different temperatures in order to find the optimal value using bioethanol as renewable reductant. The results demonstrated that the presence of MgO confers to the Fe/FeO couple a better reactivity and stabilty without any significant variation in the temperature range studied. Otherwise, the addition of Al_2O_3 led to a fastly deactivation into 2 steps CLH due to the formation of $FeAl_2O_4$. The deactivation is significantly affected by the reaction temperature becoming more evident at higher temperatures. However, the addition of an air oxidation in 3 steps CLH is fundamental to convert $FeAl_2O_4$ into Fe_2O_3 and Al_2O_3 allowing the successful utilization of this material with a constant process efficiency for 10 cycles.

ABSTRACT

The glycerol steam reforming (GSR) reaction for hydrogen production, was investigated over Ni catalysts supported on perovskite-type oxides ($Ni/BaZrO_3$, $Ni/CaZrO_3$ and $Ni/SrZrO_3$) synthesized via the auto-combustion method. The prepared catalysts were characterized via XRD and H_2-TPR, showing a high phase purity (limited formation of alkaline earth carbonate impurity phases) and reducibility. Catalytic activity evaluation revealed that $Ni/CaZrO_3$ (CaZ-Ni7) and $Ni/SrZrO_3$ (SrZ-Ni7) were remarkably active for the conversion of glycerol towards gaseous products, yielding high amounts of H_2 and preventing its consumption via side-reactions, like CO_x hydrogenation. $Ni/BaZrO_3$ (BaZ-Ni7) was found to be less effective for the gasification of glycerol, providing an overall lower H_2 yield. $Ni/SrZrO_3$ (SrZ-Ni7) was shown to be the best-performing and most resilient catalyst, exhibiting a remarkably stable performance during 20h time-on-stream at 600 °C, as it outperforms many of the employed catalysts in the literature. The produced gas has a very high H_2/CO ratio (> 20) and thus, could be fed into fuel cell stacks without extensive downstream processing.

Keywords: Glycerol steam reforming, Hydrogen production, Nickel catalysts, Perovskite oxides, Catalytic stability

INTRODUCTION

Biofuels, and especially biodiesel, are being portrayed as an attractive alternative to petrol-based fuels in a decarbonized economy [1]. The production of biodiesel proceeds through the transesterification of triglycerides found in plant-derived oils, a process which inevitably produces large amounts of crude glycerol as a by-product (> 10 vol%) [1]. As an alternative to its costly refinement process, crude glycerol can be directly gasified into H_2 and CO_x, through a process known as glycerol steam reforming (GSR) reaction, which can theoretically yield 7 mols of H_2 per mol of converted glycerol [1-3]. Ni-based catalysts are typically used in this reaction, due to the known ability of Ni to split C-C bonds in organic molecules and O-H bonds in water, favouring the production of H_2, all the while being considerably cheaper to noble metal alternatives (e.g., Rh) [1-3]. However, Ni has the disadvantages of being particularly prone to deactivation via coke deposition and of promoting the hydrogenation of CO_x, thereby consuming part of the produced H_2 [1,2,4]. Ni-perovskite systems are known to be remarkably stable towards carbon deposition, while they exhibit a very strong metal-support interaction, that can disfavour CO_x hydrogenation (e.g., methanation) [5]. Moreover, $Ni-CaZrO_3$ has already demonstrated superior stability during the dry reforming of methane [6]. Taking all this into account, this work reports on the application of Ni catalysts supported on alkaline earth perovskites ($BaZrO_3$, $CaZrO_3$ and $SrZrO_3$) for the glycerol steam reforming.

MATERIALS AND METHODS

The perovskite catalysts were prepared via the auto-combustion method. Stoichiometric amounts of metal nitrates and glycine were dissolved in d-H_2O and used as fuel. A gradual increase in temperature to approx. 250 °C was employed to ignite the auto-combustion. The rapid flame propagation that followed ended in few minutes, producing very fine and voluminous powders, which were calcined at 800 °C (CaZ-Ni7 and SrZ-Ni7) or 950 °C (for BaZ-Ni7) for 5 h to remove carbonaceous impurities. To prepare the reduced catalysts, their calcined counterparts were reduced at 800 °C for 1 h. Following the synthesis, the supports, calcined and reduced catalysts were characterized via XRD and H_2-TPR.

The steam reforming of glycerol was performed in a continuous flow stainless-steel fixed-bed reactor (ID= 14 mm) under two experimental protocols. The first one was employed to investigate the catalytic activity as a function of reaction temperature, (400-750 °C), while the reactant gas mixture consisted of 73% H_2O, 4% $C_3H_8O_3$ and 23% He (20 v.v. % of $C_3H_8O_3$ in d-H_2O). The second protocol was designed with the aim of examining the stability of the catalysts during 20h time-on-stream, performed at 600°C. More severe conditions were chosen, so as to promote carbon deposition. The reactant gas mixture in this case consisted of 63% H_2O, 7% $C_3H_8O_3$ and 30% He (31 v.v. % of $C_3H_8O_3$ in d-H_2O). For both experimental protocols used, the Weight Hourly Space Velocity (WHSV) equalled 50,000 ml g_{cat}^{-1} h^{-1}, while a prior in situ catalyst activation step was performed using a pure H_2 flow at 800 °C for 1 h. Liquid products were analyzed vai GC-MS and gaseous products via GC with a TCD detector.

RESULTS AND DISCUSSION

XRD patterns of the prepared MeZ (BaZ, CaZ and SrZ) perovskites (Fig. 1) reveal the formation of the respective perovskite phase ($BaZrO_3$, $CaZrO_3$ and $SrZrO_3$) with a remarkable phase purity. For the calcined MeZ-Ni7 catalysts (BaZ-Ni7, CaZ-Ni7 and SrZNi-7), no clear NiO reflections can be observed, which is an indication of a high solubility of Ni^{2+} ions in the perovskite lattice and/or the amorphous nature of supported NiO. Following reduction, the reduced catalysts (BaZ-Ni7 red., CaZ-Ni7 red. and SrZNi-7 red.) exhibit the emergence of the Ni^0 (111) reflection at approx. 44.4° 2θ (Fig. 1d) except for SrZNi-7 red., where the Ni^0 (111) reflection overlaps with a perovskite reflection. This is attributed to the formation of Ni^0 nanoparticles on the perovskite surface, which can be considered as partly exsolved, due to the initial solubilization of part of Ni^{2+} cations into the perovskite lattice [5]. The crystallite size of metallic Ni was calculated via the Scherrer equation as 30 nm and 25 nm for reduced BaZ-Ni7 and CaZ-Ni7 respectively. The reducibility of the perovskite catalysts was also examined via H_2-TPR, which revealed the presence of three reduction peaks (α, β and γ). α and β peaks observed for BaZ-Ni7 and CaZ-Ni7 were attributed to the reduction of NiO in the surface and sub-surface of the perovskites, whereas the γ peak found for CaZ-Ni7 and SrZ-Ni7 was ascribed to the reduction of Ni^{2+} solubilized into the perovskite lattice and therefor to the exsolution process [5,6].

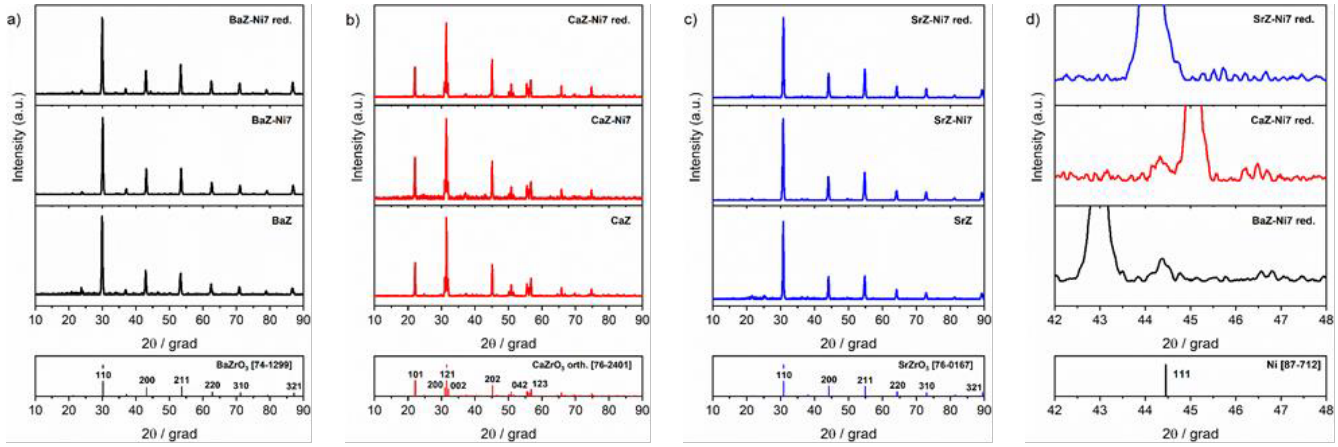

Fig. 1. X-ray diffraction patterns of calcined MeZ perovskite, calcined and reduced MeZ-Ni7 catalysts: (a) BaZ and BaZ-Ni7; (b) CaZ and CaZ-Ni7; (c) SrZ and SrZ-Ni7. (d) Patterns for 2θ = 42-48° showing the Ni^0 (111) peak for the reduced MeZ-Ni7 catalysts.

Fig. 2a-c presents the evolution of GSR catalytic activity as a function of reaction temperature. It can be observed, that CaZ-Ni7 and SrZNi-7 can offer superior catalytic performance to BaZ-Ni7 in terms of total glycerol conversion, as well as glycerol conversion to gaseous products (Fig. 2a). These two catalysts are also better in terms of H_2 selectivity and yield, with the H_2 yield being close to the theoretical maximum of 7 mols of produced H_2 per mol of fed glycerol (Fig. 2b). Moreover, the H_2/CO ratio is very high for CaZ-Ni7 and SrZNi-7 at the 550-650°C temperature range (Fig. 2c), which is well suited for fuel cell applications, where CO acts as a poison [1]. Liquid by-products of glycerol (e.g., acetol, acetone etc.) are only produced at temperatures below 550°C for CaZ-Ni7 and SrZNi-7 (Fig. 2d), whereas for BaZ-Ni7 they can be produced up to the final temperature of 750°C.

Fig. 2e-f presents the evolution of GSR catalytic activity at a constant temperature of 600°C as a function of reaction time during 20h time-on-stream under more severe reaction conditions. As expected, the lower water to glycerol feed ratio (WGFR) acts to lower the gasification of glycerol and the H_2 yield [4]. SrZ-Ni7 is more resilient to this harsher reaction conditions and presents a superior catalytic performance to many of the catalysts studied in the literature [1-4]. This can be attributed to the partly exsolved nature and strong metal-support interaction of the supported Ni nanoparticles, which act to hinder carbon deposition and preserve the structural integrity of the catalyst [5,6].

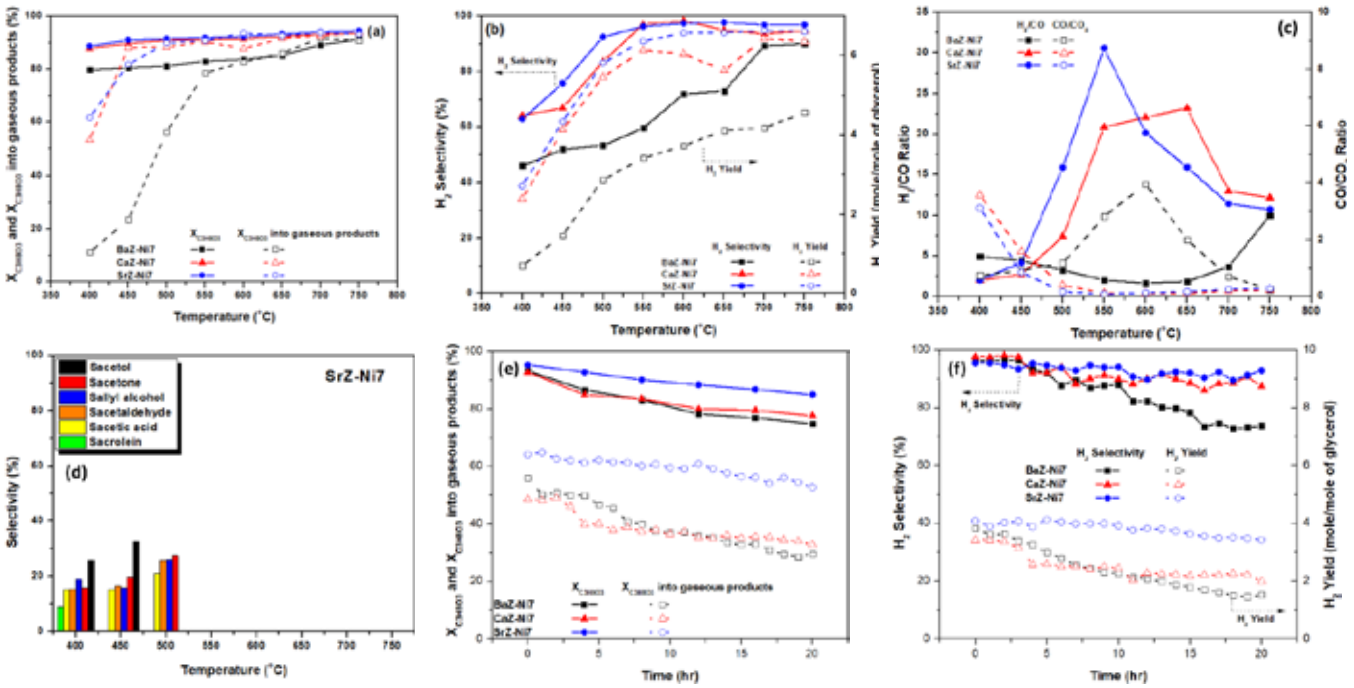

Fig. 2. Experimental Protocol #1: (a) Total glycerol conversion along with glycerol conversion into gaseous products, (b) H_2 selectivity and yield, (c) H_2/CO and CO/CO_2 molar ratio and (d) liquid products selectivity for the SrZ-Ni7 catalyst as a function of reaction temperature. Experimental Protocol #2: (e) Total glycerol conversion along with glycerol conversion into gaseous products and (f) H_2 selectivity and yield as a function of reaction time.

CONCLUSIONS

This study reported on the auto-combustion synthesis of alkaline earth perovskite supported Ni catalysts for the steam reforming of glycerol. The high structural purity of the prepared catalysts and the strong metal-support interaction induced via the exsolution of initially solubilized Ni^{2+} cations acted to enhance the catalytic activity and stability. The Ni/$SrZrO_3$ (SrZ-Ni7) catalyst provided a stable catalytic performance and H_2 yield under harsh conditions, rivaling other catalysts in the literature and demonstrating its potential for industrial implementation.

ABSTRACT

In this work a thermodynamic study and an energy analysis are performed on the autothermal and sorption-enhanced reforming of olive mill wastewater (OMW), to produce green hydrogen. The thermodynamic equilibrium compositions are calculated by using the Gibbs free energy minimization method. The effect of different parameters is assessed for the different reactor configurations. The results show hydrogen yields close to the theoretical maximum for the sorption-enhanced autothermal reforming of OMW whilst operating in thermally neutral conditions.

Keywords: *Thermally neutral; Sorption; Autothermal; Olive mill wastewater; Hydrogen*

INTRODUCTION

Hydrogen is a crucial industrial chemical. Its production has grown in recent years due to its potential to be used in fuel cells to produce energy, whilst avoiding CO_2 emissions [1]. As of now, the production of hydrogen is still largely dependent on fossil fuels. A possible alternative is the use of renewable biofuels via steam reforming [2]. One such potential biofuel, which carries economic weight, is olive mill wastewater (OMW). By resorting to the steam reforming of this waste product (Eq. 1), hydrogen can be obtained, reducing the organic load of the effluent, while simultaneously turning its treatment into a profitable endeavour. Further gain, in terms of hydrogen yield and purity, can be reached through process intensification. Carbon dioxide sorption (e.g., with CaO) can be employed to reach sorption-enhanced reforming (SER), a method which reduces emissions and favourably shifts the equilibrium of the reactions (thus improving reactor performance or allowing to reach the same performance under more moderate conditions) (Eq. 2) [1]. Partial oxidation of OMW with oxygen can also be used, simultaneously, to reach autothermal reforming (ATR), which has the potential for thermally neutral operation (Eq. 3) [3].

$$C_xH_yO_z+(2x-z)H_2O \rightarrow (\frac{y}{2}-z+2x)H_2+xCO_2 \quad \Delta H^0_{298}> 0 \qquad (1)$$

$$CO_2+CaO \leftrightarrow CaCO_3 \quad \Delta H^0_{298}=-179\ kJ\cdot mol^{-1} \qquad (2)$$

$$C_xH_yO_z+\frac{(x-z)}{2}O_2 \rightarrow xCO+\frac{y}{2}H_2 \quad \Delta H^0_{298}< 0 \qquad (3)$$

The goal of this work is to determine, from the thermodynamic point of view, thermally neutral operating conditions and maximize hydrogen production for the sorption-enhanced autothermal reforming (SE-ATR) of OMW, a novel approach to OMW treatment.

METHODOLOGY

The thermodynamic model was developed using the Aspen Plus® V11.0 software. To achieve the equilibrium composition of the chemical species at a given pressure and temperature, a non-stoichiometric method was utilized, namely the minimization of the Gibbs free energy [4]. Different reactor configurations were considered, namely, traditional reforming (TR), SER, ATR, and SE-ATR. The conditions assessed were as follows: temperature (300-900 °C), pressure (1-20 bar), steam to carbon molar ratio (S/C: 0.6-16.0), for the sorption-enhanced configurations the calcium oxide to OMW molar ratio (CaO/OMW: 0-8.0) and for the autothermal configurations, the oxygen to OMW molar ratio (O_2/OMW: 0-6.0).

RESULTS

The thermodynamic study for the TR and SER provided the optimal operating conditions. Maximum hydrogen yields were obtained for P=1 bar, T= 500-600 ºC, high S/C ratios, and for the sorption-enhanced configuration for *CaO/OMW* = 7.0. Coke formation is avoided in these conditions as well. For the TR, 98% of the maximum theoretical

H_2 yield (calculated based on reactions stoichiometry) was obtained for S/C = 16.0, whilst for the SER the same hydrogen yield was obtained for S/C = 4.0 only.
With the results obtained in the thermodynamic study, the energy balance was performed for ATR and SE-ATR. Fig. 1 a) shows that as the level of *O_2/OMW* increases, the OMW partial oxidation will provide larger amounts of energy (as it is exothermic) at the expense of a diminished hydrogen yield (yH_2). Fig. 1 b) highlights the decrease in energy requirement per mole of H_2 formed for the two configurations. Fig. 2 a) shows the effects the S/C ratio and temperature have on the yield of hydrogen for thermally neutral conditions. Together with Fig. 2 b) it is possible to observe that high hydrogen yields can be obtained (94% of the theoretical maximum) for low quantities of O_2/OMW and S/C = 2.0, a much lower amount than what was observed for TR and SER.

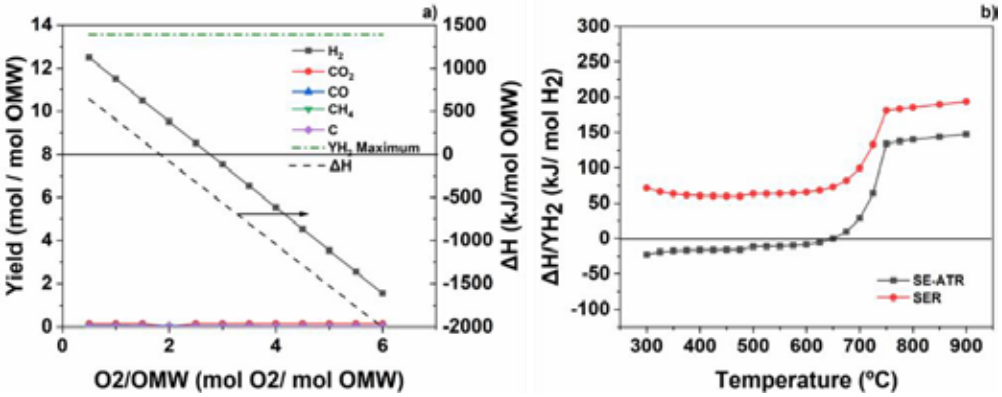

Fig. 1 Effects of O_2/OMW on the yields of the reaction products and on the heat-duty for the SE-ATR (a) and effect of temperature on the spent energy per mole of hydrogen produced for the SER and the SE-ATR configurations (b); P= 1 bar, S/C =4.0 mol H_2O/mol C, CaO/OMW = 7.0 mol CaO/mol OMW; T = 600°C (a), O_2/OMW = 2.0 mol O_2/mol OMW (for SE-ATR) (b).

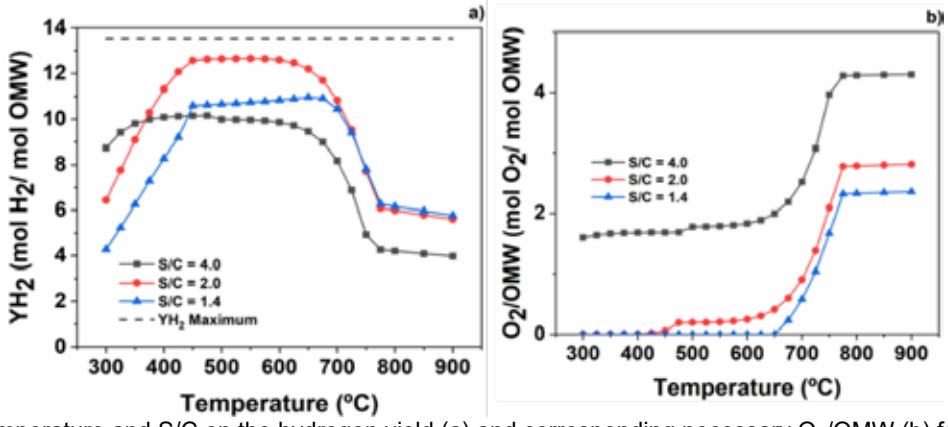

Fig. 2 Effect of temperature and S/C on the hydrogen yield (a) and corresponding necessary O_2/OMW (b) for the SE-ATR for thermally neutral operation; P= 1 bar.

CONCLUSIONS

Full conversion of OMW was reached. The autothermal reforming configurations produce less hydrogen compared to their non-autothermal counterparts, but a decreased energy requirement per mole of hydrogen is observed. The autothermal configurations can operate at thermally neutral conditions. For the ATR, the thermally neutral operation requires a high amount of oxygen, which reduces the hydrogen yield. For SE-ATR, the exothermal sorption reaction provides nearly enough energy for the process to be thermally neutral by itself. With the addition of a controlled amount of oxygen into the reaction medium thermally neutral conditions are reached without significant hydrogen loss and much less steam requirements, which is quite significant from the economics point of view.

ABSTRACT

In the work presented herein, Ce-La-xCu-O catalysts with different Cu contents were synthesised using the conventional microwave (MW) method and an enhanced microwave method where air cooling (AC) during heating was applied. The catalytic materials were then studied for the steam reforming of glycerol (GSR). It was revealed that the synthesis methods (MW and AC) had an effect mainly on the degree of Cu incorporation into the Ce-La-O fluorite lattice, leading to one or two phases system. GSR tests revealed that the Ce-La-10Cu-O (AC) catalyst showed the highest glycerol conversion, conversion to gaseous products and yield of H_2 (5.3 mol/mol of glycerol) and deactivated at slower rate. The improved performance of the AC catalyst can be correlated to a more homogeneous Cu incorporation into Ce-La-O mixed oxide thus forming more accessible active sites to reactants which overall impact on the catalytic performance.

INTRODUCTION

Crude glycerol is the main by-product of the transesterification process; it may be used for H_2 production through the process of steam reforming [1-3]. Transition metal catalysts, especially Ni, have been shown to process excellent intrinsic activity in steam reforming reactions, but as is well understood, they tend to deactivate as they are susceptible to carbon deposition and the sintering of metal particles. Bimetallic catalysts can improve metal dispersion as well as catalyst resistance towards deactivation. Another important component to consider is the modification of the support as it can have an important effect on the metal-support interactions, active phase dispersion, reducibility of the active metal, and the acid/basic properties which can control side reactions. A ubiquitous supporting material is CeO_2, because it promotes the Water Gas Shift (WGS) reaction, the dissociation of water and the reforming of methane, due to its basic character and ability to store/release lattice oxygen [4]. La_2O_3 is another promoter often used in catalytic reactions because it offers thermal stability and has the ability to store/release oxygen [5]. For the work presented herein we synthesised Cu-based catalysts by incorporating Cu in a La-modified CeO_2 matrix. In particular, Ce-La-xCu-O, (x = 3, 5, 7, 10, 20) catalysts were synthesized through the sol-gel method coupled with microwave (MW) radiation. Apart from this method (MW), we also prepared Cu-based catalysts using an enhanced MW method, where simultaneous air cooling (AC) is applied during heating. The materials were extensively characterized using XRD, Raman spectroscopy, SEM, TEM, H_2-TPR, NH_3 and CO_2-TPD, and XPS to probe the microstructure, surface and redox properties and the Cu/La doping into the ceria matrix.

MATERIALS AND METHODS

More information regarding this section can be found in ref [5]. Ce-La-Cu-O catalysts with different Cu contents were synthesized through the sol-gel method under two different conditions; (a) stand-alone conventional microwave heating and (b) enhanced microwave approach. The experiments were carried out in MARS-6 microwave system with 0-1800 W ± 5 power output. The catalysts were thoroughly studied in terms of their structural, morphological, redox, surface basicity, surface composition and catalysis performance employing XRD, Raman spectroscopy, SEM, TEM, H_2-TPR, NH_3 and CO_2-TPD, and XPS. The experimental work for GSR was performed in a continuous flow fixed-bed reactor at atmospheric pressure. Catalytic activity and selectivity were assessed in the temperature range of 400 - 750 °C. Catalytic stability was assessed at 600 °C. The Weight Hourly Space Velocity (WHSV) used was 50,000 mL g^{-1} h^{-1}. The liquid products were analysed via a combination of Gas Chromatography (Agilent 7890A) and Mass Spectroscopy (Agilent 5975C). The gaseous products were determined via an Agilent gas chromatographer (7890A).

RESULTS AND DISCUSSION

XRD patterns of the calcined (500 °C for 6 h) conventional microwave (MW) and enhanced microwave (AC) Ce-La-xCu-O catalysts are presented in Fig. 1 (left hand side). For all the metal oxides and regardless of the Cu composition (3-20 at%), the main peaks at 28.5°, 33.1°, 47.5° and 56.0° diffraction angles can be assigned to the

crystal planes (111), (200), (220) and (311), respectively, of the ceria (CeO_2) cubic fluorite structure. It is important to note that the characteristic peaks belonging to the lanthanum (III) oxide (La_2O_3) are absent in both types of microwave oxides (conventional MW and enhanced AC), suggesting a rather homogeneous Ce-La-O solid solution in which the La^{3+} cations replace the Ce^{4+} cations in the ceria lattice structure. Also, the position of the diffraction peaks for the Ce-La-xCu-O samples appear shifted towards lower 2theta values as compared to pristine CeO_2 (not presented here) which also signifies the incorporation of the larger La^{+3} (1.10 Å) ions into the lattice of CeO_2 and the subsequent lattice expansion, as anticipated. Furthermore, the substitution of Ce^{4+} in CeO_2 lattice with aliovalent cations leads to the creation of oxygen vacant sites (O_v) [4].

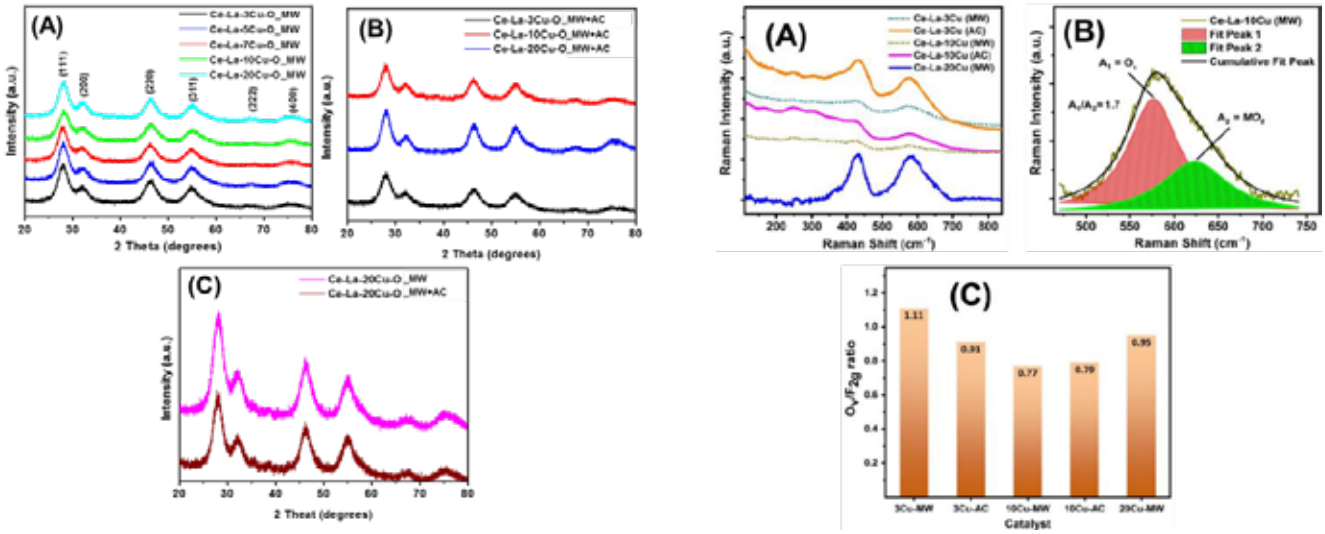

Fig. 1. Left hand side: (A) XRD patterns of the microwave prepared Ce-La-xCu-O oxides, x=3, 5, 7, 10, 20 at%; (B) XRD patterns of the air-cooled microwave prepared Ce-La-xCu-O oxides, x=3, 10, 20 at%; (C) XRD patterns of the Ce-La-20Cu-O oxide prepared using conventional and enhanced (air cooled, AC) microwave methods. Right hand side: (A) Raman spectra of Ce-La-xCu-O oxides, x=3, 10, 20 at%; prepared using conventional (MW) and enhanced (AC) microwave methods; (B) Deconvoluted Raman spectrum obtained over the Ce-La-10Cu-O MW oxide in the 500-700cm^{-1} region (defects); (C) O_v/F_{2g} intensity ratio for Ce-La-xCu-O oxide catalysts.

The Raman shift studies were conducted on calcined catalysts (500 °C/6h) in order to monitor the metal-oxygen bond environments and to evaluate the impact of La^{+3} and Cu^{+2} cations incorporation to the CeO_2 cubic lattice. For a critical comparison between the two methods, the Raman spectra of the oxides prepared through MW and AC methods and containing Cu at different concentration levels (3-20 at%) are presented in Fig. 1 (right hand side). It is known that CeO_2 exhibits a characteristic Raman band at 464 cm^{-1}, which corresponds to the vibration mode F_{2g} of the ceria lattice. The two main peaks in the Raman spectra of the Ce-La-Cu-O oxides shown in Fig. 1A are located at 433 and 580 cm^{-1} (ceria is reference oxide, not presented). The first peak can be linked to the F_{2g} vibrational mode in the fluorite lattice of the ceria-related phase and is shifting towards lower wavelength value (blue shift), caused by the lanthanum (III) doping, compared to the undoped ceria. La^{3+} substitutes Ce^{4+} in the lattice leading to a concomitant oxygen departure followed by creation of oxygen vacancies (O_v), changing the electronic structure of the oxide [5].

The stability of all catalysts was evaluated during time-on-stream experiments, for a total of 12 h. Total glycerol conversion and the conversion of glycerol towards the gaseous products are shown in Fig. 2A, while the H_2 selectivity and H_2 yield are presented in Fig. 2B. It is obvious that all catalysts experience a loss in their ability to convert glycerol during the first few hours of the experiments although X_{C3H8O3} remained rather high. The Ce-La-10Cu (AC) catalyst, despite experiencing a similar drop, from 91% to 74%, i.e., was somewhat more active. The loss in the ability to convert glycerol to gaseous products was significantly more pronounced; the drop from the first to the last measurement was 57-26% for the Ce-La-3Cu (MW), 60-27% for the Ce-La-5Cu (MW), 67-30% for the Ce-La-7Cu (MW), 67-33% for the Ce-La-10Cu (MW) and 55-22% for the Ce-La-20Cu (MW). For the Ce-La-10Cu (AC) X_{C3H8O3} (gaseous) dropped from 68% to 34%. The significant decrease in catalytic performance with time clearly suggests the deactivation of catalysts, which primarily occurs due to the carbon deposition arising from various secondary reactions and/or metal particle sintering. However, from Fig. 2B, it is quite obvious that although all catalysts retain stable S_{H2} values, these depend on the Cu content and preparation method. For example, during the 4th hour of time-on-stream, S_{H2} followed the order: Ce-La-10Cu (AC) (72%) > Ce-La-10Cu (MW) (68%) > Ce-La-7Cu (MW) (67%) > Ce-La-5Cu (MW) (60%) > Ce-La-3Cu (MW) (57%) > Ce-La-20Cu (MW) (56%).

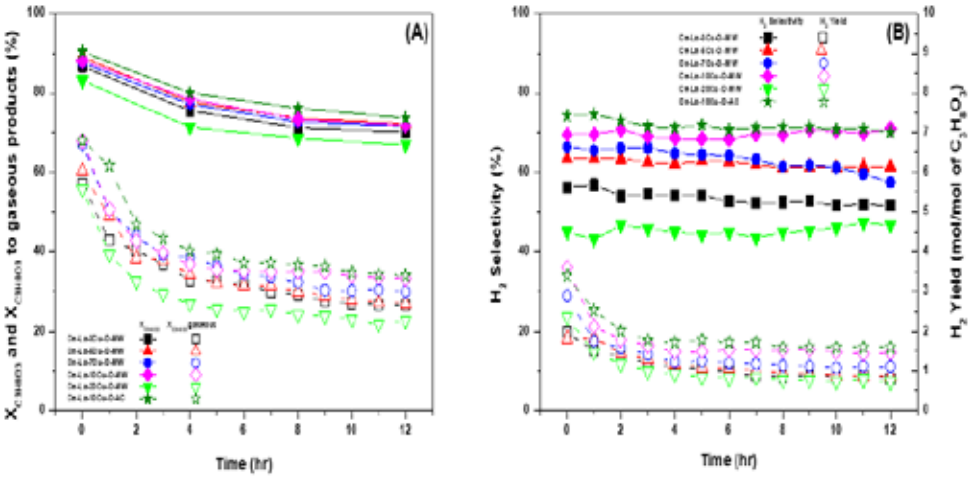

Fig. 2. (A) Total $C_3H_8O_3$ conversion and $C_3H_8O_3$ conversion into gaseous products, (B) H_2 selectivity and yield for all catalysts (time-on-stream experiments)

CONCLUSIONS

Ce-La-xCu-O catalysts with different Cu contents were rapidly synthesized through sol-gel method under two different microwave conditions; (i) conventional microwave heating (MW) and (ii) enhanced microwave (AC) condition, where simultaneous air cooling was applied while heating. It was shown that the Ce-La-10Cu-O (AC) catalyst was more active and deactivated at slower rate because of a more homogeneous Cu incorporation into Ce-La-O mixed oxide, which helped form more accessible active sites to reactants.

SODIUM FORMATE FORMATION VIA IN-SITU CATALYTIC HYDROGEN PRODUCTION FOR DECARBONIZATION

[1]Özge Coşkuner, [2]Umit Bilge Demirci,* [1]Aysel Kantürk Figen*

ABSTRACT

Hydrogenation strategies, in which hydrogen and boron hydrides are used as hydrogen and heat carriers, draw attention to reducing the carbon footprint and creating a sustainable hydrogen-boron-carbon cycle. An alternative strategy to achieve the goal of the European Green Deal is the synthesis of synthetic fuels such as methanol (CH3OH), methane (CH4), and formic acid (HCOOH) from greenhouse gases.

Within this scope, the study is focused on sodium formate formation via in-situ hydrogen production for decarbonization, especially formic acid production. For this purpose, sodium borohydride ($NaBH_4$) is used as a hydrogen and heat carrier. Cobalt-catalyzed hydrolysis of $NaBH_4$ takes place, and the reaction is accelerated in the presence of CO_2. As a result, sodium formate (NaHCOO) and an HCOO group containing borate $B(OH)_2(OOCH)$ are obtained.

Keywords: Carbon dioxide reduction; Formate; Hydrolytic conditions; Sodium borohydride

INTRODUCTION

It has been reported that the amount of anthropogenic CO_2, which increases in the atmosphere and causes global warming, was 316 ppm in 1960 and reached 417 ppm in 2021 [1,2]. To prevent a further increase and limit global warming to 1.5°C [3], it is necessary to reduce the amount of CO_2 entering the atmosphere and investigate the methods of removing it from the atmosphere if possible. According to literature, CO_2 can be used as a cheap and abundant carbon source to produce valuable chemicals such as methanol, formic acid, and methane via hydrogenation [4,5].

Borohydrides are the materials with the highest gravimetric H_2 density. As a type of borohydrides, Alkali metal borohydrides are well-known for their high reductive properties [6] and their ability to be used for CO_2 hydrogenation [7-13]. The transfer of H^- of BH_4^- to CO_2 is highly favorable and competitive with H_2 formation [14]. As metal borohydride, $NaBH_4$ is also used for the hydrogenation of CO_2. Wartik and Pearson reported the formation of sodium triformatomonohydroborate ($NaBH(OOCH)_3$) when 3 equiv of CO_2 reacts with 1 Equiv $NaBH_4$ in dimethyl ether at 25°C. On the other hand, sodium methoxyformato(oxo) borane ($NaBO(OCH_3)(OOCH)$) was obtained, where 2 Equiv CO_2 reacted with 1 equiv of $NaBH_4$ above room temperature in solvent-free media. In their study $NaBO(OCH_3)(OOCH)$ was converted to sodium formate and methanol by hydrolysis [7,8]. Knopf and Cummins studied the same reaction under a pressure of 20.7 bar CO_2 in the presence of acetonitrile at 25°C [9], confirming $NaBH(OOCH)_3$ as the hydrogenation product. The formation of formate anion has also been reported as the main product of the CO_2 hydrogenation with $NaBH_4$ in an ethanol-water mixture by Zhao et al. [10].

In our previous study [11], we reported the CO_2 hydrogenation by $NaBH_4$ in an aqueous solution with a nickel catalyst. In this study, we focused on the cobalt-catalyzed hydrolysis of $NaBH_4$ in the presence of CO_2 at ambient conditions. The hydrogenation also was carried out in the absence of catalyst following the same procedure. In addition, the structural properties of the hydrogenation products and the effect of the catalyst on the hydrogenation process were investigated.

EXPERIMENTAL

Materials

$NaBH_4$ (Acros Organics, Fisher Scientific; 98%) and cobalt chloride ($CoCl_2$) (Sigma Aldrich) were used as received. Deionized ultra-pure water (Milli-Q grade; resistivity > 18 MΩ cm) and carbon dioxide CO_2 (Linde; 5.0) were used.

Method

The hydrolysis of 120 mg of $NaBH_4$ was performed in the presence of 26.7 mg $CoCl_2$ and CO_2, following the protocol of our previous work [11]. $NaBH_4$ was mixed with $CoCl_2$ in an argon-filled glove box (MBraun M200B; H_2O and O_2 < 0.1 ppm). The hydrolysis was realized in a fume hood and a three-necked round bottom flask used as a hydrolysis reactor. The reactor was connected to the CO_2 gas line (1.05 bar), and it was filled with 50 mL of water. CO_2 was bubbled in the water for 10 min. After the step, the $NaBH_4$-$CoCl_2$ mixture was poured into the flask. While the hydrogenation was performed rapidly, it contributed to CO_2 effervescence, and the solution became milky. The flow

of CO_2 was stopped when the effervescence stopped, and then the solution returned to its transparence. The reaction was completed in 10 minutes. A clear solution with black particles was obtained. The solution was centrifuged for 10 min at 5400 rpm to remove the in situ formed Co particles. The solid product obtained from the reaction is denoted as CB-1. We repeated the hydrolysis mentioned above experiment in the absence of a Co catalyst and the solid hydrogenation product denoted as CB-2.

Characterization

The hydrogenation products were investigated by Fourier Transformed Infrared (FTIR) spectroscopy (ThermoFisher, Germany, NEXUS instrument equipped with an attenuated total reflectance (ATR) accessory; wavenumber range of 4000-600 cm^{-1}); powder X-ray diffraction (XRD; PANalytical X'pert Pro diffractometer) and scanning electron microscopy (SEM; Zeiss EVO® LS 10). The elemental content of CB-1 is also investigated by Inductively Coupled Plasma Mass Spectrometry (ICP-MS; Agilent 7800 ICP-MS).

RESULTS AND DISCUSSION

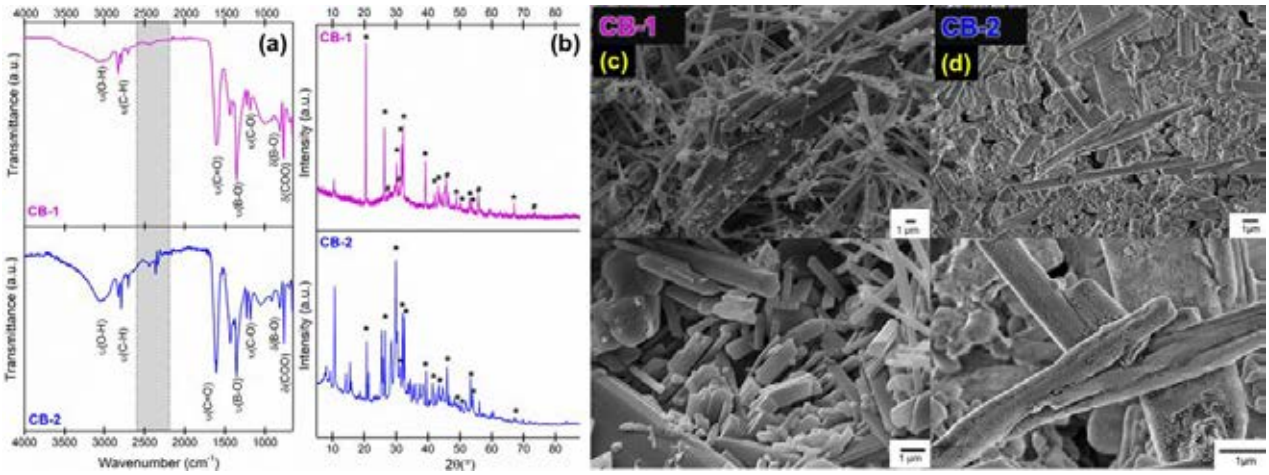

Figure 1. The comparable FTIR spectra (a) and XRD patterns (b); SEM images of CB-1 (c) and CB-2 (d)

The hydrogenation products analyzed by FTIR spectroscopy are given in Figure 1. The FTIR spectra of the products are investigated comparatively. The bands of both products observed at the wavenumber ranges are attributed to the following bonds: O-H (stretching 3600-2870 cm^{-1}), C-H (stretching 2870-2640 cm^{-1}), and B-O (stretching and deformation 1450-650 cm^{-1}). Moreover, the peaks are attributed to C-H deformation (CB-1 and CB-2 1046 cm^{-1}), C=O stretching (CB-1 and CB-2 1610 cm^{-1}), C-O stretching (CB-1 1345 cm^{-1}; CB-2 1350 cm^{-1}), COO deformation (CB-1 760 cm^{-1}; CB-2 758 cm^{-1}) [9, 15-17] and B-O-C (CB-1 1184 cm^{-1}; CB-2 1175 cm^{-1}) [9, 18]. The presence of O-H and B-O bands in both products shows the products' borate structure [15,16]. Also, the results are comparable to NaHCOO [17]. The FTIR spectra of CB-1 and CB-2 were very compatible with the hydrogenation product of our previous study [11]. It can be observed that there is no B-H band in the structure of the hydrogenation product we obtained in our previous study and the CB-1 product in this study. However, a B-H band between 2600-2200 cm^{-1} was found in the structure of the hydrogenation product CB-2, which was carried out in a catalyst-free environment [19]. This shows that the BH_4^- conversion is completely realized with the hydrogenation carried out in the presence of a catalyst.

The XRD patterns of CB-1 and CB-2 were also given in Figure 1. Most of the diffraction peaks (indicated by a star) of the products are ascribed to the structure of NaHCOO (ref. 00-011-0724). The diffraction peaks (indicated by number sign) of CB-1 are also ascribed to NaCl (ref. 00-001-0996) [20]. The excluded broad peaks below 20°, between 25-35° and 40-50° belong to the amorphous phase [11], and based on the XRD and FTIR analysis results, we assume the formation of crystalline and/or amorphous $B(OH)_2(OOCH)$.

The elemental content of CB-1 was investigated by ICP-MS analysis to observe Co content in the structure. The results show that the sample has 6.28±0.63% B, 22.26±0.96% Na and 0.573±0.063% Co elemental content by weight.

The hydrogenation solids were visualized by SEM (Figure 1). The solids consist of needle-like crystals of mixed sizes. CB-1 crystals' have lengths varying from 0.5 µm to 11.8 µm and a thickness in a range 0.24-of to 0.8 µm. CB-2 have a thickness from 0.3 µm to 12.3 µm and length from 0.6 µm to 2 µm.

CONCLUSIONS

In conclusion, the study proves that CO_2 could hydrogenate in an aqueous $NaBH_4$ solution at ambient conditions and NaHCOO is obtained as the chemical conversion product of CO_2. The hydrogenation product CB-1 is a mixture of NaHCOO, $B(OH)_2(OOCH)$, and NaCl. The usage of cobalt catalyst in the process provides the total BH_4^- conversion.

ABSTRACT

Previously, water hyacinth (*Eichornia crassipes*) was anaerobically digested with anaerobic sludge in batch system at varying total solid (TS) contents of 3.3 and 4.3% and at 35°C. In this study, high organic content of the digested biomass was evaluated in hydrothermal gasification in batch reactor system at different temperatures (200-500°C) to produce biofuels and biochemicals. Hydrothermal gasification was performed in sub- and super-critical water (T_c=374°C, P_c=221 bar) conditions. Prevailing products are biochemicals (glycolic acid, formic acid, acetic acid, furfural, 5-methyl furfural, phenols etc.) at lower temperatures (200-300°C) while biofuels (especially hydrogen and methane) are produced at higher temperatures (400-500°C). Nearly 63% of the feed was converted to gas and aqueous products at 500°C.

Keywords: Hydrothermal gasification, Water hyacinth, Hydrogen, Methane

INTRODUCTION

Water hyacinth is a free-floating aquatic weed those spreads very rapidly and causes damage to aquatic life. Besides the harmful properties of this plant, it provides wastewater reclamation by removing pollutants such as toxic organic compounds and heavy metals [1]. These plants are usually burned or dumbed into landfills causing green house gas emissions. Uncontrolled growth of aquatic plants is problematic in many countries such as India, Pakistan, France, Italy, Portugal, Spain and South America [2]. Recently, surface of the Asi River in Turkey has been covered by water hyacinth plants [3]. High organic content of water hyacinth can be evaluated in energy production. Anaerobic digestion (AD) is the most used method for biogas and fertilizer productions from aquatic plants. Usage of digestate as fertilizer is not suitable because of low capacity for application in agriculture, different pollutions like heavy metals and organic compounds, danger of infection, legal problems, and transportation distances [4]. Digestate can also be converted into biofuels and biochemicals via hydrothermal gasification (HTG). Simultaneous production of hydrogen and methane rich gas can be accomplished with HTG process. Main advantages of HTG are to gasify biomass without drying, fast degradation and less formation of coke and CO gas. Former application of AD process also provides pumpable biomass slurry for continuous HTG process. AD process can be used as a kind of pre-treatment method for better dissolution of lignocellulosic structure of aquatic plants that will be further degraded in HTG with higher yields without requirement of catalyst usage. Final solid residue can also be evaluated as bio-adsorbent, catalyst support and fertilizer. Usage of a hybrid process integrating AD and HTG is a novel method for producing biofuels and biochemicals with net zero waste.

MATERIALS AND METHODS

In a previous study, water hyacinth was anaerobically digested with anaerobic sludge at different TS contents (3.3% for D1 and 4.3% for D2) and at 35°C. D1 represents only anaerobic sludge while D2 includes both sludge and water hyacinth. Remaining digestate were used as feedstock for hydrothermal studies. Proximate analysis of digested biomass solution after anaerobic digestion was given in Table 1.

Table 1. Proximate analysis of digested biomass solution after anaerobic digestion

Run Code	D1	D2
TS (Total Solid, %)	6.1	6.7
VS (Volatile Solid, %)	60.1	61.8
TC (Total Carbon, %)	26.8	29.1

Digested biomass solution with a volume of 15 mL was used in all hydrothermal studies. Hydrothermal studies were performed between 200-500°C (pressure range of 0-340 bar). Only studies at 500°C represents the super-critical condition, others are sub-critical conditions. Experimental conditions for hydrothermal studies were given in Table 2.

Table 2. Experimental conditions for hydrothermal studies

Run Code	D1T200/ D1T300/ D1T400/ D1T500	D2T200/ D2T300/ D2T400/ D2T500
Gasification Temperature (°C)	200/300/400/500	200/300/400/500
Gasification Pressure (bar)	0/80/150/340	0/80/150/340
Mass of TS in feed (g)	0.915	0.927
Mass of VS in feed (g)	0.549	0.572

Digested biomass solution was put into batch reactors with a volume of 100 mL. Reactor was purged for 15 min with nitrogen gas and placed into heaters that provide constant heating rate of 6 K min^{-1}. After reaching gasification temperature, reactor was heated for 1 h when the reaction reached the equilibrium conditions. At the end of this time, reactor was rapidly cooled by fans and then submerged in cool water. The volume of gas products was measured by water-displacement method. They are analyzed by gas chromatography (GC). Inside of the reactor was washed with water and then filtered to separate aqueous product and solid residue. Before analysis, aqueous products were stored in a refrigerator at 4°C.

Analysis of gas products: Composition of the gaseous products (H_2, CO_2, CO and C_1-C_4 hydrocarbons) was analyzed by Agilent HP 7890A model GC equipped with 3 detectors (FID-TCD-TCD) and serially connected 7 columns. Technical features and operating conditions of GC were given in previous work [5].

Analysis of aqueous products: Total organic carbon (TOC) and inorganic carbon (IC) contents of aqueous phase were analyzed by a TOC analyzer (Shimadzu TOC-V_{CPH}, Japan). The amounts of carboxylic acids, aldehydes, ketones, furfurals and phenols present in the aqueous solutions were analyzed by Shimadzu LC-20A model High Performance Liquid Chromatography (HPLC, Japan). Technical features and operating conditions of TOC and HPLC systems were given in previous work [5].

Analysis of solid residue: The TOC content of solid residue was analyzed by SSM-TOC analyzer (Shimadzu TOC-V_{CPH}, Japan).

RESULTS AND DISCUSSION

Carbon gasification efficiency (CGE in g C in gas/g C in digestate), carbon liquefaction efficiency (CLE in g C in aqueous/g C in digestate) and residue (RE in kg C in residue/kg C in digestate) were calculated as given in our previous work [5]. Gas products were not obtained at 200°C. Gas composition and product efficiencies were given in Figs.1 and 2, respectively.

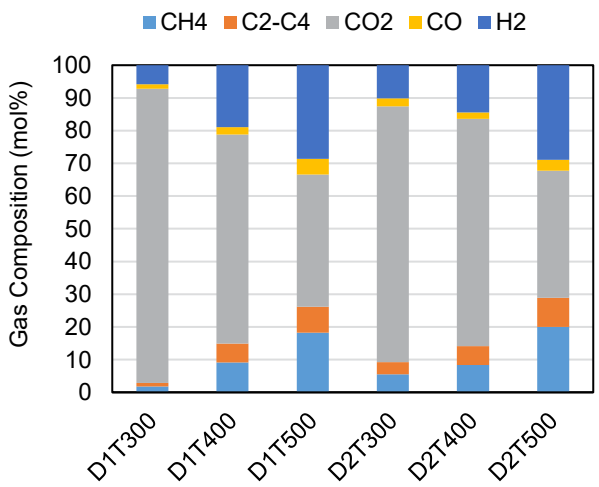

Fig. 1. Gas composition

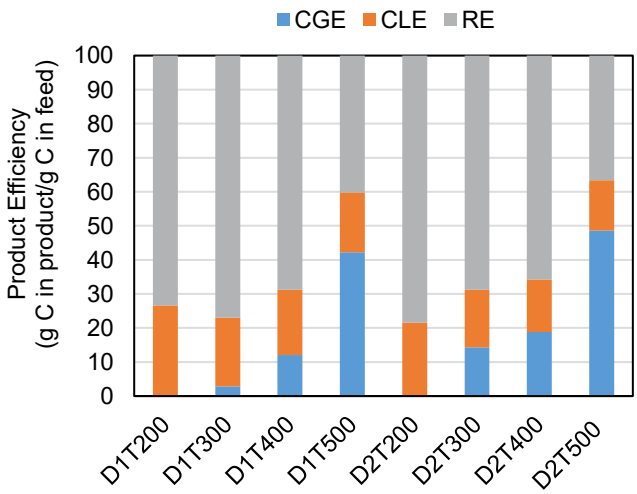

Fig. 2. Product efficiencies

Main composition of gas product was carbon dioxide, hydrogen, and methane. As the temperature increased from 300 to 500°C, share of the hydrogen and methane in the gas mixture increased while carbon dioxide decreased. Nearly half of the gas was composed of hydrogen (29 mol%) and methane (20 mol%) at 500°C for sample D2 which has higher VS and TS (Fig.1). These findings are better than that obtained in a previous study (15 mol% H_2 and 25 mol% CH_4) with sewage sludge at 500°C [6]. Product was composed of aqueous and residue parts at lower temperatures and nearly 63% of the feed was converted to gas and aqueous products at 500°C (Fig.2). Carbon content and composition of aqueous phase were given in Figs.3 and 4, respectively.

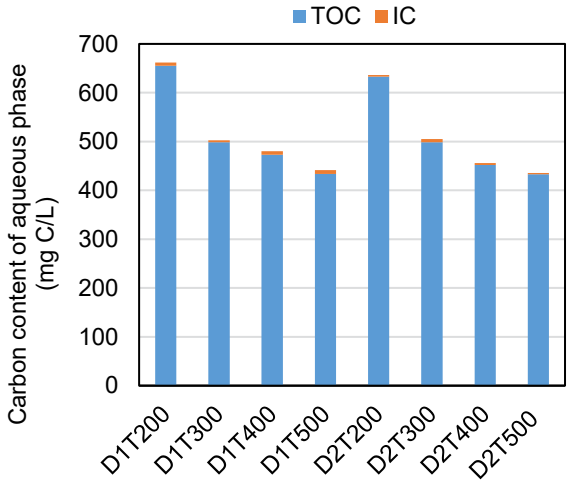

Fig. 3. Carbon content of aqueous phase

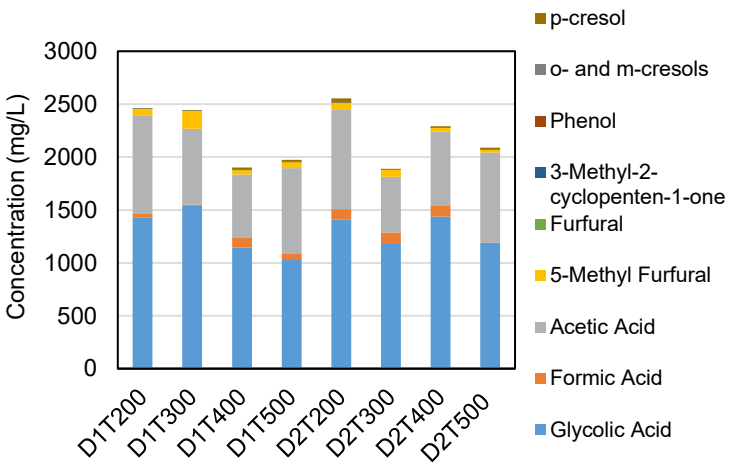

Fig. 4. Composition of aqueous phase

The TOC content of the aqueous product was relatively higher at 200°C since the degradation rate was lower. The IC content of the aqueous phase was extremely low at all conditions (Fig.3). Aqueous phases were mostly composed of carboxylic acids such as glycolic acid, formic acid and acetic acid which are the main degradation products of furfural or 5-HMF (Fig.4). Carboxylic acids are temperature-resistant and not converted to gas products. Phenols (phenol and cresols) are the main degradation products of the lignin structure and found quietly low in aqueous phase.

CONCLUSIONS

Consecutive application of AD and HTG gasification processes provides evaluation of anaerobically digested water hyacinth as biofuel and biochemical source. The AD process accelerated the dissolution rate of lignocellulosic structure of the aquatic plant and resulted in high conversion to gas and aqueous products.

ACKNOWLEDGEMENT

We gratefully acknowledge the financial support provided by Ege University, National Research Project Grants-BAP-ONAP (Project No: FOA-2021-22343). This research work is the continuation of our previous research work supported by SAN-TEZ (Project No. 0330.STZ.2013-2). We are grateful to IZSU Çiğli Advanced Biological Wastewater Treatment Plant, Izmir for giving us waste sludge for biogas production. We are grateful to Profs M.Yüksel and M.Sağlam for their great efforts to establish the infrastructure in the Chemical Technologies laboratories where this research study was carried out. We would like to thank Assoc.Prof.Dr. A. Gunes for providing us water hyacinth seedlings and MSc student G. Öztep for previous anaerobic digestion studies. We would like to thank Mr. Gürsel Serin for supporting the mechanical work.

ABSTRACT

In this study, thermodynamic analyses and simulations are performed via using the Aspen Plus software to examine the Boron based thermochemical hydrogen production cycle in detail. There are four main reactions in the cycle and one of them is performed in electrolyzer. Therefore, the cycle requires heat, electricity and water to obtain hydrogen. The electrolyzer efficiency is around 60%, and the overall cycle exergy efficiency varies between 70%-85%.

Keywords: Boron cycle, Hydrogen production, Thermochemical water splitting

INTRODUCTION

There are several ways to produce hydrogen. One of the cleanest and popular hydrogen generation technique is that thermochemical water splitting and hydrogen generation cycles. Thermochemical hydrogen production techniques came to the fore in the 1970s [1]. Water can be split into oxygen and hydrogen at over 2500 K temperature [2]. Thermochemical hydrogen production cycles can be divided into pure and hybrid production cycles. Hybrid cycles need electrical energy and heat , on the other hand, pure cycles require only heat [3]. There are several studies regarding boron-based thermochemical cycle that evaluates the energy and exergy efficiency of the cycle [4,5].

The boron based thermochemical cycle consists of four main reactions to generate hydrogen. One of the four reactions is the electrolyzing of magnesium chloride. In this study, the reactions of the cycle are modeled and investigated using Aspen Plus and EES thermodynamically.

MODELING

The Boron based thermochemical cycle consists of four necessary reactions to produce hydrogen and oxygen. The reactions can be summarized as follows:

$$3MgCl_2 \rightarrow 3Mg + 3Cl_2$$
$$3Mg + B_2O_3 \rightarrow 2B + 3MgO$$
$$3MgO + 3Cl_2 \rightarrow 3MgCl_2 + 1.5O_2$$
$$2B + 3H_2O \rightarrow 3H_2 + B_2O_3$$

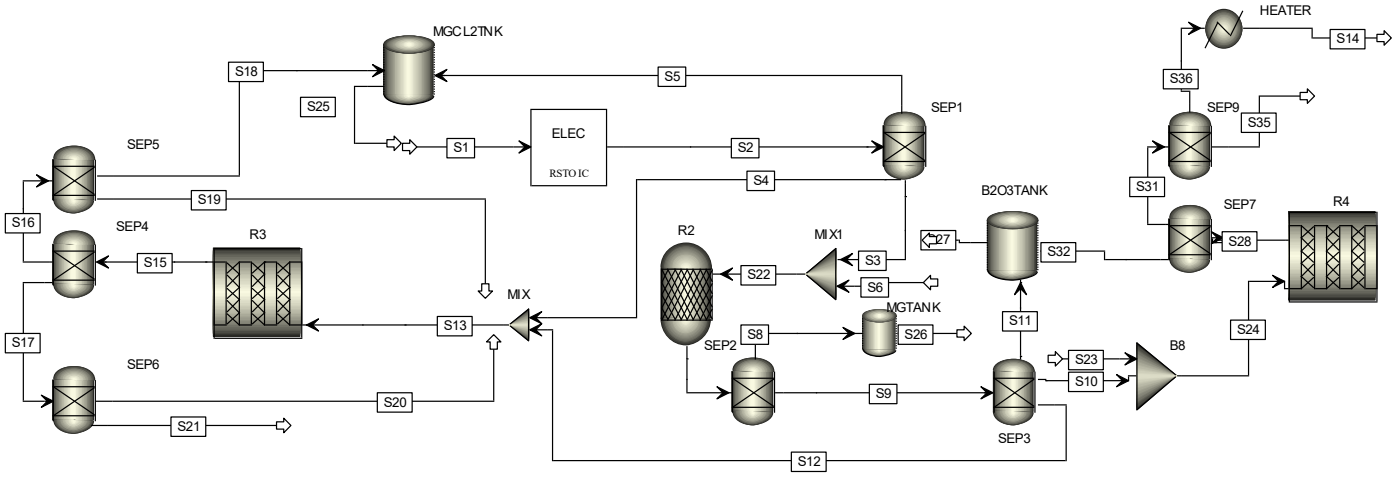

Fig. 1. AspenPlus flowsheet of Boron based thermochemical hydrogen production cycle

The cycle is required water, heat and electricity to perform. The heat source can be nuclear, renewable, or any kind of heat supply. One reaction required electrolyzer to obtain magnesium and chloride. The other reactions can be occurred without electricity. The AspenPlus flowsheet of the cycle is shown in Fig.1.

RESULTS AND DISCUSSION

The characteristic of the electrolyzer is shown in Figure 2. When the modeling is compared with the experimental data, it can be said that it is in full agreement. It is calculated that the efficiency of the electrolyzer is around 60%, respectively by considering the cycle operating conditions.

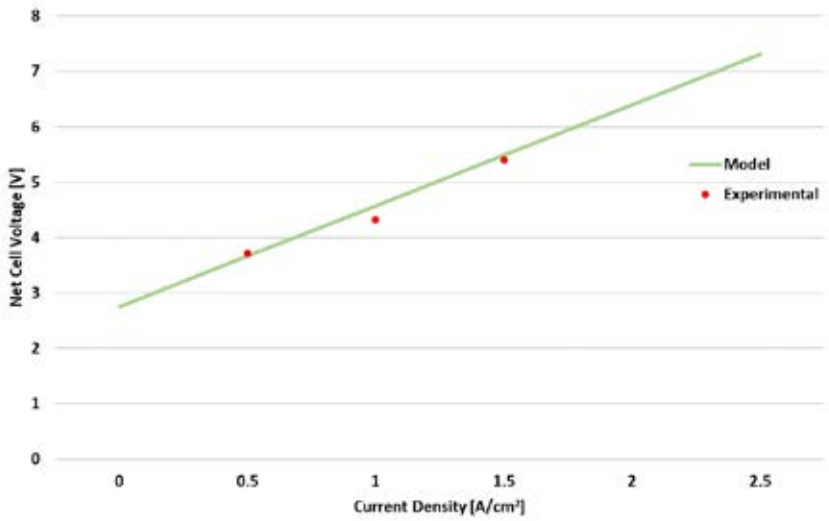

Fig. 2. The effect of current density on the net cell voltage

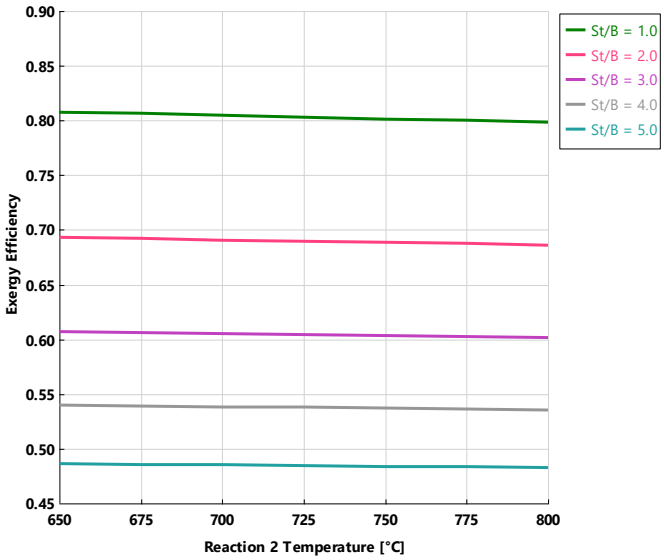

Fig.3. Variation of exergy efficiency with the change of reaction (Boron Production) temperature at different St/B molar ratios

The variation of the exergy efficiency of the cycle according to the Steam/Boron ratio and the reactor temperature in the boron production reaction is seen in Figure 3. The highest cycle efficiency is obtained when the steam/boron ratio is 1.0. The variation of exergy efficiency of MgO chlorination reaction according to temperature and steam/boron ratio is given in figure 4. Similarly, the highest exergy efficiency is obtained when the steam/boron ratio is 1.0 and the temperature is 470°C.

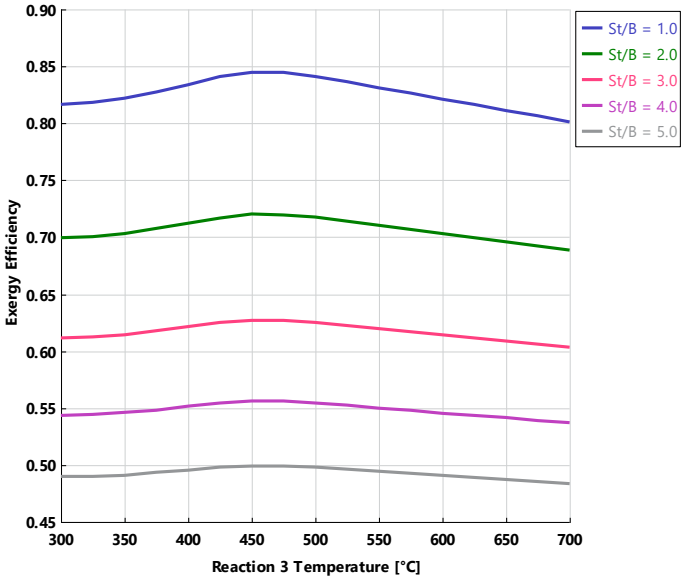

Fig.4. Variation of exergy efficiency with the change of reaction (MgO Chlorination) temperature at different St/B molar ratios

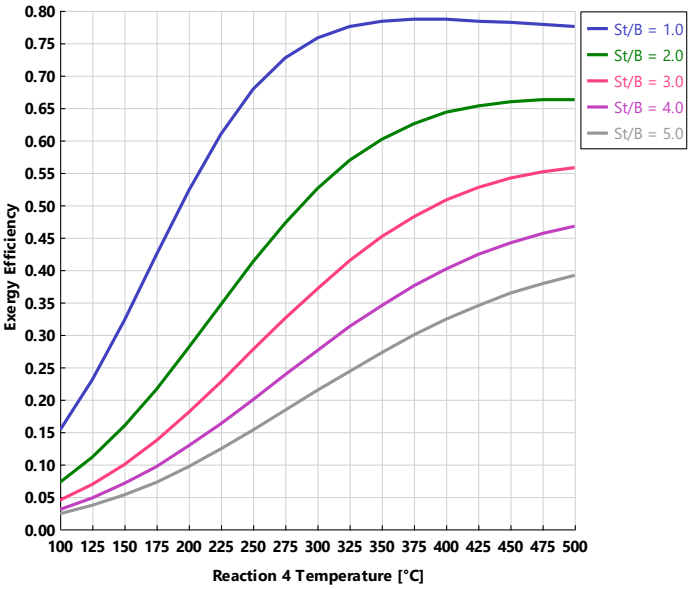

Fig.5. Variation of exergy efficiency with the change of reaction (Boron Hydrolysis) temperature at different St/B molar ratios

In Figure 5, the variation of exergy efficiency of the hydrolysis reaction according to temperature and steam/boron ratio is given. The highest efficiency can be obtained when the steam/boron ratio is 1.0 and the temperature is 350 °C for the analysis and assessment.

CONCLUSIONS

In this study, the Boron based thermochemical cycle is analyzed thermodynamically. The main findings can be found below.

- The first reaction of the boron-based thermochemical cycle is the $MgCl_2$ electrolysis process. As a result of the modeling studies carried out in EES with electrochemical modeling, the electrolysis process has an efficiency in the range of 60% - 65%.
- The exergy efficiency of the cycle varies between 70% - 85%.
- The reason for the higher efficiency of the boron-based thermochemical cycle compared to the other cycles is that it requires low heat and low temperature. In addition to these, the reactions that make up the cycle have kinetically high yield values.

ABSTRACT

Due to excessive emissions contributed by transportation sector, electrification of vehicles has become extremely essential. In this regard, battery electric vehicles are a promising solution however, a downside to electrification is its impact on power grid. To reduce pressure on power grid, utilization of renewable energy sources is essential. Thus, this paper presents a novel idea of a solar energy based integrated system where a thermochemical hydrogen production system is combined with an electric vehicle charging station. The hydrogen produced through the thermochemical process is utilized for electricity generation through a proton exchange membrane fuel cell. The thermal energy requirements of the thermochemical cycle are fulfilled by both solar thermal energy and internal heat recovery while the electrical energy requirements of the entire system are met though solar photovoltaic energy.

Keywords: Solar energy, Hydrogen, Fuel cell, Charging station, Cu-Cl cycle.

INTRODUCTION

Transportation sector is one of the major sources of environmental pollution due to excessive greenhouse gas emissions as a result of combustion of hydrocarbon-based fuels. To prevent the environmental degradation through road transport, electrification is considered as an extremely promising option. However, this puts an additional pressure on the power grid to provide the electricity to charge electric vehicles (EVs). Thus, exploitation of renewable energy can potentially address this issue. Solar energy is an extremely important source of both thermal and electrical energies and can thus be exploited by either directly using it via photovoltaic (PV) panels for electricity generation or by utilizing it as a thermal energy source to supply heat to various power generation systems. In addition, hydrogen is one of the cleaner fuels and an excellent energy carrier and can be converted into electricity via fuel cell technology. Copper-chlorine (Cu-Cl) thermochemical water-splitting process is one of the most environmentally benign pathways of producing green hydrogen. Several systems have been proposed in the literature that suggest the integration of solar energy with either Cu-Cl cycle for hydrogen production or directly with EV charging stations. In this regard, a solar PV energy based EV charging station was proposed by Fathabadi [1] and a hybrid solar energy and fuel cell-based EV charging station was investigated by Fathabadi and He [2] where hydrogen was produced through water electrolysis. In addition, a solar and geothermal energy based trigeneration system was developed by Siddiqui et al. [3] where hydrogen production was considered through a Cu-Cl cycle. However, based on the literature review, there are no studies that consider the integration of Cu-Cl cycle with a fuel cell system to supply electricity for EV charging station. Thus, in the present study, a novel renewable energy-based Cu-Cl cycle is coupled with a proton exchange membrane (PEM) fuel cell system. Another novelty of this study is that both the electrical and thermal energy requirements of the system are met via solar energy by incorporating a solar tower and PV panels. Thus, the specific objectives of this study include: (i) to develop a new solar energy-based thermochemical hydrogen production system integrated with a fuel cell system to produce electricity for an EV charging station, (ii) to thermodynamically model and investigate the cycle through energy and exergy approaches to evaluate the overall performance of the system, and (iii) to recover waste heat from the Cu-Cl cycle to supply thermal energy within the cycle to improve the overall system efficiencies.

SYSTEM DESCRIPTION AND ANALYSIS

This study proposes a solar energy driven power generation system as schematically represented in Figure 1. The present system comprises a four-step Cu-Cl water-splitting cycle for hydrogen production, a solar tower to provide the required thermal energy for the cycle, a multi-stage hydrogen compression system, a hydrogen storage system, solar PV panels to supply electrical energy to various system components, a PEM fuel cell for converting hydrogen into electricity, a battery storage system, and an EV charging station. The Cu-Cl cycle is incorporated with internal heat recovery which reduces the thermal energy requirements of the cycle. The PV panels not only fulfils the electricity requirements of the integrated system but also supplies excess electricity to be stored in the battery storage system to be used during nighttime when sufficient hydrogen is not available to be converted into electricity by PEM fuel cells. The total number of fuel cells are taken as 10. The Cu-Cl cycle constitutes four main processes namely hydrolysis, thermolysis, electrolysis, and drying. The details of the chemical reactions and operating temperatures of the various steps in the cycle are given elsewhere [3].

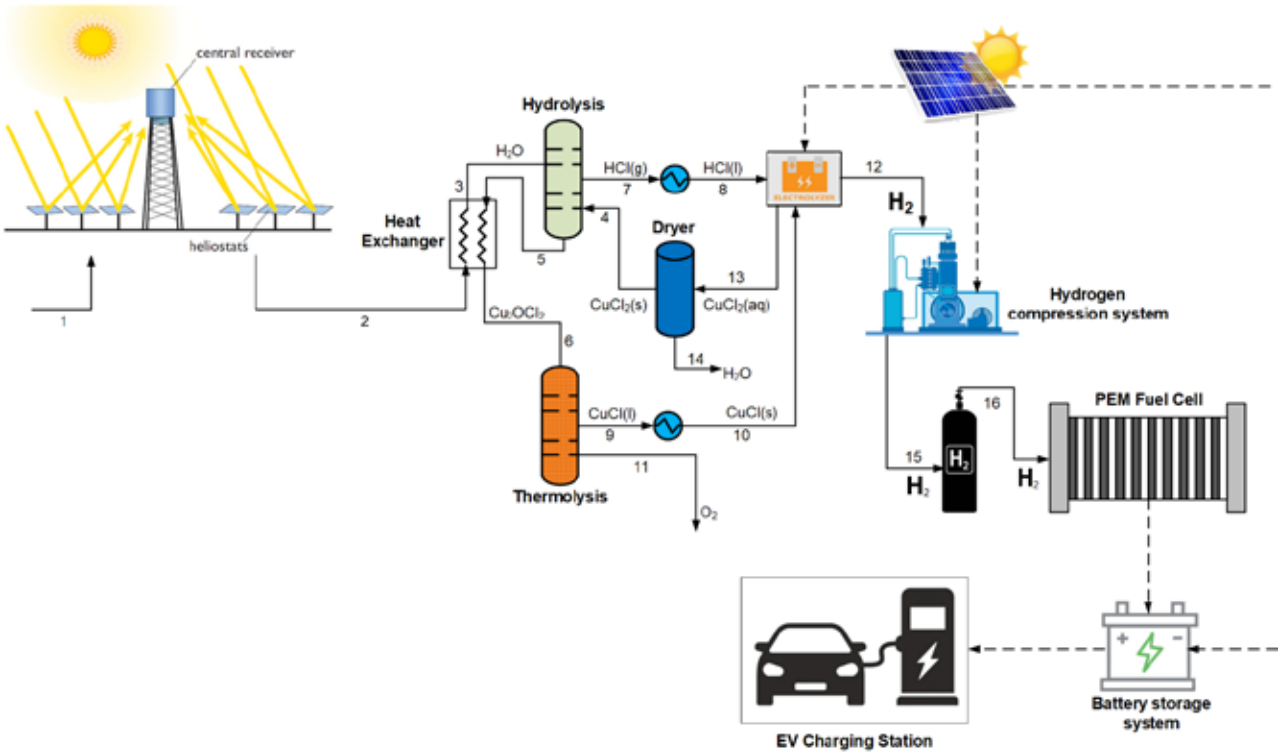

Fig. 1. Schematic illustration of the proposed integrated system for electricity generation

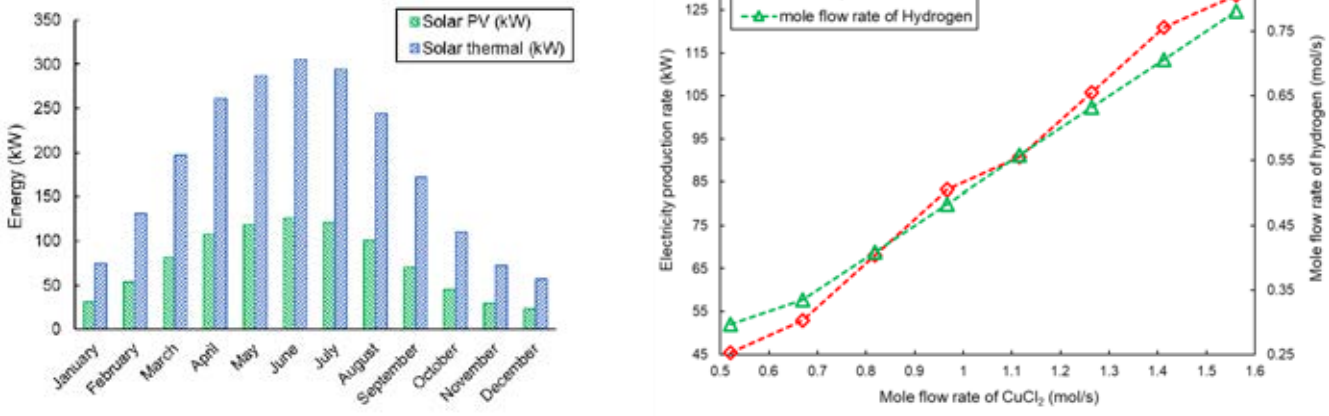
The solar radiation intensity is considered for the chosen location of Cochrane, Ontario for which the annual solar radiation intensity is 336 W/m^2 [4]. The heliostat mirror dimensions are taken as 2.25m × 2.25m, the number of heliostats are taken as 135, and the heliostat efficiency is taken as 80%. The PV panel area is taken as 1250 m^2 and the PV module efficiency is taken as 20%. The overall energy and exergy efficiencies of the system are defined as follows:



$$\eta = \frac{\dot{W}_{PEM.FC}+\dot{W}_{PV}-\dot{W}_{elec}-\dot{W}_{HCS}}{\dot{Q}_{solar,Thermal}+\dot{Q}_{solar,PV}} \quad (1)$$

and

$$\psi = \frac{\dot{W}_{PEM.FC}+\dot{W}_{PV}-\dot{W}_{elec}-\dot{W}_{HCS}}{\dot{Q}_{solar,Thermal}\left(1-\frac{T_0}{T_{sun}}\right)+\dot{Q}_{solar,PV}\left(1-\frac{T_0}{T_{sun}}\right)} \quad (2)$$

RESULTS AND DISCUSSION

The system is modeled using both Engineering Equation Solver and Aspen-plus software. The total thermal energy produced by the solar tower is estimated to be 184 kW while the total electrical energy produced by PV panels is evaluated to be 75.6 kW. The hydrogen produced by the Cu-Cl cycle is 0.448 mol/s. Each fuel cell is modeled to produce 7.56 kW with 10 fuel cell units eventually producing a total electricity of 75.6 kW. The electricity consumed by the electrolyzer and hydrogen compression system is 22.12 kW and 15.16 kW, respectively. The system results in an overall energy efficiency of 18.8% and an exergy efficiency of 18.99%. Figure 2a shows the solar thermal and electrical energies available to be produced during the 12 months of the year. The highest thermal and electrical energies can be obtained during June and July while the lowest corresponding values can be achieved during November and December due to the highest and the lowest solar radiation intensities in the respective months. Figure 2b shows the effect of the input mole flow rate of cupric chloride on the production mole flow rate of hydrogen and electricity production rate of fuel cells. The flow rate of cupric chloride is found to linearly increase the hydrogen and electricity production rates. At a flow rate of 0.52 mol/s of cupric chloride, the hydrogen flow rate is evaluated as 0.297 mol/s and the electricity production rate is estimated as 45.36 kW while increasing the input cupric chloride flow rate to 1.56 mol/s causes the hydrogen and electricity production rates to increase to 0.781 mol/s and 128.52 kW, respectively.

(a) (b)

Fig. 2. (a) Solar thermal and electrical energy production during various months of the year and (b) effect of cupric chloride mole flow rate on hydrogen and electricity production rates

CONCLUSIONS

In this study, a novel solar energy driven thermochemical hydrogen production system integrated with a PEM fuel cell-based electricity generation system is proposed and its performance is investigated. The system is found to operate at energy and exergy efficiencies of 18.8 and 18.99%, respectively. The Cu-Cl cycle produces hydrogen at a rate of 0.448 mol/s while the total electricity produced by the fuel cells is 75.6 kW The mass flow rate of cupric chloride in the Cu-Cl cycle is found to influence the hydrogen production rate and consequently the total electricity production through fuel cells.

ABSTRACT

This study presents a novel photoelectrochemical apparatus configuration for producing hydrogen to maximize the light harvested by the photoelectrode. The new design of the photoelectrode can receive the maximum amount of light energy at any angle of sunlight. Two trapezoidal photoanode and cathode are immersed in potassium hydroxide alkaline solution. The photoanode, cathode, and Nafion membrane are positioned in the potassium hydroxide solution in the new reactor design. The multiphysics simulation of the novel photoelectrochemical reactor configuration for hydrogen production is conducted. The energy and Navier-Stokes equations of the photoelectrochemical apparatus design are solved for the hydrogen bubbles and the solution flow using CFD software. The fluid flow simulation results confirm that this new design can completely clean the adhered bubbles over the surface of the electrodes due to the unique configuration that leads to an exceptional flow distribution.

Keywords: Multiphysics simulation, Hydrogen production, Novel photoelectrode, Photoelectrochemical reactor, Photonic energy

INTRODUCTION

Recently, the use of fossil fuels increased to meet the energy demand leading to an increase in the carbon dioxide concentration (CO_2) that affects global climate change [1]. Therefore, clean energy sources must be used to address climate change issues. Hence, hydrogen is one of the most potential energy sources for the future due to its cleanliness. Various sustainable energy sources could be utilized for green hydrogen production, such as solar energy, wind energy, geothermal energy, biomass energy, and nuclear energy. Photoelectrochemical (PEC) is one of the most promising applications for green hydrogen production [2]. The energy of the light source can generate electricity when it hits the photoelectrode to dissociate the water molecules for producing hydrogen at the cathode side [3]. The excess electrons in the valence bands are excited by the photonic energy to reach the conduction bands leaving holes that need new electrons to be balanced [4]. The generated electron holes will oxidize water molecules to generate oxygen along with hydrogen ions. Hydrogen ions react with the transported electrons on the cathode surface to generate hydrogen.

Researchers have listed the most critical parameters that affect the performance of PEC reactors. Bubble coverage is one of those parameters that can significantly affect PEC reactors' performance [5]. The hydrogen bubbles tend to stick on the cathode surface as an increasing hydrogen generation rate. These adhering bubbles can reduce the active area, increasing the cathode's ohmic losses and decreasing the associated current density. Thus, this study concerns developing the flow distribution to be able to clean the cathode's surface from any adhered bubbles.

METHOD AND ANALYSIS

The photoelectrochemical reactor can split water into oxygen and hydrogen using light energy. The PEC process entails a light source, two electrodes (one of them photoelectrode or two photoelectrodes), membrane, and solution electrolyte. The photoelectrode is responsible for generating electrons using light energy. The light energy can move the excess electrons in the photoelectrode from the valence electrons' bands to the electrons' conduction bands. The light energy must overcome the energy bandgap of the photoelectrode material. Figure 1. shows the proposed PEC device with two novel electrodes and a Nafion membrane. The current photoelectrochemical cell is studied to develop the fluid flow analysis through presenting the temperature plan, streamlines, velocity contours, and hydrogen volume fraction. All governing equations of the electrolyte can be written at transient conditions in 2D of the coordinates r and z [6].

Continuity equation:

$$\frac{\partial \rho}{\partial t} + \frac{1}{r}\frac{\partial (r\rho v_r)}{\partial r} + \frac{\partial (\rho v_z)}{\partial z} = 0 \quad (1)$$

Momentum equations:

$$\rho\left(\frac{\partial v_r}{\partial t} + v_r\frac{\partial v_r}{\partial r} + v_z\frac{\partial v_r}{\partial z}\right) = -\frac{\partial p}{\partial r} + \rho g_r + \mu\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_r}{\partial r}\right) - \frac{v_r}{r^2} + \frac{\partial^2 v_r}{\partial z^2}\right) + F_s \quad (2)$$

$$\rho\left(\frac{\partial v_z}{\partial t}+v_r\frac{\partial v_z}{\partial r}+v_z\frac{\partial v_z}{\partial z}\right)=-\frac{\partial p}{\partial z}+\rho g_z+\mu\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z}{\partial r}\right)+\frac{\partial^2 v_z}{\partial z^2}\right)+F_s \quad (3)$$

$$F_s=\nabla[\sigma(I+(-n\,n^T))\delta] \quad (4)$$

$$\delta=6|\varphi(1-\varphi)||\nabla\varphi| \quad (5)$$

$$\rho=\rho_1+(\rho_2-\rho_1)\varphi \quad (6)$$

$$\mu=\mu_1+(\mu_2-\mu_1)\varphi \quad (7)$$

Energy equation:

$$\rho C_P\left(\frac{\partial T}{\partial t}+v_r\frac{\partial T}{\partial r}+v_z\frac{\partial T}{\partial z}\right)=\frac{k}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right)+k\frac{\partial}{\partial z}\left(\frac{\partial T}{\partial z}\right)+2\mu\left(\frac{\partial v_r}{\partial r}\right)^2+2\mu\left(\frac{v_r}{r}\right)^2+2\mu\left(\frac{\partial v_z}{\partial z}\right)^2+\mu\left(\frac{\partial v_z}{\partial r}+\frac{\partial v_r}{\partial z}\right)^2+\nabla q^r \quad (8)$$

$$\nabla q^r=\int_0^\infty \alpha_\lambda\left(4\pi I_{b\lambda}-\int_{4\pi} I_\lambda\, d\Omega\right)d\lambda \quad (9)$$

Interface equation (level set):

$$\frac{\partial\varphi}{\partial t}+v_r\frac{\partial\varphi}{\partial r}+v_z\frac{\partial\varphi}{\partial z}=\gamma\left(\frac{\partial\varphi}{\partial r}+\frac{\partial\varphi}{\partial z}\right)\left(\varepsilon_{ls}\left(\frac{\partial\varphi}{\partial r}+\frac{\partial\varphi}{\partial z}\right)-\varphi(1-\varphi)n\right) \quad (10)$$

where $n=\frac{\nabla\varphi}{|\nabla\varphi|}$ (11)

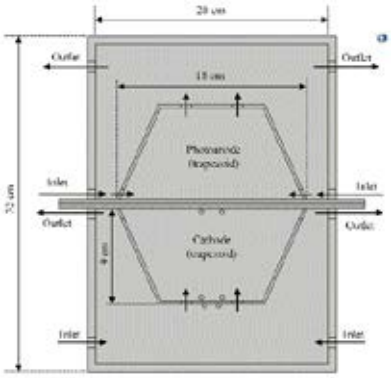

Fig. 1. The proposed PEC reactor with two novel electrodes.

RESULTS AND DISCUSSION

The fluid flow modeling of the novel PEC device is conducted to eliminate the issue of the sticky bubbles on the cathode surface. COMSOL packages are employed to simulate the hydrogen evolution process in the PEC devices. The PEC device is considered as a 2D configuration due to the symmetry of the design and to reduce the cost of the computational process. The current case study is simulated at a transient condition to evaluate the hydrogen evolution process with time. The mesh independence test is conducted to determine the best mesh size. By solving the above governing equations of the PEC device, the velocity surface, streamlines, and hydrogen volume fraction are calculated. The simulation results of the electrolyte flow confirm that the velocity distribution can remove any adhered bubbles from the cathode surface. As shown in Fig. 2 through the velocity surface and streamlines, the electrolyte flow has high values adjacent to the cathode surfaces to prevent hydrogen bubbles from not sticking on the metal surface. Moreover, the hydrogen gas volume fraction is presented at three different times in Fig. 3. It is clearly obvious that hydrogen bubbles are completely moving to the outlet of the cathode chamber due to the flow distribution of the new PEC design.

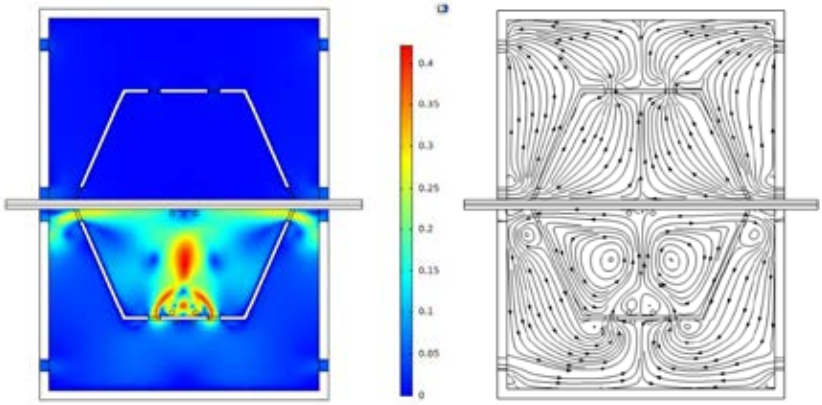

Fig. 2. Velocity surface and streamlines of the electrolyte of the novel PEC device.

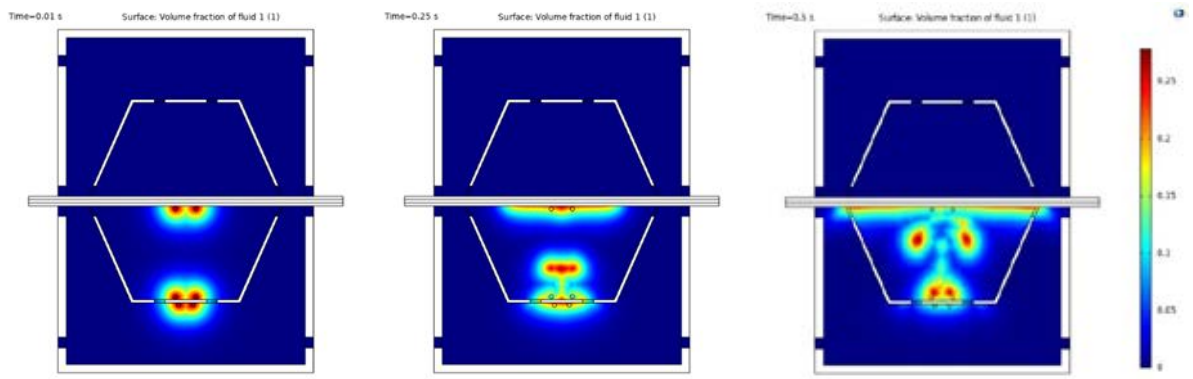

Fig. 3. The volume fraction of hydrogen for the novel PEC device at different times.

CONCLUSIONS

A CFD study of a novel PEC reactor device for sustainable hydrogen production is conducted. The energy and Navier-Stokes equations of the new PEC device are solved by the COMSOL tool. The physical flow characteristics of the flow are evaluated to define the velocity surface, streamlines, and hydrogen gas volume fraction. The results of the current PEC design indicated that the flow could generate enough circulations to prevent hydrogen bubbles from not sticking on the cathode surface. This PEC design can keep the cathode resistance at the lowest level due to cleaning its surface from any adhering bubbles. Moreover, the present PEC design is easier than earlier designs to fabricate, manufacture, build, assemble, and disassemble.

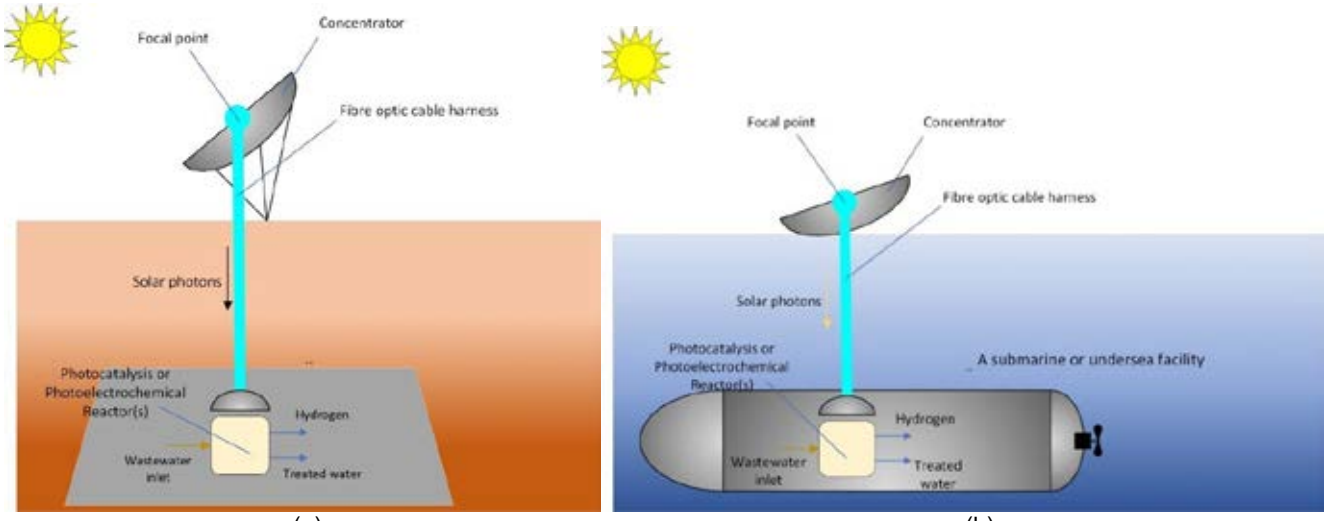
ABSTRACT

This study investigates the potential use of photocatalysis and photoelectrochemical reactors in underground and underwater applications for hydrogen production and wastewater treatment. The solar photons are transmitted by fibre optic cables. At the end of the present study, it is observed that the efficiency of the system is limited to the low efficiency of photocatalysis and photoelectrochemical reactors. Today's fibre optic technology provides a satisfactory performance for solar transmission. The biggest obstacle for the proposed system is the cost of fibre optic cables. It may be more suitable for the defence industry and space technology applications.

Keywords: Hydrogen; wastewater treatment; sustainability; underground energy systems; underwater energy systems.

INTRODUCTION

One has to note that hydrogen, as an energy carrier, energy storage medium, fuel, and feedstock, is undertaken now a ground-breaking technology for sustainable future. Today, hydrogen systems have already taken placed in many sectors, and it is expected that hydrogen-powered systems will be more commonly deployed in the near future with the extension of the hydrogen economy all around the world.



Underwater and underground facilities, vehicles and hence systems are considered critical for from research activities to defense industry, from energy applications to environmental research. Hydrogen is one of the most effective fuel and power source for underwater and underground applications as using hydrogen is a process that is air-independent propulsion. Sezgin et al. [1] have reviewed the use of hydrogen in the underwater application. They have emphasized that proton exchange membrane (PEM) fuel cells can be used as the power source. Also, as hydrogen storage options compressed, and metal hydride based H_2 storage techniques are suitable for small to medium submarines. On the other hand, there are various attempts for combining hydrogen production and wastewater treatments. Photocatalysis and photoelectrochemical reactors are used for this purpose. While photocatalysis is a light-driven process where chemical reactions occur under the presence of a catalyst, photoelectrochemical cells produce hydrogen along with photocurrent upon absorption of light. Aydin et al. [2] have reviewed the hydrogen production methods with wastewater treatment. Finally, the use of the fibre optic cables in the solar-driven system is not actually a novel aspect. Kribus et al. [3] have studied the potential use of optical fibers for solar thermal power generation. They have concluded that the use of fibre optic cables in concentrated solar power (CSP) systems is feasible at under specific conditions. They have additionally emphasized that the cost of optical fibre is the key cost driver for the proposed system.

Hydrogen-driven systems are now expected to be an essential option for underwater and underground systems due to their unique advantages: silent operation, environmentally friendly process, high efficiency, and low thermal dissipation. Photocatalysis and photoelectrochemical methods have a significant potential for hydrogen production along with wastewater treatment. The solar input for photocatalysis and photoelectrochemical reactors can be provided by fibre optic cables for the locations where do not have direct solar access such as underground and underwater. This study offers a unique system for hydrogen production and wastewater treatment with photocatalysis and photoelectrochemical for underground and underwater applications with carried solar photos via fiber optic cables.

MATERIALS AND METHODS

Fig. 1 depicts the schematics for the proposed systems. In order to receive solar input intensity, a dish concentrator is included in the system. Solar trackers can be included in the proposed system. The solar input is collected by a fibre receiver and carried to the location where photocatalysis and photoelectrochemical reactors are located. A fibre optic distributor is used for distributing solar photons to the reactors. Wastewater is sent to the reactor for hydrogen production and water treatment. The produced hydrogen is used for power generation in the PEM fuel cells. Stationary dishes with two-axis solar trackers can be used in the underground system. In the underwater systems, while floating dishes can

be used, foldable structures such as the submarine periscopes can also be used. Similar to the underground system, solar photons collected by fibre optic receivers are carried to the location where reactors are located via optical fibre cables. Thus, hydrogen is produced along with the wastewater treatment.

(a) (b)

Fig. 1. The system layouts for the proposed system a) underground application and b) underwater application

RESULTS AND DISCUSSION

The main challenge in the use of the proposed system is the cost of the fibre optic cables, especially for higher capacities, since they require a larger diameter cable harness. However, when the investment costs of the underwater and underground technologies are considered, it can be an acceptable level, especially for the defence industry applications such as submarines. The efficiency of the proposed system is limited to the low efficiency of photocatalysis and photoelectrochemical reactors. Today's photocatalysis and photoelectrochemical technologies offer up to 5-6% hydrogen production efficiency. Also, generating hydrogen from wastewaters is not a common method yet. However, the use of photocatalysis and photoelectrochemical methods for hydrogen production and wastewater treatment is a promising technique due to their potential lower carbon footprint impacts. Today's fibre optic technologies serve a tremendous performance to carry the sunlight. So, there are no significant losses in solar photon transmission in the fibre optic cables. Consequently, although today's photocatalysis and photoelectrochemical technologies do not offer high performance, they will probably offer better performance for hydrogen production and wastewater treatment in the near future. When the increasing need for silent operation, environmentally friendly process, high efficiency, and low thermal dissipation for underwater and underground applications is taken into consideration. The proposed system can play a significant role in those applications for hydrogen production and wastewater treatment.

CONCLUSIONS

This paper has dealt with the potential use of photocatalysis and photoelectrochemical hydrogen generating reactors in underground and underwater applications with a wastewater treatment option where the solar photons are transmitted by fibre optic cables with a satisfactory performance for solar transmission. Due to an increased efficiency and enhanced use of hydrogen, such systems offer a great potential for applications in defence and space industries.

ABSTRACT

Hydrogen could be generated from both renewable and non-renewable sources of energy. Using nonrenewable energy sources to produce hydrogen will result in greenhouse CO_2 gas emissions and cause global warming. Photocatalytic systems for generating hydrogen from solar energy have a great deal of potential to solve the global warming problem because of the totally renewable green source of sun and water. Because of its superior properties, such as a proper and narrow bandgap, better chemical stability, non-toxic, photo-corrosion resistance, and suitable optimum conduction and valance band potentials, the tin disulfide (SnS_2) photocatalyst has great potential to be used for producing H_2 from the splitting of water via solar energy. In this study, SnO_2 powders were successfully thermally sulfurized to SnS_2 powders at 500°C for 24 hours under an Argon (Ar) atmosphere. The XRD analysis verified the hexagonal SnS_2 crystals. UV-vis spectroscopy was used to determine the band gap value of the generated powder, which is 2.24 eV.

Keywords: Tin disulfide, Photocatalyst, Solar energy, Water splitting, Hydrogen production

INTRODUCTION

Hydrogen can be solution for climate crisis as stated by the latest decision taken by the European Parliament and of the Council on 30 June 2021. Hydrogen is one of the leading sources of renewable energy as an alternative to fossil fuels. Hydrogen may be produced from both renewable and nonrenewable sources of energy. However, using non-renewable energy sources in hydrogen production will cause greenhouse gas emissions and cause global warming. The production of H_2 by splitting water with solar energy as a renewable energy source through photocatalytic and photo-electrochemical methods has great potential to be alternative energy source to satisfy the need for energy of the world [1-3]. Photocatalysts are semiconductor materials that are activated by light energy and initiate a series of electrochemical reactions. Many photocatalytic semiconductor materials have been studied, such as metal oxides, metal nitrides, oxy-nitrides, metal sulfides, and organic materials. Metal oxides (e.g., TiO_2) have suitable band structures that provide the thermodynamic requirements for splitting water, and they are resistant to photo-corrosion. However, they are active under ultraviolet light, which constitutes 4% of the solar spectrum due to its wide band gap value, and because of this they have very low efficiency, which limits their uses [4,5]. On the other hand, metal sulfide (CdS, ZnS, CdZnS, SnS_2) photocatalysts have suitable band gaps (2.3-3.2) and valence and conduction band levels to harvest the visible light region of the solar spectrum. In this way, they have the advantage of possessing greater efficiency of H_2 by splitting water as compared to metal oxides (TiO_2). Due to their low oxidation ability, sacrificial electron donors (SO_3^{-2}) as an oxidation reaction for photocatalytic H_2 production were used [4,5]. Amongst metal sulfides SnS_2 has an optimum band gap value of 2.3 eV. Because of this, it has a high potential to have a high H_2 production efficiency. [6,7,8] In the literature, there is a limited number of research on the SnS_2 photocatalyst. The research has done in this paper to fill this gap.

Within the scope of this study, it is aimed to synthesize SnS_2 photocatalyst to produce H_2 with high efficiency by splitting water via solar energy. SnS_2 will be synthesized by the thermal sulfurization method since it is simple and affordable to synthesize SnS_2.

EXPERIMENTAL

Synthesis of tin disulfide (SnS_2)

Tin disulfide (SnS_2) powder has been synthesized from tin oxide (SnO_2) nano-powders (≤100nm average particle size obtained from sigma Aldrich) by sulfurization using 99.9% pure sulphur powder in a Protherm hot-wall tube furnace at 500°C.

As indicated in Fig. 1, 100 mg of SnO_2 powder was put in an alumina crucible and placed in the center of the heating zone at 500 °C, while the crucible containing elemental sulphur was placed outside of the heating zone at a temperature between 180-200 °C. The system was flashed with argon gas for 40 minutes before the furnace was heated. The furnace reached 500 °C by heating at a rate of 10 °C/min and was kept constant at this temperature for 24 hours under

the flow of Ar gas. The rate of Ar gas flow was set to 0.15 liters per hour. At the end of 24 hours, the furnace was switched off and the powder was left to cool in the furnace to room temperature.

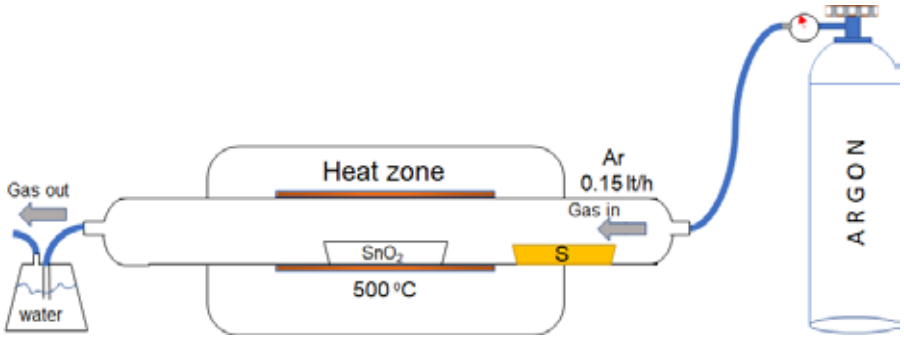

Fig. 1. Schematic representation of a tube furnace for the thermal sulfurizing of SnO_2 powder at 500°C for 24 hours.

Characterisation of Powders

X-ray diffraction measurement technique was used to identify the present phases and crystal structures of produced powder samples using a Bruker D2 Phaser. Scan was performed between $10° \leq 2\theta \leq 90°$ using Cu-Kα radiation of wavelength 1.5406A°.

UV-vis spectrophotometry tests were performed to measure the band gap values of synthesized powders in the wavelength range of 300-900 nm.

RESULTS AND DISCUSSION

An image of pristine SnO_2 and thermally sulfurized powder at 500 °C for 24 hours in an Ar atmosphere can be seen in Fig 2. Due to the yellow color of SnS_2, sulfurization of SnO_2 powder, which is white (Fig 2a), to SnS_2 resulted in a powder with yellow tones (Fig 2b), as expected [9].

An XRD analysis was carried out before and after thermal sulfurization to confirm the formation of the SnS_2 phase. Normalized XRD pattern of SnO_2 and SnS_2 powders given in Fig 3. The diffraction peaks clearly prove the existence of a SnS_2 phase having a hexagonal crystal structure with lattice parameters a= 3,645 b=3,645 c= 11,802 A° (PDF 01-089-2357). The major peaks of SnS_2 were detected at 15.13°, 32.13°, 41.87° 50.05° and 52.5°. These peaks correspond to the (002), (102), (104), (110), and (112) planes of hexagonal structure, respectively. This repeatable (2 times) results indicated that 24 hours thermal sulfurization needed to obtain fully sulfurized SnO_2 powder under Ar flow at 500 °C .

Fig. 2. Photograph SnO_2 powder a) Before sulfurization b) After sulfurization at 500°C for 24 hour

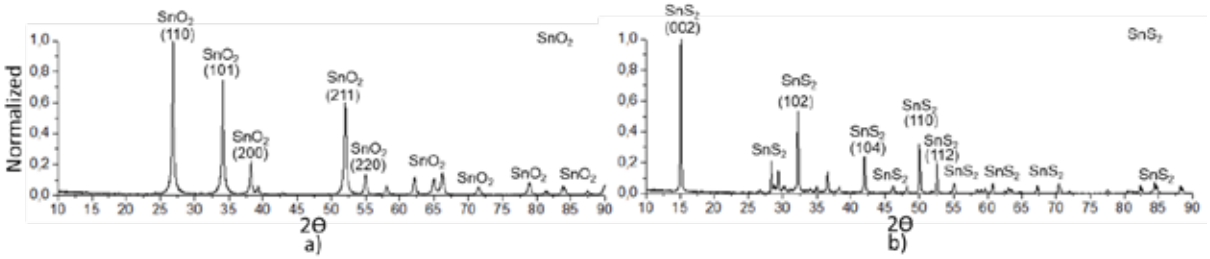

Fig. 3. XRD patterns SnO_2 powder a) Before sulfurization b) After sulfurization at 500°C for 24 hours.

The band gap value (Eg) of the produced SnS_2 powder was determined by measuring the powder spectrum absorption using UV-Vis absorption spectroscopy. In Fig. 4, the UV-Vis reflectance spectra and Tauc plot can be seen. The Eg value of SnS_2 powders was calculated by applying the Kubelka-Munz theory and drawing a Tauc plot to the data obtained from the UV-vis spectrometer measurement [10]. According to the Tauc plot, SnS_2 powder has an indirect band gap of around 2.24 eV, which is within the expected range of earlier reported values in the literature [6–9].

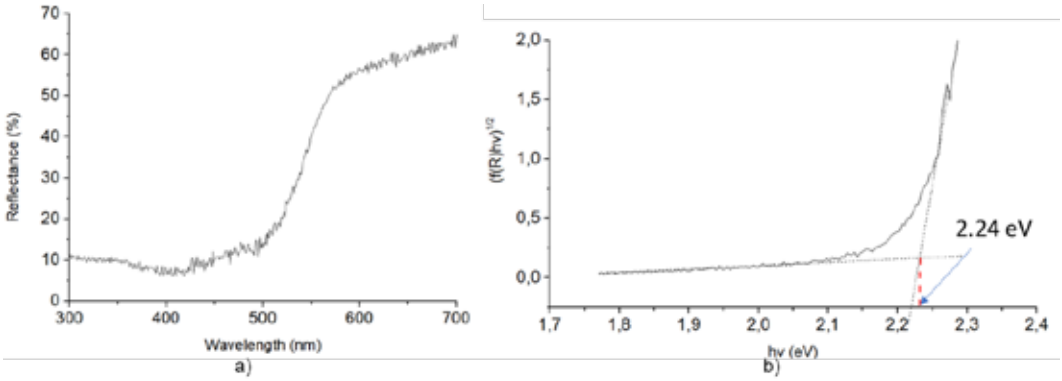

Fig. 4. a) UV-Vis diffuse reflectance spectra of SnS_2 b) Tauc plot for determine the band gap of SnS_2

CONCLUSION

SnS_2 powders were successfully synthesized from SnO_2 powders in a tube furnace at 500 ^oC for 24 hours under the Ar atmosphere, and fully sulfurized SnS_2 phases were confirmed via XRD analysis. The band gap value of the produced powders was determined as 2.24 eV of indirect band gap. With 2.24 eV band gap, SnS_2 is considered to be an ideal choice for photocatalytic water splitting amongst the metal sulfides. The characterization of the photoelectrochemical behaviour of SnS_2 and the measurement of H_2 gas production efficiency by splitting water with the presence of a sacrificial agent such as SO_3^{-2} will be carried out in the future.

ABSTRACT

The Iodine–Sulfur (IS) thermochemical water-splitting cycle is regarded as one of the most promising hydrogen production methods with the advantages of high efficiency, low cost and zero carbon emissions. Several research institutions have done extensive studies in this field. The CEU initiated the IS research in 2004 and constructed a pilot-scale facility made of industrial structural materials with the design rate of 5 m^3/h in 2019. In this paper, the pilot-scale facility is briefly introduced, and the results of preliminary continuous test is shown.

Keywords: Thermochemical hydrogen production, Iodine sulfur cycle, Pilot-scale facility

INTRODUCTION

Hydrogen, as a clean and environmentally-friendly energy carrier, has attracted worldwide attention. Comparing all types of hydrogen production methods, the Iodine–Sulfur (IS) thermochemical water-splitting cycle is the most promising one. Since 1980s, several research institutions, such as the General Atomics Corp (GA), Italian National Agency for New Technologies (ENEA), Japan Atomic Energy Agency (JAEA) and Institute of Nuclear and New Energy Technology of Tsinghua University (INET) et al., had attempted to construct and operate the IS system [1-4]. The State Key Laboratory of Clean Energy Utilization (CEU) of Zhejiang University in China initiated the IS research in 2004. Then a bench-scale facility using glass with hydrogen production rate of 50 L/h was built in 2015. After that, a pilot-scale facility made of industrial structural materials with the design rate of 5 m^3/h (IS-5m^3 system) was built in 2019. A preliminary continuous experiment was carried out in September of 2021.

SYSTEM DESCRIPTION

The IS-5m^3 system includes three sections: Bunsen reaction section, HI decomposition section and H_2SO_4 decomposition section. After a series of anti-corrosion experiments, TC4 was chosen for Bunsen reaction section and HI decomposition section, while Hastelloy C276 and SiC were chosen for H_2SO_4 decomposition section. The photographic images of the whole system, the HI decomposer and H_2SO_4 decomposer are shown in Fig. 1.

Fig. 1. The photographic images of the whole system, the HI decomposer and H_2SO_4 decomposer

RESULTS AND DISCUSSION

In September of 2021, the continuous test of the closed IS cycle was carried out. The initial molar ratio of H_2SO_4:HI:I_2:H_2O was set to be 1:2:2:12. The test lasted for about 4 hours with the hydrogen production rate of 80 L/h and the oxygen yield of 40 L/h, as shown in Fig. 2.

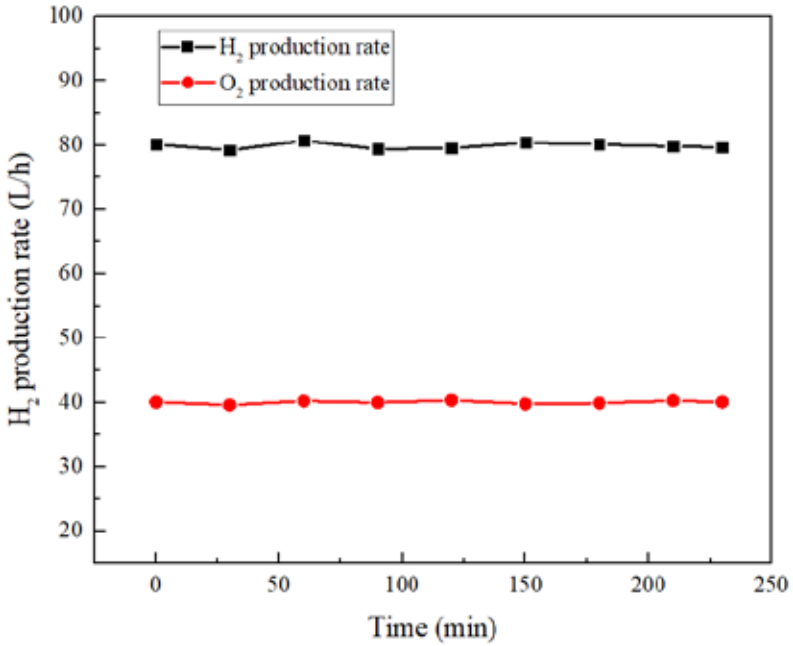

Fig. 2. The hydrogen and oxygen production rate of continuous test

CONCLUSIONS

The continuous test verifies the feasibility of the IS process and the stability of major industrial structural materials. A further modification on this system is now underway. Higher hydrogen gas yield and longer operation time are expected to happen soon.

ABSTRACT

Photocatalytic reforming of biomass-sourced molecules is a promising method for green hydrogen production from solar energy. Current photocatalysts cannot use the entire solar spectrum efficiently, and an alternative approach is to couple photovoltaics with LED technology to convert the highest solar spectrum fraction into a monochromatic light. Such a process has yet to be energetically optimized to be competitive with conventional heliophotocatalytic processes, and numerous parameters can be tuned such as LED current intensity, carbohydrate concentration, temperature, or catalyst amount. In this study, it has been shown that these parameters significantly affect the hydrogen production rate, and their optimization is necessary to maximize energy-to-hydrogen efficiency and so the hydrogen production cost. It was however observed, using the H2A tool, that the optimum of energy efficiency is not necessary the optimum of hydrogen production cost and a careful cost analysis should be carried out to design the best industrial operating point.

Keywords: Photocatalysis, Reforming, TiO_2, Woven optical fiber

INTRODUCTION

The development of new technologies to make renewable intermittent energy available and affordable is necessary to face global warming. Photocatalysis is a promising method to convert solar energy into solar fuels such as hydrogen [1] (Figure 1.a). The main challenge is to find a photocatalyst able to use efficiently the entire solar spectrum, which is still at the research stage. But even in that case, this technology would be in direct competition with photovoltaics. An alternative approach is to take assets of both these methods, by coupling them using an efficient and fast-growing technology, LEDs (Figure 1.b). This innovative concept has however to be cleverly engineered to maximize the hydrogen yields and costs and make it competitive with conventional heliophotocatalytic or electrocatalytic processes.

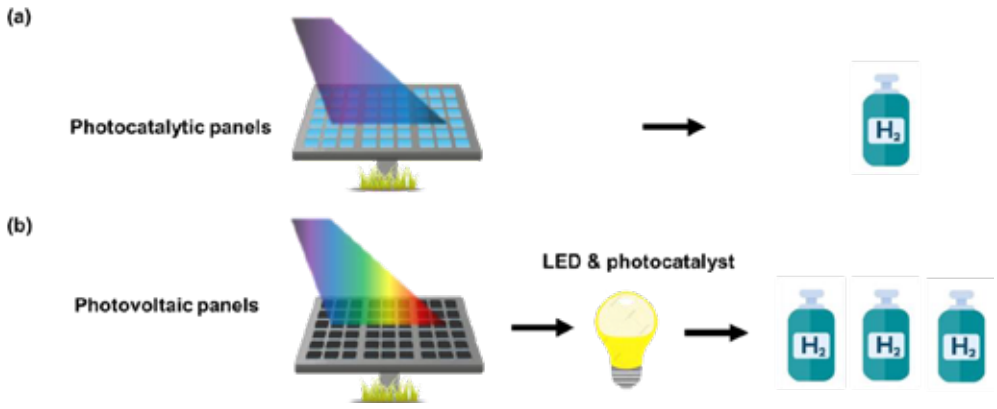

Fig. 1. Conventional heliophotocatalysis (a) against photovoltaic-coupled photocatalytis (b) for solar fuels production

H2TEX project aims at developing an optimized photoreactor for carbohydrate reforming, using LED-powered UVTEX® photocatalytic textiles from BrochierTechnologies [2], [3]. This technology has the advantage to maximize the contact between light, catalyst, and reagents, but also to minimize the photoreactor land occupation since textiles can be superimposed in the reactor to operate in three dimensions.

While some studies have characterized the effect of different operating parameters on H_2 production rate via carbohydrate photoreforming [4]–[8], no quantitative link between them and the overall efficiency & cost of the process have been established. This step is yet mandatory to evaluate the potential of this technology compared to other hydrogen production methods, but also to determine on which part of the process research should focus on [9]–[11].This study quantifies experimentally the effect of several operating factor that can be tuned to maximize the

H2TEX process efficiency, and evaluate their impact on the final hydrogen price considering feedstock expenditures, OPEX and CAPEX evolutions.

MATERIALS AND METHODS

Photocatalytic data have been recorded using a semi-batch photoreactor containing 200 mL of a glycerol/water solution, with various volume ratio from 1 to 50%vol. The reactor temperature was varied between 10 and 45°C using thermostated water recirculating in a double wall. UVTEX® textiles (Figure 2) were coated with a commercial P-25 TiO_2 catalyst using dip coating and spraying methods, on which a platinum based cocatalyst is photodeposited. A LEDENGINE UVA LED operating between 100 and 900mA was used as a light source. Technico-economic analysis has been carried out using the H2A tool v3.2018, considering a daily H_2 production of 50 000kg and feedstocks & energy prices from 2016.

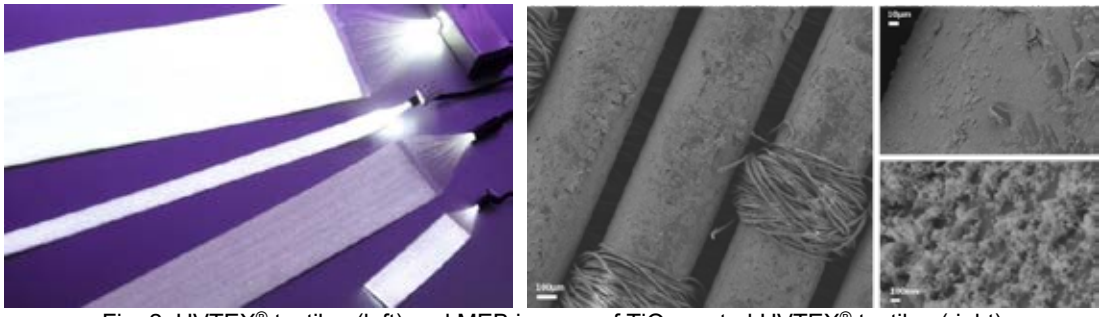

Fig. 2. UVTEX® textiles (left) and MEB images of TiO_2 coated UVTEX® textiles (right)

RESULTS AND DISCUSSION

As reported for different carbohydrates [4], [8], glycerol concentration has a positive effect on H_2 production rate which follows a Langmuir-Hinshelwood profile. Since energy consumption (*i.e.,* renewable electricity) accounts for more than half of the hydrogen cost with the reference case (Figure 3a), the increase of glycerol concentration decreases significantly the H_2 production cost by improving the process efficiency.

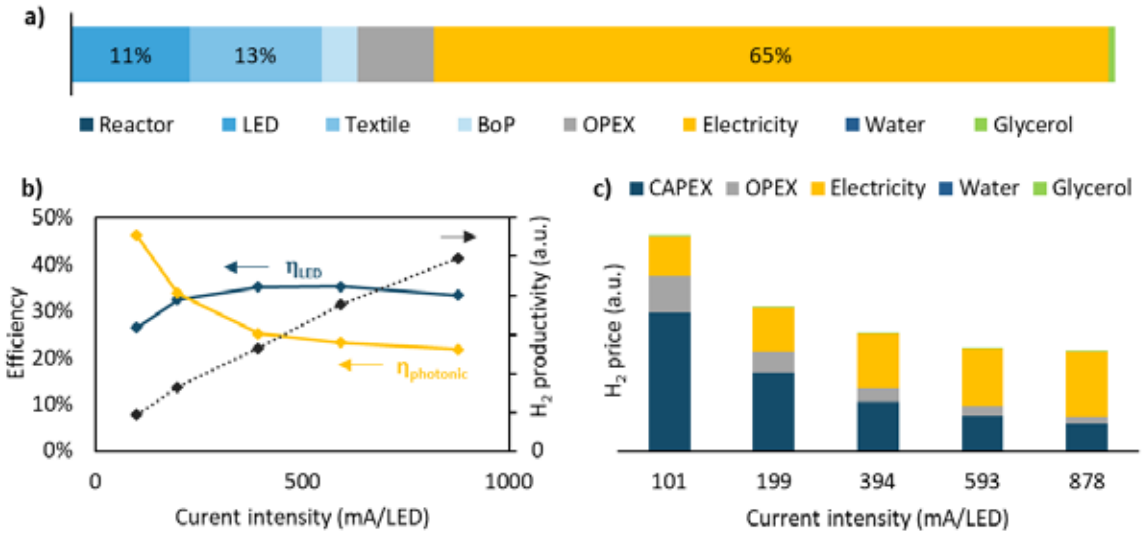

Fig. 3. (a) Hydrogen cost structure, effect of current intensity on (b) LED efficiency, photonic yield, H_2 productivity and (c) cost

The effect of catalyst loading and temperature are also in line with literature [4], [5], [12] since these two parameters can be well described using Beer-Lambert and Arrhenius laws respectively. Considering the relatively low amount of catalyst involved in the photocatalytic textile and assuming that heat is recovered from LED cooling, the energy consumption is globally reduced when increasing catalyst mass and temperature, and so is the cost.

The most interesting result concerns the light intensity effect: its increase induces an increase of the H_2 production rate, but not in a perfectly linear manner as illustrated on Figure 3b. The increase starts to slow down at high intensities, which traduces lower electric to hydrogen yields. This is first linked to the LED efficiency, that diminishes

slightly at high current intensities due to the Shockley behavior [13], but mostly because electrons/holes recombinations are accelerated at high intensities [14]. Yet, H2A analysis shows that despite an increase of the electricity consumption, higher current does not significantly impact the hydrogen production cost: CAPEX is also reduced in the same time due to a higher rate of amortization (Figure 3c). Thus, the optimum of efficiency does not necessary correspond to the optimum of cost, and a carreful price analysis should be performed to evaluate a photocatalytic process viability or its optimum operational point.

CONCLUSIONS

LED-powered photocatalytic reforming is a promising route for hydrogen production since the process efficiency can be significantly increased by optimizing catalytic parameters such as photocatalyst loading, temperature, light intensity or reagents concentration. This optimization can significantly reduce the H_2 production cost since renewable electricity accounts for more than half of the total cost in most of cases. Yet, it should be noted that the optimum of cost is not necessary the optimum of efficiency: an optimum between H_2 production rate and efficiency should be determined to minimize the overall hydrogen production cost, which is today the main obstacle to its deployment.

ABSTRACT

Steam reforming of methanol (SRM) is a chemical reaction in which methanol and water vapor are decomposed through a catalyst, thereby producing gas rich in hydrogen and other substances. The $CuO/ZnO/Al_2O_3$ catalysts have been synthesized, X-ray diffractometer (XRD) and temperature programmed reduction (TPR) (<200°C) have been used to characterize reduction property and catalyst structure. The catalyst was filled into the packed reactor, and the gas composition after the SRM reaction was analyzed by a gas chromatograph (GC-TCD) (WHSV=10 h^{-1}). The research shows that the catalyst activity of $CuO/ZnO/Sm_2O_3/CeO_2$ and $CuO/ZnO/Gd_2O_3/CeO_2$ promoters modified Cu-Zn catalysts have been improved, with conditions as the T_{95} is at 250°C, and the value of Y_{H2} is close to 3.0. Compared with promoter doped $CuO/ZnO/Al_2O_3$ catalyst, bare Cu-Zn catalyst (T_{95}: 240°C, Y_{H2} < 2.7) have been considered as limited efficacy of SRM reaction. In this study, the hydrogen production from SRM reaction have been applied in self-made U-shaped tube filled reactor (filled with 2.5 g of catalyst) combined with fuel cells, which can produce 20W of electricity successfully.

Keywords: Copper-Zinc catalyst, SRM, Samarium, Gadolinium, Hydrogen.

INTRODUCTION

In order for the SRM reaction to produce hydrogen-rich gas (HRG), the quality of the catalyst is the primary key. In the literature, $CuO/ZnO/Al_2O_3$ catalysts are mostly used for steam reforming of methanol (SRM) reaction. Methanol is liquid form at normal temperature and pressure, it is easy to store and transport, and has low sulfur content (< 5 ppm), which is not easy to poison the catalyst. The methanol steam reforming reaction uses methanol decomposition to generate CO, and then reacts with water vapor and CO to obtain CO_2 and H_2. In this experiment, different promoters (Promoter): samarium (Sm) and gadolinium (Gd) are added to the base of copper, zinc, and aluminum to modify the catalyst, which is expected to reduce reaction temperature (T_{95}) (conversion rate > 95%), reducing carbon monoxide (CO) concentration in the product, and increasing hydrogen yield (F_{H2}). Moreover, the reaction temperature (200 - 350 °C) of SRM is similar to the proton exchange membrane fuel cell (PEMFC) (80 - 120 °C), and the generated hydrogen can be directly supplied to the PEMFC without additional heating. Therefore, SRM is often regarded as the liquid fuel of PFEMC hydrogen source [1,2]. The difference between the $CuO/ZnO/Al_2O_3$ catalyst and these catalysts with promoters is the adsorption capacity of methanol. In this study, copper-zinc catalysts with high activity and high durability were prepared by adding different co-activators, the influence on the catalytic activity was discussed as well [3,4]. Among of them, the precious metal additions have been considered as an outstanding method to improve the SRM [5]. Moreover, the economic value of CuO/ZnO SRM system have been attracted scientists' attentions, base on the design of multi-tubular reactor [6]. Finally, the best experimental conditions were found, and the recombines were made from them.

MATERIALS AND METHODS

Co-precipitation (CP) and homogeneous precipitation (HP) preparation process of catalyst precursor is as follows; take 1000 mL of deionized water (DI water), and add appropriate amount of $Cu(NO_3)_2$. Nitrate precursors such as $2.5H_2O$, $Zn(NO_3)_2.6H_2O$, $Al(NO_3)_3.9H_2O$, etc., are stirred to dissolve and uniformly dispersed in the solution. (1) Co-precipitation process: dropwise with 0.5N sodium carbonate aqueous solution, control its pH value between 7-8 and continue stirring for 2 hours, and maintain the temperature at 70°C. (2) Homogeneous-precipitation process: Add urea aqueous solution, start to heat up to 90°C, and maintain at 90°C, so that the pH value rises to 7-8. After 2 hours, the fully stirred aqueous solution was filtered to remove the precipitate, and then the precipitate was washed with DI water to ensure no chlorine residue. The precipitate was dried in an oven at 70°C, taken out and ground into fine powder. Then calcined at 400°C for 4 h. Heating rate: 3°C/min.

RESULTS AND DISCUSSION

Figure 1(a) shows the TPR spectra of CP and HP-XM catalysts, which can have demonstrated the Cu^{2+} - Cu^0 reduction temperature (Tr) of calcinated catalysts. It can be seen that the lye concentration is postive with the Tr of HP-catalyst, which is explaining the tends of HP-0.5M (Tr = 210°C) and HP-3M (Tr = 222°C). However, HP-1M have showed some plus signal in TPR spectra. Compared with HP and CP catalysts, the reduction temperature of HP is slightly lower, and the reducibility of the catalyst: HP-0.5M > HP-1.5M = CP > HP-2M > HP-1M > HP-2.5 M > HP-3M.

Figure 1(b)shows the XRD patterns of CP and HP-XM catalysts. The effects of different lye concentrations and different methods on catalyst particles are discussed. The main peak pf copper oxide and zinc oxide have demonstrated at 38.8°, which was used as the benchmark to compare the size of copper particles. Among four samples, it can be found that the characteristic front of HP-0.5M copper is broadened, which described the tend of size decreasing of Cu nanoparticles.

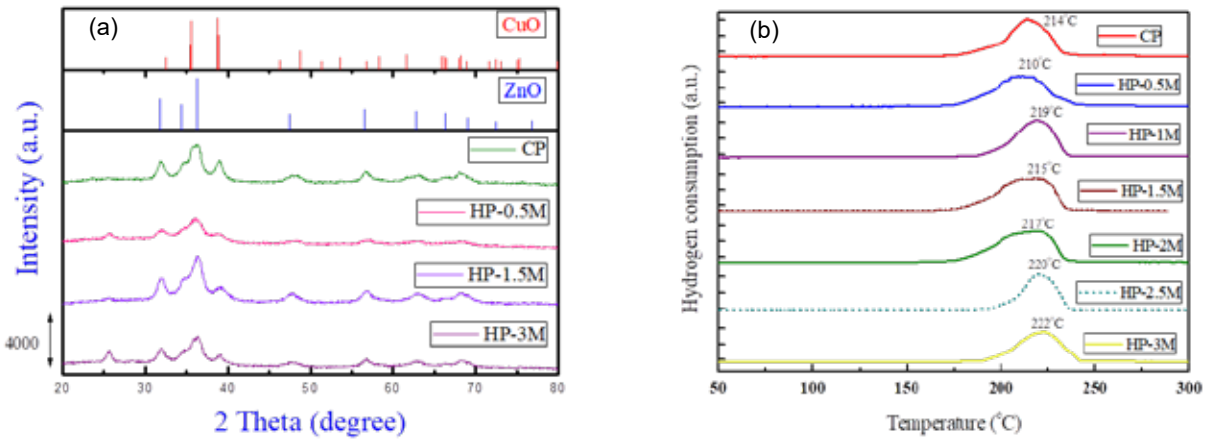

Figure 1 (a) XRD patterns and (b) TPR spectra of catalysts prepared by HP and CP methods.

In this study, the Sm_2O_3, CeO_2 and Gd_2O_3 have been indicated as promoters of copper-zinc catalyst. The electron orbitals of Sm and Gd are [Xe]6s24f6 and [Xe]4f75d16s2, respectively, it is easy to grab an electron with other elements. The reduction temperature has been depended on the type of metal oxide and the force between the metal and the support. Therefore, the effect of the support force on the reduction properties of CuO was obtained by TPR analysis. Figure 2 (a) shows the TPR spectrum of Cu/RE-Zn catalyst, the higher reduction temperature of CuZnAlSm and CuZnAlGd (227°C) than CuZnAl catalyst (210°C). However, CuZnGdCe and CuZnSmCe showed shifted tends than CuZnAl, which was below 200°C. Figure 2(b) XRD pattern of Cu/RE-Zn catalyst. After the two promoters of Sm and Gd are added, the specific peaks of CuZnAl catalyst can hardly observe the characteristic peaks, and only a very broad peak can be seen when 2 Theta = 30° - 40°.

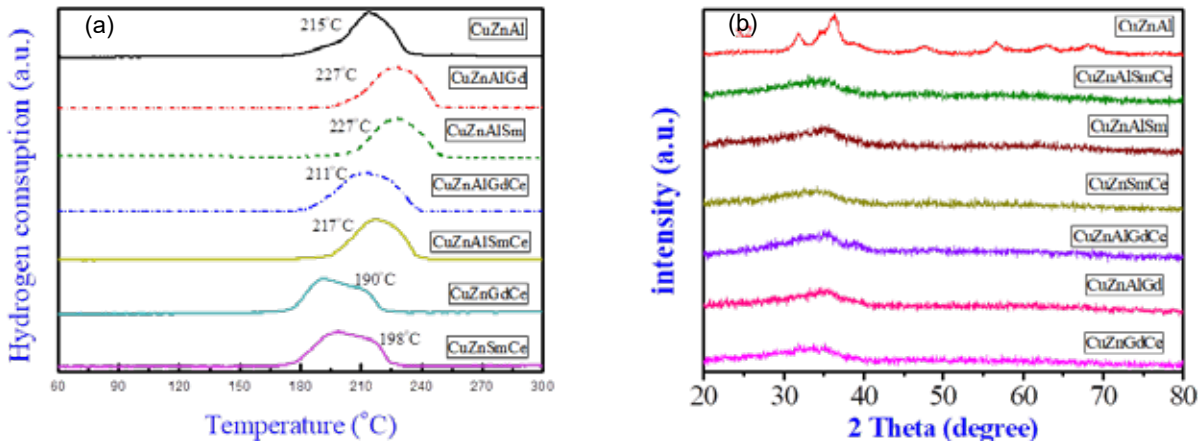

Figure 2 (a) TPR spectra and (b) XRD patterns of CuZnAl with Gd/Sm/Ce catalysts.

Figure 3(a) is the activity test of Cu/RE-Zn catalyst, the most important test data of activity test. First, take 0.5 g of catalyst and place it in a quartz tube with an inner diameter of 4 mm, and feed water and alcohol (S/C=1.1). In the SPM reaction, flow rate was WHSV = 10 h^{-1}, and no carrier gas was added, the reaction temperature range was 180 - 270°C, and the test was performed every 3 °C. Figure 3(b) is a graph showing the comparison between methanol conversion and hydrogen yield. The two catalysts, CuZnGdCe and CuZnSmCe, have the best reactivity, and the conversion rate of methanol is more than 90% at 240°C. Based on this, the addition of the promoter has an increasing effect on the hydrogen yield, illustrating the potential for application in fuel cells. Therefore, the order of reactivity is CuZnGdCe = CuZnSmCe > CuZnGdAl > CuZnSmAl > CuZnAlCeSm > CuZnAlCeGd.

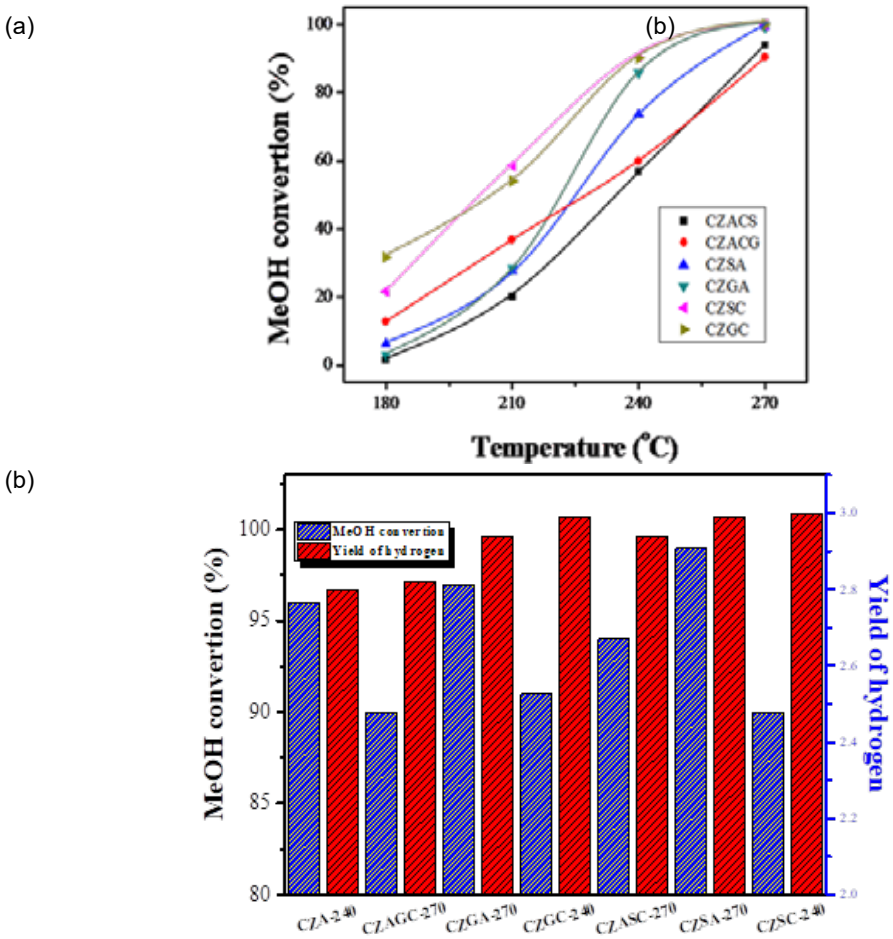

Figure 3 (a) Activity test and (b) methanol conversion and hydrogen yield of CuZnAl with Gd/Sm/Ce catalysts.

CONCLUSIONS

In this research, different preparation methods and the promoter additions have been used to modify the catalyst, the influence of modification on the reaction performance of the catalyst was studied. The catalyst was filled into the self-made reactor to carry out the system combined with the fuel cell. Compared with the traditional CP method, the catalyst prepared by the HP method has smaller catalyst particles and better uniformity. When the concentration of urea is 1.5M, it has performed the best reactivity in this study. It can be seen from the XRD results that the addition of Gd_2O_3 and Sm_2O_3 can increase the dispersion of copper-zinc catalysts, because it is known from the spectrum that in addition to a wide peak in the middle of 2 theta = 30° - 40°, other Cu, Zn, and rare earths The special micro-peaks of the metal could not be found at all, which was an amorphous state. In this experiment, the methanol vapor reformer is combined with the fuel cell system. It is found that the performance of the reactor is determined by the heat transfer efficiency. The heat transfer performance is good, in addition to making the catalyst play its role, it can more effectively produce 24W of electricity.

ABSTRACT

Methanol aqueous-phase reforming (APR) is a simpler and more energy-efficient process compared to traditional gas-phase reforming. Methanol APR is considered to be a potential technology for providing *in-situ* hydrogen (H_2) production, mainly for H_2-powered fuel cell technology. The performance evaluation of a Pt/Al_2O_3 catalyst in methanol APR under various operating conditions is reported. Studies were conducted at various temperatures, pressures, methanol concentrations, and residence times to evaluate APR performance. An increase in methanol conversion was observed with increased operating temperature and decreased system pressure. It was also noted that higher methanol concentration in the feed had an adverse effect on APR performance.

Keywords: Aqueous-phase reforming, Methanol, Hydrogen production, Catalyst, Pt/Al_2O_3

INTRODUCTION

As the world tackles the challenges of global warming, energy decarbonization, and CO_2 emission caused mainly due to the usage of fossil fuels, H_2 has emerged as a promising energy vector [1]. However, an inexpensive infrastructure for H_2 storage and transportation is yet to emerge [2]. Therefore, *in-situ* H_2 production from renewable resources (*e.g.* alcohols) is an economical and efficient perspective to overcome the aforementioned challenges. Among other alcohols, methanol can be considered the most advantageous H_2 carrier with the highest H/C ratio and in the liquid state at room temperature [3]. Apart from widely accepted methanol steam-reforming (MSR) [4], methanol APR is an emerging competitive approach for H_2 production [5]. Methanol APR provides multiple advantages, namely elimination of vaporization of methanol solution, single-step process, and minimized carbon monoxide formation from water-gas shift (WGS) reaction compared to MSR. APR can produce H_2 and CO_2 at temperatures between 200 °C - 250 °C and in the pressure range of 1.5 MPa - 5.0 MPa [6]. However, reforming and WGS reactions are kinetically favored by higher temperatures. Methanation side reaction is also thermodynamically favored in methanol APR operating conditions. Additionally, system pressure plays a vital role in APR performance since APR is a multi-phase system with reaction kinetics often controlled by the diffusion of products through an aqueous phase. Therefore, it becomes necessary to evaluate the effects of operating conditions on methanol APR for optimal performance. The purpose of this study is to further explore methanol APR kinetics characteristics to propel much-needed research on novel catalysts and reactor design. In this work, we report the performance of a Pt/Al_2O_3 catalyst under various operating temperatures, operating pressures, residence times, and feedstock concentrations in methanol APR.

EXPERIMENTAL

An in-house designed set-up was used to evaluate catalyst performance in APR under different operating conditions. A commercial Pt/Al_2O_3 (5 wt. % Pt) catalyst supplied by Sigma-Aldrich was placed in the mid-section of a fixed-bed reactor mixed with equal amounts of glass beads. The reactor was placed vertically in a temperature-controlled oven. The catalyst was reduced *in-situ* at 300°C for 2 h in a flowing H_2/N_2 (1:1) atmosphere. Afterward, the reactor was purged with N_2 gas (50 mL·min^{-1}) for 30 min to remove the adsorbed H_2. Aqueous methanol solutions, with concentrations of 5 wt. % and 55 wt. % of methanol was fed to the reactor in an upwards direction by an HPLC pump, with weight hourly space velocity (WHSV) between 0.1 h^{-1} - 21.2 h^{-1}. All these experiments were performed with N_2 co-feeding of 30 mL·min^{-1}. The outlet stream from the reactor was cooled down in a condenser at *ca.* 0°C to separate liquid-phase effluents and gaseous products. The formed gaseous products were measured with online gas chromatography. A back pressure regulator was used to regulate the operating pressure of the reforming reaction. The catalytic performance in methanol APR under various operating conditions was evaluated in terms of methanol conversion (%) as shown in Eq. (1). Herein, n denotes the number of moles, M_{in} is the inlet methanol stream, and M_{out} is the outlet methanol stream.

Methanol conversion (%) = 100 x ($n\,M_{in} - n\,M_{out}$) / $n\,M_{out}$ (1)

RESULT AND DISCUSSION

Effect of temperature

Fig.1 shows the methanol conversion as a function of WHSV at temperatures of 190°C, 210°C, and 230°C with an operating pressure of 3.2 MPa and 6.0 MPa for (a) 5 wt. % and (b) 55 wt. % methanol solution respectively. 6.0 MPa operating pressure was applied to keep 55 wt. % methanol solution in the liquid phase.

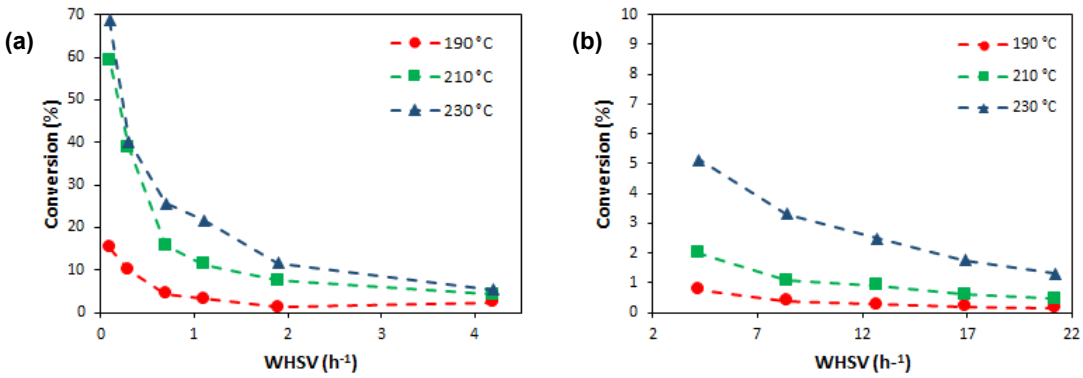

Fig. 1. Methanol conversion vs residence time in APR for (a) 5 wt. % and (b) 55 wt. % methanol aqueous solution at operating temperatures of 190°C, 210°C, and 230°C. Operating pressure of (a) 3.2 MPa and (b) 6.0 MPa, and 5 wt. % Pt/Al_2O_3.

As Fig. 1 depicts, an increase in methanol conversion was observed with increasing temperature and decreasing WHSV. However, methanol conversion did not increase significantly when using high methanol concentration (55 wt. % of methanol). With increased methanol concentration and WHSV, the contact time between reactants and catalyst decreased, which adversely affected methanol conversion [7]. For lower operating temperatures, the reforming reactions are inhibited and catalyst deactivation due to carbon depositions becomes a possibility [8].

Effect of pressure

Fig.2 shows the effects of operating pressure on methanol conversion at an operating temperature of 230°C. For 5 wt. % methanol APR, the inhibited reforming reactions at higher operating pressure can be caused by the high partial pressures of the products and unavailability of active sites (caused by high H_2 concentration on catalyst surface) [6], [9]. The catalyst was more sensitive to changes in system pressure near the bubble point pressure, as the conversion stays nearly constant beyond 4.0 MPa. The effect of operating pressure was negligible on the conversion when using high methanol concentration (55 wt. %). Even methanol reforming performed below the bubble point pressure (gaseous phase) did not yield conversions higher than methanol APR (Fig.2). This is indicative that reforming reactions are affected more by feed concentration than operating pressure.

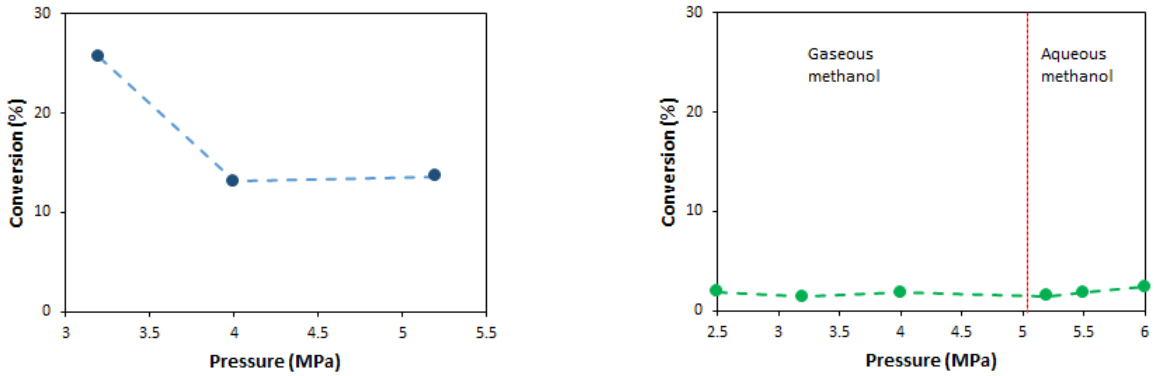

Fig. 2 Methanol conversion as a function of pressure for (a) 5 wt. % and (b) 55 wt.% methanol aqueous solution. Operating temperature of 230°C, residence time of (a) 0.7 (h^{-1}) and (b) 12.7 (h^{-1}), and 5 wt. % Pt/Al_2O_3.

CONCLUSIONS

Kinetic characterizations were performed for methanol APR over Pt/Al_2O_3 catalyst using two different feedstock concentrations at various temperatures, pressures, and residence times. Methanol conversion increased with increasing temperature and decreasing operating pressure for methanol (5 wt. %) APR. However, these effects were not prominent for 55 wt. % methanol APR. At all operating temperatures and pressures for this concentration, the highest conversion achieved was 6 %, indicating that APR performance was inhibited by high methanol concentration. For decreasing residence times, reforming reactions were inhibited for both methanol concentrations.

Ni-BASED CATALYSTS FOR CO_2 REFORMING OF GLYCEROL TO H_2

Ozge Selcuk, Ahmet K. Avci
Department of Chemical Engineering, Bogazici University, Bebek 34342, Istanbul, Turkey

*Corresponding author e-mail: avciahme@boun.edu.tr

ABSTRACT

Dry reforming of glycerol is a recently emerging pathway for making H_2. The route is promising due to the consumption of glycerol, a side product of biodiesel synthesis, with CO_2, a major greenhouse gas. This study aims to develop Ni-based catalysts for providing insight into the role of support material on activity towards glycerol dry reforming. In this respect, Ni/La_2O_3, Ni/ZrO_2 and Ni/La_2O_3-ZrO_2, all loaded with 5% Ni by mass, are synthesized. The catalysts are tested at 750°C, molar inlet CO_2-to-glycerol ratio (CO_2/G) between 1-5 and residence time of 0.25 mg min NmL^{-1}. The results clearly showed that Ni/La_2O_3-ZrO_2 was more active than the single-oxide supported counterparts. The catalyst showed superior durability with only 12% loss in CO_2 conversion after the 72-h time-on-stream stability test. On the other hand, Ni/ZrO_2 and Ni/La_2O_3 were completely deactivated at the 47th and 63rd h of the stability tests, respectively. Superior activity and stability of the Ni/La_2O_3-ZrO_2 is attributed to the fine dispersion of the Ni nanoparticles and durability against coke deposition.

Keywords: Catalyst, CO_2, Glycerol, Hydrogen, Reforming

INTRODUCTION

Biodiesel is conventionally synthesized by the trans-esterification of animal-based or vegetable oils in the presence of methanol or ethanol, yielding glycerol as a side product which typically accounts ~10% by mass of the resulting mixture. This fraction, however, causes a notable surplus of glycerol when the scale of biodiesel production is considered. Unless valorized into useful products, surplus glycerol will elevate the cost of biodiesel synthesis. Among several options of valorization, catalytic transformation of glycerol to hydrogen (H_2) receives increasing interest. This transformation is carried out typically by reforming glycerol with steam. However, recently, replacing steam with CO_2 is considered with the motivation of making H_2 through a carbon-negative path, *i.e.,* by consuming CO_2 (*i.e.,* a greenhouse gas) and glycerol (*i.e.* waste of biodiesel synthesis).

$$C_3H_8O_3 + CO_2 \rightleftharpoons 4CO + 3H_2 + H_2O \qquad \Delta H° = 292 \text{ kJ/mol} \qquad (1)$$

The overall Reaction (1) can be considered as the combination of glycerol decomposition (2) and the reverse water–gas shift (RWGS, (3)):

$$C_3H_8O_3 \rightarrow 3CO + 4H_2 \qquad \Delta H° = 251 \text{ kJ/mol} \qquad (2)$$

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \qquad \Delta H° = 41 \text{ kJ/mol} \qquad (3)$$

Despite its reformate H_2-content is less than that obtained from the steam reforming route, glycerol dry reforming (GDR) is receiving increasing interest in the recent years, with the Ni–based catalysts being the most studied ones [1]. It is commonly reported that the performance of the Ni-based catalysts is dictated by the support material [1]. While some of them showed promising activities, quantified by glycerol conversion to gaseous products, Ni-based catalysts generally deactivated rapidly primarily due to coking and/or sintering of the active species [1]. Recently, Ni supported by Al_2O_3-ZrO_2-TiO_2, a ternary oxide, is reported to deliver CO_2 and glycerol conversions close to the pertinent thermodynamic limits and superior stability [2]. In an effort to provide further insight into the roles of the support, the present study aims enriching the expanding GDR literature by screening of numerous single and binary metal oxide supported Ni catalysts for their activities quantified both by CO_2 and glycerol conversions.

MATERIALS AND METHODS

Catalyst Synthesis

Research grades (purity: >99.99%) of La_2O_3 (Sigma-Aldrich), ZrO_2 (Alfa-Aesar) and La_2O_3-ZrO_2 (Daiichi Kigenso Kagaku Kogyo) were used as the support materials. All the catalysts used in this study were prepared by incipient wetness impregnation of the aqueous solution of $Ni(NO_3)_2.6H_2O$ (Sigma-Aldrich) onto the pertinent porous support as described in detail elsewhere [2]. Nominal value of the Ni loading is fixed to 5% by weight in all catalysts.

Catalytic performance experiments

The experiments were conducted in a down-flow quartz tubular packed bed reactor placed inside a three-zone furnace. Catalyst bed consists of 10 mg catalyst supported by a quartz wool plug. Flow of liquid glycerol was set to deliver 4 NmL min^{-1} of glycerol. Inlet flow of CO_2 was determined based on CO_2/G and the balance gas N_2 flow rate was set according to the feed ratio to obtain a constant total flow rate of 40 NmL min^{-1}. Liquid effluents were retained inside cold traps before online gas chromatograph (GC) units. Two GC units were used to detect products and determine their compositions. Further details of reactant dosing, flow reaction and product analysis systems can be found in [3].

Catalytic experiments were carried out at 750 °C, CO_2/G=1-5 and residence time=0.25 mg_{cat} min NmL^{-1}. Duration of the catalytic activity tests was fixed at 5 h. The first data was taken 30 min. after the start of experiment, then the rest were taken every following 45 min. Catalytic activity was quantified by CO_2 conversion (X_{CO2}) and glycerol conversion to gaseous products (X_G) calculated using Eqs. 4 and 5, respectively:

$$X_{CO_2}(\%) = \frac{F_{CO_2,in} - F_{CO_2}}{F_{CO_2,in}} \times 100 \quad (4)$$

$$X_G(\%) = \frac{2F_{H_2} + 4F_{CH_4} + 4F_{C_2H_4} + 6F_{C_2H_6}}{8F_{G,in}} \times 100 \quad (5)$$

In Eqs. 4 and 5, $F_{i,in}$ (mol min^{-1}) is the molar flow rate of species i fed, F_i (mol min^{-1}) is the molar flow rate of i in product stream. Glycerol conversion was calculated *via* elemental H balance, which includes all detectable species containing H-atom in the gas phase. In addition to the catalytic experiments, blank tests involving reactor packing with only inert α-Al_2O_3 and quartz wool were conducted to figure out homogeneous (non-catalytic) reactions.

RESULTS AND DISCUSSION

Thermodynamic Analysis

In order to determine equilibrium conversions of CO_2 and glycerol and yields of products, thermodynamic analysis was carried out by the Gibbs free energy minimization technique at the current operating conditions in CHEMCAD 7.1.4 suite. The results are presented in Table 1 in the form of product yields, CO_2 conversion, and glycerol conversion. No liquid organic products, and solid carbon were predicted in the product stream.

Table 1. Product yields (moles product/moles glycerol fed) and reactant conversions at thermodynamic equilibrium

CO_2/G	Y_{H2}	Y_{CO}	Y_{CH4}	Y_{C2H4}	Y_{C2H6}	X_{CO2} (%)	X_G (%)
1	3.49	3.40	0.03	0	0	43.0	88.6
2	3.17	3.78	0.01	0	0	39.3	80.0
3	2.90	4.07	0.01	0	0	35.7	73.0
4	2.67	4.30	0.01	0	0	32.7	67.1
5	2.48	4.50	0.00	0	0	30.1	100.0

Catalytic Activity Experiments

Two single oxide supported catalysts, Ni/La_2O_3 (Ni/L) and Ni/ZrO_2 (Ni/Z), and binary oxide supported catalyst, Ni/La_2O_3-ZrO_2 (Ni/LZ), are comparatively tested for their CO_2 conversions reported in Fig. 1. The results clearly show that Ni/LZ catalyst is more active than any of the single-oxide supported catalysts in the entire range of operating conditions. It is also observed that CO_2 conversions are the highest between CO_2/G=3-4. The common decrease in catalytic activity at CO_2/G=1, the lowest range of feed ratio, can be attributed to coke formation which is likely to occur due to the lack of CO_2 that acts as a gasifying agent [2]. Moreover, formation of steam, another coke gasifying agent, via RWGS (Reaction 3) is less promoted at CO_2-lean conditions. This pattern is observed predominantly on Ni/L which fails to show any activity at CO_2/G=1. Despite its poor activity at CO_2-lean conditions, the fast increase in CO_2 conversion on Ni/L at CO_2/G >2 can be attributed to the removal of coke species by means of oxygen vacancies provided by La_2O_3. Molecular level evidences of these findings are in the course of being obtained by detailed characterization studies including TGA, SEM imaging and RAMAN spectroscopy.

Glycerol conversion to gaseous products of the screening catalysts, on the other hand, have complex response to the CO_2/G ratio and this behaviour is seen in Figure 1. Blank experiments carried out at CO2/G=1-5 (details not shown here) give glycerol conversions between 49-51%, which is more than half of the catalytic glycerol conversions reported in Figure 1. The same experiments, however, did not show any activity towards CO_2. In this regard, CO_2 conversion is used as a more reliable metric for monitoring catalytic response.

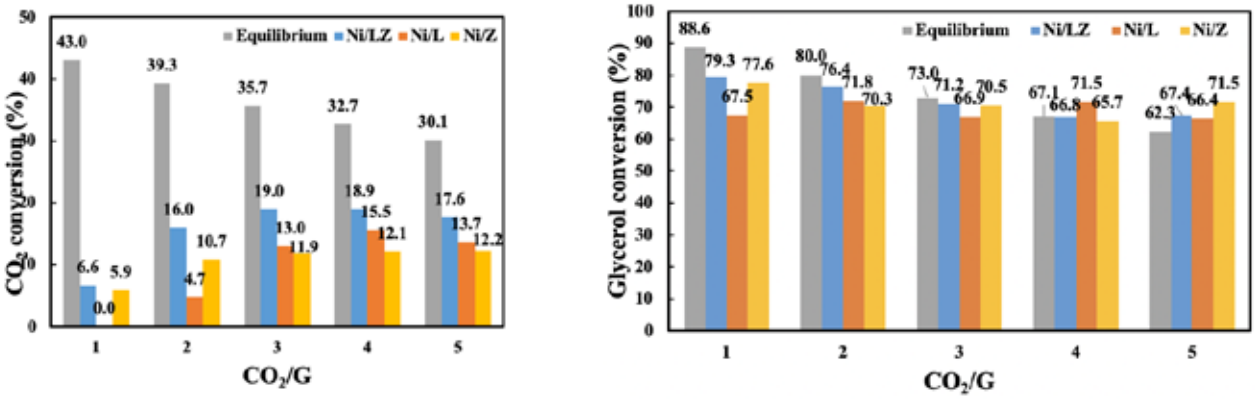

Fig. 1. CO_2 (left) and glycerol (right) conversions obtained on Ni-based catalysts

In addition to activity screening, 72 h time-on-stream experiments are performed at 750°C and CO_2/G=2 for providing insight about stability performance of prepared catalyst. According to findings, Ni/LZ has exceptional behavior with only 12% activity loss. However, Ni/L and Ni/Z are completely deactivated at the end of 47th and 62nd h of the stability experiments. Superior stability of the Ni/LZ catalyst can be associated to the fine dispersion of the Ni nanoparticles and its resistance against coke deposition. These possible mechanisms are currently under investigation by means of molecular level characterization of the catalyst samples before and after the reaction tests.

CONCLUSIONS

The goal of this study was to develop active Ni-based catalysts for GDR. The results clearly showed that Ni/La_2O_3-ZrO_2 was more active than the single-oxide supported counterparts in the complete span of the operating conditions. The catalyst also showed superior durability with only 12% loss in CO_2 conversion after the 72-h time-on-stream stability test. Superior activity and stability of the Ni/La_2O_3-ZrO_2 is attributed to the fine dispersion of the Ni nanoparticles and durability against coke deposition.

ABSTRACT

The chalcostibite electrocatalysts are using towards energy conversion processes including hydrogen evolution reaction (HER) due to its excellent properties as low-cost and high activity. Herein, the ternary chalcostibite copper-antimony sulfides in different shapes and as nanodot (D-$CuSbS_2$) and microrod (R- $CuSbS_2$) were synthesized by hot-injection approach. These chalcostibite materials were firstly investigated on the electrocatalytic HER in alkaline media. Microrod shape of catalyst displayed enhancing catalytic activity of HER in alkaline conditions when compared to spherical shape of catalyst. This result may be explained by efficient charge separation efficiency of 1D materials, which is microrod shape.

Keywords: Electrocatalytic hydrogen evolution, Copper-antimony sulfide,

INTRODUCTION

The demands of sustainable and environmental-friendly energy sources are inevitably increasing because of the growing of population and solding current fuels. Hydrogen is the most promising energy source due to the high energy capacity, unlimited availability, clean and sustainable properties [1]. Recently, the studies of hydrogen evolution reaction (HER) have been showed that water splitting is the most appropriate way to produce hydrogen on a large scale [2]. During the past decades, electrocatalytic hydrogen evolution has been substituted among energy conversion processes including sustainable energy technologies developed with the aim of reducing global energy crisis [3]. So, it has been intensively focused on the discover of electrocatalysts with low cost and high activity for hydrogen production [1]. Despite noble metal-based electrocatalysts (especially platinum-based) have been preferred due to its excellent activity during the HER, these materials could not use because of their structural properties such as high cost and low abundance [2,4-6]. Cu-based Transition metal chalcogenides (TMCs) have been alternatively developed as an alternative to noble-metal electrocatalysts for HER because of its noble-metal-like electronic structures. Thereby, it has been thought that copper sulfides may have suitable for water splitting applications owing to its unique anisotropic structure, rapid electron transfer pathways and small optical band gaps [1,7-10]. Ternary chalcostibite copper-antimony sulfide ($CuSbS_2$ or CAS) which is one of four forms (Cu_3SbS_4, $CuSbS_2$, Cu_3SbS_3, and $Cu_{12}Sb_4S_{13}$) of the ternary copper antimony sulfide (CuxSbySz) system is a copper-based semiconductor multicomponent chalcogenide [11]. Among these phases, the photovoltaic properties of $CuSbS_2$ as a solar absorber has attracted much attention in solar energy conversion and optoelectronic applications due to its appropriate bandgap of 1.5 eV [12,13], hole mobility of 49 $cm^2 (Vs)^{-1}$, a high absorption coefficient $\cong 10^5\ cm^{-1}$ [13-16], tunable hole concentration in a range of 10^{16}-10^{18} cm^{-1} [17-19].Therefore $CuSbS_2$ has been proposed as earth abundant, low toxicity and environmental friendly materials for sustainable and cost-efficient photovoltaics [20-23].

Herein, we have reported that electrocatalytic hydrogen evolution for the first time in alkaline conditions by the different shape of $CuSbS_2$ (nanodot and microrod), which were prepared by a simple hot-injection method as reported previously [24]. It has been determined that the electrocatalytic activities of these $CuSbS_2$ were enhanced by changing shapes. It has been observed 474 mV and 508 mV overpotential values in which are using R-$CuSbS_2$ and D-$CuSbS_2$, respectively, at the current density at 10 mA cm^{-2}. The microrod electrocatalyst exhibited high electrocatalytic activity than its spherical form by efficient charge separation efficiency of R-$CuSbS_2$ which has 1D structure.

MATERIALS AND METHODS

The HER catalysts were dispersed in the ethanol solution. The dispersed solution was added to the glassy carbon electrodes with drop casting method. Prepared electrodes were used for the electrocatalytic HER in the oxygen-free alkaline solution (1.0M KOH). Linear sweep voltammetry (LSV) measurements were performed from 0 to-0.5 V (vs. RHE) with 10 mV/s. Cyclic voltammetry measurements were carried out from -0.3 to -0.2 V (vs. RHE) with different scan rates (10–90 mV/s).

RESULTS AND DISCUSSION

The electrocatalytic HER experiments of copper-antimony sulfides were carried out in the anaerobic 1M KOH solution by using three electrode cells with glassy carbon electrode, Ag/AgCl and Pt as working, reference and counter

electrodes, respectively. The electrocatalytic activities of R-$CuSbS_2$ and D-$CuSbS_2$ were determinated by linear sweep voltammetry (LSV) and cyclic voltammetry (CV) methods. The measured potentials vs. Ag/AgCl were converted to the reversible hydrogen electrode (RHE) scale according to the Nernst equation:

$$E_{RHE} = E_{Ag/AgCl} + 0.059\ pH + E^{o}_{Ag/AgCl}$$

where E_{RHE} is the converted potential vs. RHE, $E^{o}_{Ag/AgCl}$ = 0.1976 at 25°C, and $E_{Ag/AgCl}$ is the experimentally measured potential against Ag/AgCl reference [25]. Catalytic activities of R-$CuSbS_2$ catalysts were also compared to D-$CuSbS_2$. The overpotential values are observed 474 mV and 508 mV in which are using R-$CuSbS_2$ and D-$CuSbS_2$, respectively, at the current density at 10 mA cm^{-2} (Fig 1a). R-$CuSbS_2$ has been displayed the lowest overpotential.

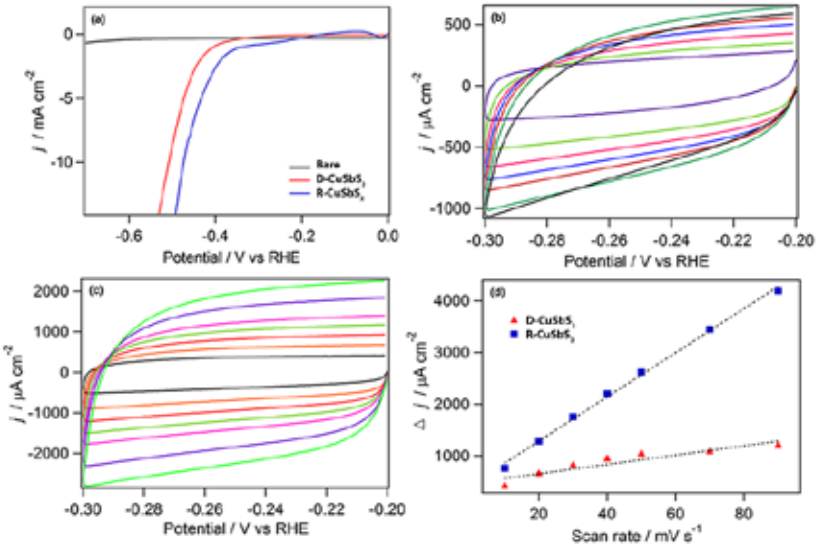

Fig 1. (a) Polarization curves, cyclic voltammograms of (b) D-CuSbS2 and (c) R-CuSbS2, (d) plots of (Cdl) linear fitting of the capacitive currents of catalysts for the electrocatalytic HER in alkaline media.

Measuring the electrochemical capacitance, different scan rates (10, 20, 30, 40, 50, 70, 90 mV/s) were carried out by sweeping between -0.3 and -0.2 V vs. RHE (Fig. b ve c). Double-layer capacitance (C_{dl}) was calculated from cyclic voltammetry method, where no faradaic processes were detected. The effective active sites of R-$CuSbS_2$ and D-$CuSbS_2$ catalysts can be determined from C_{dl}. C_{dl} values are also related to effective active sites. The observed capacitive current differences were plotted as a function of specific capacitances and scan rate, and then C_{dl} were found out by the slopes of the linear fitting (Fig. d). C_{dl} values of the R-$CuSbS_2$ and D-$CuSbS_2$ catalysts were founded as 42.67 mF and 8.97 mF, respectively, which are having harmony with overpotentials of catalysts. Consequently, it was revealed that, R-$CuSbS_2$ exhibit larger C_{dl} than D-$CuSbS_2$, which asserted more active site area for the HER [26]. Electrocatalytic activities related to shapes of these catalysts which might be explained by efficient charge separation efficiency of 1D materials.

CONCLUSIONS

It was carried out electrocatalytic hydrogen evolution reaction (HER) by using different shapes of copper-antimony sulfide in alkaline media for the first time, which are using towards energy conversion processes including due to its excellent properties as low-cost and high activity. It was found out that the electrocatalytic activity of $CuSbS_2$ may enhanced by changing of shapes. The microrod shape of $CuSbS_2$ exhibited high electrocatalytic activity than spherical shape of $CuSbS_2$ owing to the efficient charge separation efficiency of 1D structure. These results may use different energy conversion applications such as photocatalytic HER, solar cell and supercapacitors.

ABSTRACT

Efficiency increment of hydrogen evolution reaction (HER) is great challenge in the literature. Nanocomposite based catalysts are significant drawn attention due to the increasing active sites for hydrogen evolution. Herein, it is reported that in situ electrodeposition of metallic nanoparticles on multi-walled carbon nanotube or reduced graphene oxide by using organic sacrificial electron donor decamethylferrocene (DMFc) at liquid/liquid interfaces. The nucleation and catalytic reactions have been tracked by using 4-electrode voltammetry and biphasic reactions. The catalytic activities of metallic nanoparticles on carbon-based nanocomposites are founded as higher activities than that of non-metallic nanocomposites for biphasic catalysis.

Keywords: Hydrogen evolution, Liquid/liquid interface, Electrodeposition

INTRODUCTION

Providing sustainable energy in an affordable and eco-friendly manner is one of the challenges in the literature. Hydrogen is regarded as ideal energy carrier and good alternative to the fossil fuels due to the pollution-free, energy efficiency, recyclability and sustainability. Catalytic hydrogen evolution by water splitting gives a promising solution to growing demands for clean and sustainable energy. Platinum group metals (PGMs) are well-known and efficient catalyst for the HER. Although developing PGM-free catalyst, their catalytic activities did not reach the PGM catalysts up to now. Because of this disadvantage, efficient and durable PGMs are still under investigation. Electrocatalytic reactions are generally performed on the solid electrodes. Energy conversion reactions such as oxygen reduction, CO_2 reduction and H_2 production reactions can be carried out at soft liquid/liquid interfaces. Hydrogen evolution reaction (HER) can be figured out by different organic electron donor molecules like osmocene, decamethylosmocene, decamethylruthenocene and decamethylferrocene (DMFc) [1]. DMFc is most used sacrificial molecules and its reaction rate can be increased by using different catalysts [1]. However, these catalysts are generally used as synthesized. Recently, in situ electrodeposited electrocatalysts have been investigated for the hydrogen evolution reaction at liquid/liquid interfaces. Our group have been reported that catalysis of HER at water-1,2-dichloroethane (DCE) interface by in situ electrodeposited Pt, Pd, Cu and Cu/CNT catalysts [2-4]. The electrodeposition at liquid/liquid interfaces is generally carried out by using Pd. For example, research group of Dryfe is investigated the Pd electrodeposition at the water/DCE interface. Structural, morphological and electrochemical characterizations of the electrodeposited Pd nanoparticles have been investigated at templated and bare soft interfaces [5-8]. Herein, the using templates were supplied to control the electrodeposition of Pd. Electrodeposition begins at the soft interface with nucleation of particles, and then the particles are growth on the templates.

Carbon based materials like carbon nanotubes, graphene, or fullerenes, can be improved the catalytic activity because of increasing surface area, active sites as well as supplying electrical contact between donor molecule and catalyst surface [9]. We have been aimed to increase catalytic activity of free-standing Pd nanoparticles at water/DCE interface. There is no study reported that hydrogen evolution by using in situ electrodeposited CNT/Pd catalyst at the liquid/liquid interfaces.

Herein, in situ electrodeposition of CNT/Pd have been reported for both electrochemical characterization and catalytic HER at the water/DCE interface by using organic sacrificial agent DMFc. The catalytic activity of CNT/Pd is also compared to only Pd. The nucleation and catalytic activities are followed by 4-electrode voltammetry and chromatographic techniques with biphasic reactions. The obtained results were providing comparable results for different non-noble metallic or non-metallic composites.

MATERIALS AND METHODS

4-electrode voltammetry experiments have been carried out by using the cell having 1.53 cm^2 geometric area (two Ag/AgCl reference electrode and two Pt counter electrode in the organic and aqueous phases) with or without catalyst precursor. Biphasic hydrogen evolution experiments were carried out in headspace vials having 11 mL volume with stirring conditions in the absence and presence of Pd or CNT/Pd. the whole experiments have been performed under the anaerobic conditions in glovebox. The evolved hydrogen amount has been measured by gas chromatography

(Shimadzu, GC 2010 Plus, using thermal conductivity detector (TCD) and argon carrier gas), after biphasic reactions. Galvani potential difference is determined by using tetraethylammonium cation (TEA^+) [10,11].

RESULTS AND DISCUSSION

Obtaining and electrochemical characterization of Pd nanoparticle and CNT/Pd nanocomposite were tracked by using 4-electrode voltammetry technique. Firstly, blank voltammogram was obtained by using only supporting electrolyte in both phases and potential window was determined between -0.2 V and 0.3 V. Then, organic sacrificial agent DMFc was added to DCE phase to observe assisted proton transfer from water to organic phase, which can be explained small current increasing and potential shifting at the positive potential edge [12]. Both DMFc and $(NH_4)_2PdCl_4$ were added to organic and aqueous phases, respectively, were displayed a nucleation loop and robust current increasing, which is based on the formation of Pd nanoparticles [2]. When both $(NH_4)_2PdCl_4$ and CNT added to aqueous phase in the presence of DMFc in the organic phase, there is no nucleation loop due to the larger capacitive current, which related to adsorption of CNT at the water/DCE interface.

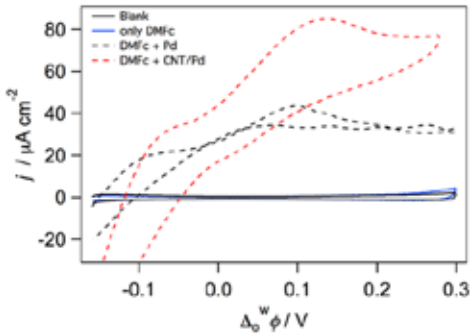

Figure 1. The nucleation of Pd and CNT/Pd at the water/DCE interface.

The catalytic activity of CNT/Pd nanocomposite is also investigated by biphasic reactions, which is also known as shake-flask. This technique is based on chemical polarization of interface with distribution of common ion TB^- both liquid phases. The catalytic HER was carried out by chemically controlled Galvani potential difference at water/DCE interface. In the absence of catalyst, reaction rate is very slow, and the amount of evolved hydrogen reached only 0.8 μmol after 24 hours of shaking. Using only CNT in the aqueous phase, HER rate is a little increased, which might be originated from metallic impurities in the CNT [4]. When Pd precursor and/or CNT added to aqueous phase, evolved hydrogen amount was increased dramatically. These results show that Pd and CNT/Pd occurred by in situ electrodeposition during the HER and they were catalyzed the HER at water/DCE. Gas chromatogram of HER is given in the figure 2 and it shows that electrodeposited Pd and CNT/Pd catalyzed HER efficiently. After 30 min of shake-flask experiments, Pd and CNT/Pd were produced 2.8 and 4.2 μmol hydrogen, respectively.

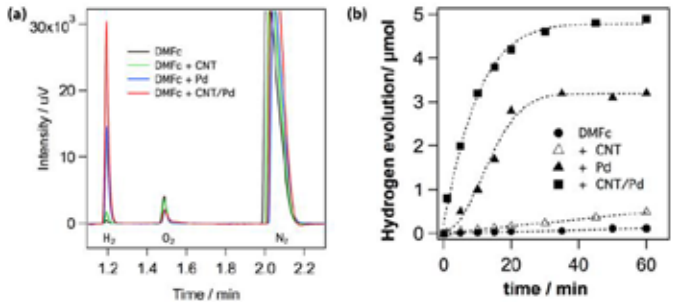

Figure 2. (a) Gas chromatograms of biphasic HER after 20 min both in the absence and presence of CNT, Pd or CNT/Pd catalysts. (b) Time dependent evolved hydrogen amount

The HER mechanism at the water/DCE interface is proceeded by proton coupled electron transfer (PCET) mechanism. Herein, electrons from DMFc injected to the CNT/Pd and protons adsorbed on the Pd nanoparticles is reduced into hydrogen gas. The role of CNT is that the electrons “pooled” in the CNT are highly mobile along the CNT “electron superhighway” [13]. CNT-based catalysts show also more catalytic activity than that of rGO-based once because 1D properties of CNT increase the charge carrier ability than 2D graphene-based materials. The obtained experimental data by using nanocomposite catalysts for the HER were given the comparable results with the non-metallic composites.

CONCLUSIONS

This work reported that catalytic hydrogen evolution reaction at the water/DCE interface by *in situ* spontaneous electrodeposited CNT/Pd nanocomposite for the first time. While nucleation is monitored by 4-electrode voltammetry, catalysis of HER is followed by biphasic reactions. HER activity of Pd is enhanced by using CNT/Pd nanocomposite due to the high electron transport efficiency of CNT. This activities differences between free Pd and CNT/Pd may be originated from preventing the aggregation of Pd nanoparticles by using CNT. This study paves the way a new approach for catalysis by using in situ spontaneous electrodeposited nanocomposite catalysts instead of as synthesized catalysts.

ABSTRACT

This study aims to investigate the effects of different catalysts on biomass gasification. Two different types of red mud (RM1, RM2), white mud (WM), and aluminum - nickel alloy were used as catalysts with biomass mixture for the lab-scale gasification studies by using an updraft and a downdraft fixed bed reactors. Green waste (GW), sewage sludge (SS) and olive pomace (OP) were used as feedstock. The results showed that the highest concentration of H_2 (47 vol.%) was observed in mixed sample with 0.05 L/min dry air at 900°C in updraft gasifier. In downdraft gasifier, max. H_2 concentration was measured for mixed sample at 800°C while 0.1 L/min dry air was applied. In general, it has been observed that RM increases the H_2 gas in the syngas between 1-7 vol.% at 900°C in updraft gasifier. In the downdraft reactor, on the contrary, H_2 concentration in the syngas decreased by 2-6% with the addition of RM. However, when aluminum - nickel alloy was added to the samples, syngas production drastically increased and its H_2 content was found more than 65% for both reactors. This study presents the research results on the catalytic effects on the syngas composition in detail.

Keywords: Gasification, Hydrogen, Biomass, Catalyst, Renewable energy

INTRODUCTION

Energy security and environmental pollution are two major concerns worldwide. The negative effects of fossil fuels on the environment have accelerated the research need for renewable resources such as biomass, which is a sustainable and valuable fuel source. In recent studies, it has been stated that more importance is given to energy and hydrogen production from biomass, since biomass is more advantageous than fossil fuels in terms of carbon emissions and carbon density (Al-Zareer et al., 2018). In addition, gasification as a thermochemical conversion process involving various chemical reactions, heat, and mass transfer is considered as one of the most promising methods for the use of biomass. H_2 produced by biomass gasification is a clean energy source. However, the enrichment of hydrogen is a great concern. The usage of catalysts might be an important alternative to increase the hydrogen yield in biomass gasification. Chai et al. (2020) have found that catalysts can affect H_2 production. New catalyst with high catalytic activity is to be developed to improve hydrogen production. Nickel catalysts are widely used in biomass gasification due to their low cost and high activity for C-C bond breaking. Alumina-based materials (Al_2O_3) are often used as supports due to their chemical and physical stability and suitable mechanical properties (Alvarez et al., 2014). In this study, the catalytic performance of different catalysts for biomass gasification was evaluated in terms of improving syngas quality and increasing H_2 gas content and its effect on tar formation. RM and aluminum-nickel alloy showed a more effective catalytic performance for gasification at high temperature and low agent flow rate. This experimental study can be considered as a preliminary study to improve the performance of a large-scale gasification plant operation.

MATERIALS AND METHODS

In this study, GW, SS and OP was used as biomass mixture. GW samples were taken from Manisa Metropolitan Municipality while SS samples were provided from Cigli Wastewater Treatment Plant in Izmir. OP samples were taken from a chemical plant working on olive oil soap located in Izmir, Turkey. In the gasification experiments, a biomass mixture consisting of GW, SS and OP samples was prepared as fuel. 25g was taken from each sample and a total of 75g sample was fed to the reactor system. Dry air was used as the gasification agent at different flow rates (0.05-0.1-0.2 L/min) The gasifier temperatures were used as 700°C, 800°C, and 900 °C.. RM1, the waste product of an aluminum processing plant for catalytic tar/tar removal was used as a low-cost catalyst. RM2 and WM catalysts are commercially used muds and aluminum - nickel alloy was provided from Merck. The photographs of the biomass samples and catalysts were given in Figure 1 and Figure 2.

Figure 2. Catalysts, (a) RM1, (b) Commercial RM2, (c) Dried commercial RM2, (d) Commercial WM, (e) Dried commercial WM,

The characterization studies on GW, SS and pomace OP were carried out in Department of Environmental Engineering, Sludge Laboratory at Dokuz Eylul University. pH, electrical conductivity (EC), salinity, dry solids content (DS), volatile solids content (VS), loss of ignition (LOI), higher heating value (HHV), total nitrogen (TN), total phosphorus (TP), thermogravimetric analyses (TGA) were done.

The reactors having a maximum 3 L of volume are designed as updraft and downdraft fixed bed systems and constructed from high temperature resistant AISI 310 S stainless steel. They were operated at different amounts of biomass at different temperatures and gasifying agent's flow-rates. The outer wall of the reactors was covered with a ceramic jacket. The syngas produced in the reactors are circulated in the reactors several times and then passed through the cyclone and taken to the cooler. Updraft fixed bed reactor system were set up in Dokuz Eylul University (DEU), Izmir while the downdraft system was installed in Istanbul University-Cerrahpasa (IUC), Istanbul, Turkey. The biomass mixture samples were gasified by adding different amounts of catalysts. Syngas measurements were done by MRU brand VARIOluxx model online gas analyzer and ABB brand syngas analyzer in DEU and IUC, respectively. These analyzers contain O_2, CO, CO_2; CH_4 and H_2 sensors and calculate the calorific value of the produced gas.

RESULTS AND DISCUSSION

In the characterization studies, VS of GW was found as 79.7% while it was determined as 48% and 74% for SS and OP, respectively. Ultimate and proximate analysis of biomass samples were given in Table1. GW and OP have higher VS and calorific value than SS.

Table 1. The physico-chemical properties of biomass samples

Ultimate Analysis (wt.%)				Proximate Analysis (wt.%)			
	GW	SS	OP		GW	SS	OP
C	38.88	32.23	47.57	Moisture	6.80	6.54	8.97
H	5.59	5.02	6.40	Volatile Solids	79.71	47.53	73.98
N	1.90	2.14	1.65	Fixed Carbon	7.73	12.84	12.83
S	0.12	0.70	0.12	Ash	12.56	39.63	13.19
O (by difference)	40.86	20.37	31.06	Bulk Density, kg/m3	25	365	600
				LHV, MJ/kg	15.95	12.65	17.32

In the gasification experiments, the max. H_2 concentration varied between 41 vol. % and 47 vol.% in updraft gasifier. In the downdraft gasifier, the max. H_2 concentration vary between 36 vol. % and 41 vol.%. Max. H_2 (47%) was observed in the syngas with using 0.05 L/min dry air and at 900 °C. When RM1 and RM2 were added to the mixed sample, the max. H_2 concentration was obtianed between 33% and 50 vol.% in updraft gasifier and between 30% and 37 vol.% in downdraft gasifier. Max. H_2 (50%) was observed using RM1 and RM2 with using 0.05 L/min dry air

and at 900 °C in updraft gasifier. The H_2/CO ratio was found between 2-4 for biomass mixture. In the catalyst added mixed sample, this ratio was ranged between 1.6 and 6. The calorific values of syngas were recorded between 8-13 MJ/m^3 in mixed samples with RM1, RM2, WM and aluminum – nickel alloy catalysts. When aluminum - nickel alloy was added to the samples, syngas production drastically increased and its H_2 content was found more than 60% for both reactors.

CONCLUSIONS

In this experimental study, gasification of the mixture sample formed by different biomass sources was done. The effects of different catalysts as RM1, RM2, WM and aluminum- nickel alloy on syngas formation was investigated by using fixed bed updraft and downdraft gasifiers. The max. H_2 and CH_4 concentrations were achieved approximately as 47 and 8 vol.% in updraft gasifier. These values are observed 50 vol.% and 5 vol.% for RM1 (7.5 g) added mixed sample. When 15g RM2 was used as catalysts, the max. H_2 and CH_4 concentrations were obtained in updraft gasifier 50 vol.% and 4 vol.%, respectively. Compared to the H_2 content produced without the catalyst addition, an increase of 3 vol. % H_2 concentrations were determined. As the amount of RM1 increased in the biomass mixture, a lower concentration of H_2 gas was formed. It was observed that the calorific value of the syngas slightly decreased when RM1 was added in the same conditions. When WM was added as a catalyst, syngas with the highest calorific value was found. The max. calorific value was determined approximately 13 MJ/m^3. In this study, the effects of different catalysts usage were determined to improve the syngas performance in biomass gasification. The detailed results of the experimental studied will be debugged for the achieving higher syngas efficiency.

ABSTRACT

Fe thin films electrodeposited on FTO substrate were thermally oxidized to hematite. The photocurrents values, indication of H_2 production efficiency in PEC cell were improved by optimizing thermal oxidation parameters of undoped hematite photoanode such as oxidation atmospheres (air and argon), oxidation temperatures (450 and 550°C) and oxidation time. The effect of these parameters on the photocurrents measured in PEC cell in hematite photoanode were characterized by using LSV (the linear sweep voltammetry), Mott Schottky and, EIS analyses. The effect of oxidation time on photocurrents were studied. Photocurrents first increased and reached the maximum values and then decreased with oxidation time in both argon and air atmospheres at 450°C and 550°C. The photocurrents measured at 0.6 V vs. SCE for hematite at 450°C and 550°C in argon atmosphere were greater compared to the photocurrents measured in hematite synthesized in air. The highest photocurrent of 0.56 mA/cm^2 at 0.6 V vs. SCE was measured for the hematite synthesized in argon atmosphere at 450°C with oxidation time of 96 hours.

Keywords: Hematite, Photoanode, Water splitting, PEC, Thermal Oxidation.

INTRODUCTION

Today, climate change whose effects are clearly visible by increasing greenhouse gases has become a global problem and dealing with it requires taking global action. The EU plays an active role in climate change set a target to reduce carbon emissions by at least 55%, by 2030, compared with 1990 levels [1]. Thus, renewable energy is essential for reducing carbon dioxide emissions that mainly occurred by fuel fossil and for satisfying the increasing clean energy demand. Photoelectrochemical (PEC) water splitting which converts solar energy directly into chemical energy is promising renewable energy source.

Hematite has attractive properties for use in photoactive semiconductor materials due to the significant light absorption (ideal bandgap with a 2.0-2.2 eV), its abundance, non-toxicity and its maximum theoretical STH efficiency of 16% with a photocurrent of 12.6 mA/cm^2 [2]. In previous studies, hematite showed a low performance (highest known photocurrent value ~6 mA/cm^2 at 1.23 V vs. RHE [3]) compared with theoretical value because it has some limitations such as its poor electrical conductivity, low hole diffusion length and high overvoltage requirement despite its promising properties [2].In the literature, it has been investigated that the photoelectrochemical performance of hematite was affected by changing synthesis conditions such as atmosphere (oxygen partial pressure), temperature and time [4-7]. Chnani et al. studied the parameters of thermal oxidation of Fe thin film i.e. time, temperature and rapid heating-cooling under ambient air and they reported that the increasing temperature and time had a positive effect on the photocurrent [4]. Smart et al. used first-principal calculations to predict the polaron concentration in hematite depending on synthesis conditions such as temperature and oxygen partial pressure. As a result of this study, they proposed that the electron concentrations of undoped hematite increase dramatically when the synthesis temperature is increased, or the oxygen partial pressure is decreased [5].

In this paper, the photoelectrochemical performances of undoped hematite photoanode were studied by optimizing thermal oxidation parameters such as time, temperature, and atmosphere. In addition to literature, the first time the effect of the oxidation time in argon atmosphere was investigated.

MATERIALS AND METHODS

First, the FTO substrates were carefully cleaned by ultrasonic rinsing in acetone, ethanol, and deionized water for depositing homogenous films. Then, Fe thin films were prepared on FTO by electrodeposition that was carried out in a two-electrode setup cell in a galvanostatic mode by using Bio-Logic galvanostat. During the deposition process, the distance between an FTO substrate (working electrode) and a platinum wire (counter electrode) was kept at about ~1.5 cm. The time for deposition was 50 s and the current density was 5 mA/cm^2. After electrodeposition, thermal oxidation of Fe thin film samples was performed in a Protherm tube furnace to study the effect of different synthesis conditions for hematite. The synthesis parameters were oxidation temperatures (450℃ and 550℃), oxidation atmospheres (air and argon) and oxidation times. In oxidation in Ar atmosphere, the system was flushed with Ar (1.5 L/min) for 30 minutes

before switching on the furnace. The heating rate was 10℃/min for all samples. At the end of the oxidation, the samples were left to cool in the furnace to room temperature. More details about the oxidation process are given in the following Table 1.

Table 1. The details of the oxidation process for the samples

Atmosphere	Temperature	Time
Air	450℃	5 h
		24 h
		68 h
	550℃	15 min
		30 min
		5 hour

Atmosphere	Temperature	Time
Argon	450℃	48 hour
		96 hour
		192 hour
	550℃	5 hour
		24 hour
		48 hour

After oxidation, all samples were connected to the copper wire using conductive paint for making photo-electrodes. Photoelectrochemical experiments (I-V, EIS and, Mott Schottky) were performed in a three-electrode system using a saturated calomel electrode as the reference electrode, a platinum wire as the counter electrode and a hematite photoanode as the working electrode. The measurements were conducted in 0.1 M sodium hydroxide electrolyte using a potentiostat (Bio-Logic VSP) and carried out under AM1.5G solar irradiation from an Abet solar simulator (100 mW cm^2).

RESULTS AND DISCUSSION

Photocurrents measured for hematite in the argon atmosphere at 450ºC with various oxidation times (48, 96 and 196 hours) were plotted in Fig. 1a. Photocurrent measured at 0.6V vs. SCE first increased and reach the maximum value of 0.56 mA/cm^2 at 96 hours and then decreased at 192 h. The similar trend was found for hematite formed in air, Fig. 1b [8]. Maximum photocurrents measured at 0.6V vs.SCE for argon and air atmosphere were 0.56 mA/cm^2 and 0.38mA/cm^2 respectively. The highest photocurrent density value of 0.56 mA/cm^2 for argon atmosphere was 1.5 times of the best photocurrent density obtained in air for 24h at 450°C (0,38 mA/cm^2) in Fig. 1. In agreement with the literature, the results showed that decreasing oxygen partial pressure in argon atmosphere increased the PEC performance of hematite annealed at 450°C for 96h.

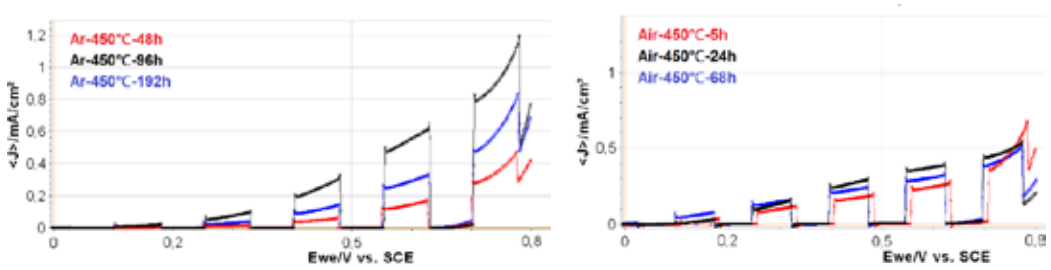

Figure 1. LSV under the light condition of hematite photoanodes oxidized for (a) 48h, 96h and 192h in argon (b) 5h, 24h and 68h in air atmosphere at 450 ℃

According to Fig. 2, increasing the oxidation temperature from 450°C to 550°C improved the photocurrent at the initial potentials but as potential increased further the photocurrent decreased in both air and the argon atmosphere. The photocurrent measured at 0.6V vs. SCE in argon atmosphere at 450ºC was significantly greater than the photocurrent measured at 550ºC, Fig. 2a. Unlike argon atmosphere, the best photocurrents of samples oxidized at 450°C and 550°C were similar in air in Fig. 2b and photocurrent measured at 0.6V vs. SCE was 0.32-0.38 mA/cm^2 range for both at 450°C and 550°C in air.

The defect concentration (Nd) and flat-band potential (Vf) obtained from the Mott Schottky measurement for the samples oxidized under argon atmosphere at 450ºC for different oxidation times, Fig. 3 was given in Table 2. The hematite annealed for 96 h in argon atmosphere, exhibited the highest defect concentration compared to others. EIS impedance results indicated similar results. The electrical conductivity was the highest for the hematite synthesized in argon at 96 hours. As a result, the photocurrent of the sample synthesized at 450ºC in argon has the highest value because of its high conductivity and high defect concentrations.

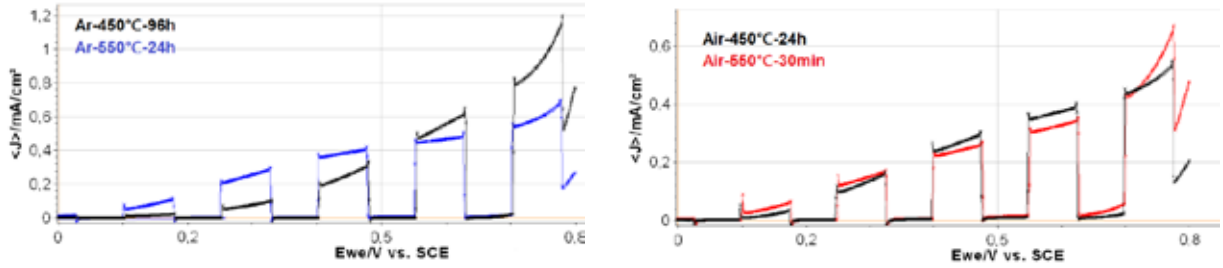

Figure 2. LSV under the light condition of hematite photoanodes oxidized under a) argon and b) air atmosphere at 450 and 550 ℃

Table 2. Mott Schottky analysis data of the samples oxidized in argon atmosphere at 450℃ under the light conditions

Sample	Frequency	Flat band potential	Donor Density
Ar-48h	1 kHz	-0,824 V	$0.583x10^{21}cm^{-3}$
Ar-96h	1 kHz	-0,806 V	$1.114x10^{21}cm^{-3}$
Ar-192h	1 kHz	-0.771 V	$0.332x10^{21}cm^{-3}$

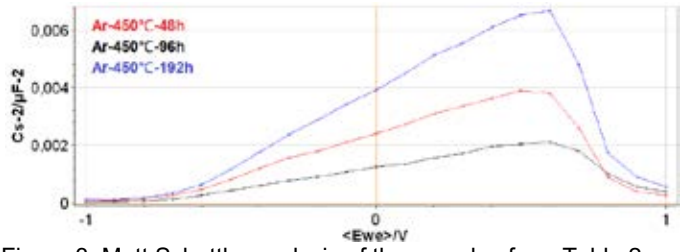

Figure 3. Mott Schottky analysis of the samples from Table 2

CONCLUSIONS

- The photocurrent changes with oxidation time. The photocurrent first increased and reached the maximum and then decreased with increasing oxidation time for the hematite synthesized in both argon and air at 450°C and 550°C. The highest photocurrents were found at 24 hours at 450°C and 30 minutes at 550°C in air while that was found at 96 hours at 450°C and 24 hours at 550°C in argon atmosphere.
- The photocurrent measured at 0.6 V vs. SCE for hematite at 450°C in argon atmosphere was the highest (0.56 mA/cm^2) with the highest defect concentration and conductivity compared to the photocurrents measured in hematite synthesized in air.

ABSTRACT

The problem of today is the increasing disposal of waste materials and the increasing depletion of natural resources. Therefore, the European Commission is adapting further regulations on waste management to the principles of the circular economy. Gasification of waste materials has not yet been established as one of the methods of waste utilisation, but a considerable number of studies on the subject point to a number of advantages of this method while reducing greenhouse gas emissions. One waste whose disposal is a global problem is sewage sludge (SS). In addition to SS, plastic waste is also a major issue due to the growing problem of microplastic contamination. In this work, the following wastes were used for gasification: SS from the wastewater treatment plant (WWTP) Zagreb and mixed plastic wastes (MP) originating from one of the waste collectors on the territory of the Republic of Croatia. Gasification was carried out in a rotary reactor. SS was gasified at temperatures of 1100°C and MP at temperatures of 900°C. The syngas produced from SS has a lower heating value (LHV) of 6.1 MJ m^{-3} and a volume fraction of H_2 in the syngas of 22.94%, while the syngas produced from gasification of MP has a better LHV of 14.4 MJ m^{-3} and a volume fraction of H_2 of 48.56%.

Keywords: Gasification, Sewage sludge, Mixed plastic waste, Syngas, Hydrogen

INTRODUCTION

Under European Union law, the disposal of organic waste is increasingly prohibited. In addition, much is being done to reduce the use of fossil fuels, and the possibilities of converting energy from a diversified waste stream into fuel gas and/or electricity are increasingly being considered. In addition to energy recovery, gasification also offers the advantages of less waste to dispose of, less harmful impact on water and air, and lower disposal costs.

Sewage sludge (SS) is a waste that is a problem in many countries around the world. However, due to its high organic matter content, the use of dry SS as an alternative solid fuel in gasification processes is increasingly being investigated. Plastic waste is a complex waste that is inadequately recycled. Much of the non-recyclable plastic waste must be disposed of in an appropriate manner. The disposal of this type of waste is becoming increasingly important, especially because of the increasing pollution that can be caused by microplastics. Gasification produces the following gases in particular: Hydrogen and Carbon Monoxide. The solid residues are mainly collected as inorganic ash. The use of hydrogen as an energy carrier and environmentally friendly fuel is on the rise.

In this work, gasification of waste materials was carried out in a rotary reactor on a semi-industrial scale. The gasification reactor was designed and built by Dok-ing Energo Ltd. Two experiments were conducted with two types of wastes. The wastes used were SS and mixed plastic (MP). The composition of syngases from two types of waste was determined and their heating value was determined. The aim of this work is to investigate the possibility of obtaining hydrogen-rich syngas from waste materials, the disposal of which is a challenge.

MATERIALS AND METHODS

The SS samples used in this study were from the Zagreb WWTP (1.2 million PE with secondary treatment stage), after anaerobic digestion and dewatering (with approximately 33% DM), collected in December 2021. The samples were collected in plastic containers and brought to the laboratory. The SS was then dried at 105°C for 24 hours. The moisture content of the dried SS was 2 wt.%. The lower heating value (LHV) was determined by the method HRN EN 15170:2010 and was 7.15 MJ kg^{-1} (DM). The dry SS was subjected to a grinding process to obtain particles of approximately equal size.

The MP waste was supplied by a company that collects waste in the Zagreb region. The moisture content of the MP waste was 0.05 wt.%. The heating value (LHV) of MP was also determined according to the method HRN EN

15170:2010 and was 28.3 MJ kg^{-1} (DM). The MP waste was delivered as shredded and ready for the gasification process.
Gasification of waste materials was carried out in a pilot plant consisting of the following units (Fig. 1)

1. Dosing system
2. Drying system
3. Main gasification reactor with rotary kiln
4. Syngas purification system with cyclone and wet scrubbers (scrubbing liquid - water)
5. Solid residue storage system

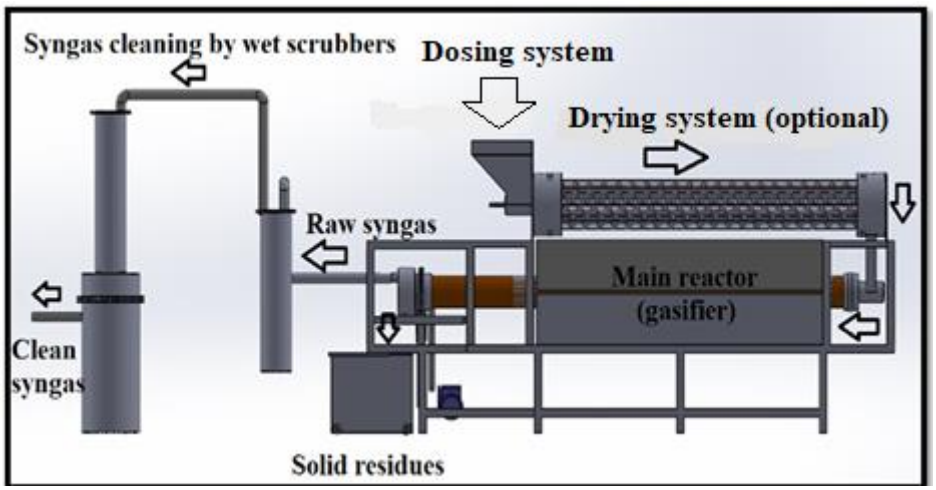

Figure 1 Gasification pilot plant with rotary kiln

The first experiment was performed with 10 kg of waste SS gasified at a temperature of 1100°C in a low-oxygen atmosphere (max. 5% oxygen per volume). Air was used as the gasification agent.

The second experiment was performed with 4.3 kg of MP waste gasified at a gasification temperature of 900°C, also in a low-oxygen atmosphere (max. 5% oxygen per volume). And again, air was used as the gasification agent.

The syngas produced passes through a purification gas system consisting of a cyclone and a scrubber. After purification, the composition of the produced syngas was determined using a syngas analyzer from the company MRU (vario luxx -syngas analyzer).

RESULTS AND DISCUSSION

The analysis of the synthesis gas obtained from SS and MP is shown in Fig. 2. The composition of the syngas obtained by gasification of SS has significantly lower fractions of hydrogen compared to the syngas obtained from MP. The nitrogen content is the largest fraction in the syngas obtained from SS, which affects the reduced heating values of the syngas, as can be seen in Fig. 3. (left). Fig. 3 (right) shows the presence of the acid gas H_2S in the syngases after treatment.

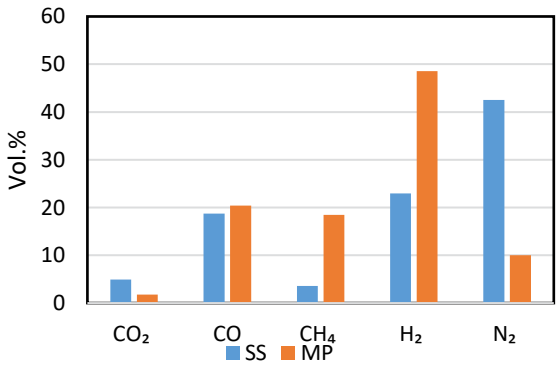

Figure 2. Composition of syngas from SS and MP

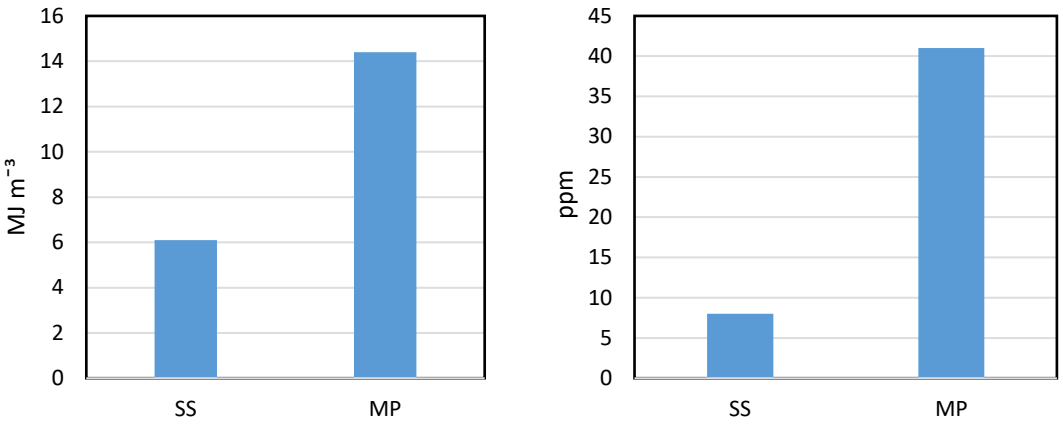

Figure 3. Comparison of LHV value of syngas from gasification of SS and from MP (left)
Presence of the acid gas H_2S in the syngases (right)

CONCLUSIONS

Gasification of waste materials SS and MP was carried out in a semi-industrial plant with a rotary reactor. In both cases, a significant amount of hydrogen predominates in the syngas. The waste material MP with a higher initial heating value (LHV) also resulted in a higher heating value (LHV) of the syngas.

ABSTRACT

Photocatalysts containing rich sulphur vacancies and bulk-twinned homojunctions have showed good prospects for solar hydrogen production. In this work, we synthesized photocatalysts composed of bulk-twinned homojunction $Cd_xZn_{1-x}s$ solid solutions along with rich sulphur vacancies to promote charge transfer and prevent the recombination. The photocatalysts were prepared via a simple hydrothermal method and then characterized by X-ray diffractometer to study the phase purity and crystallographic structure. UV-vis spectra were also carried out to investigate the optical properties. The achieved $Cd_xZn_{1-x}s$ photocatalysts exhibited a high solar hydrogen production activity in comparison with the sulphur vacancies free or non-twinned $Cd_xZn_{1-x}S$ solid solutions.

Keywords: Photocatalysts, Visible light, Hydrogen production

INTRODUCTION

Photocatalysis, which refers to the induction of spontaneous and efficient reactions at ambient temperatures under sunlight radiation, has been given so much attention. Because of its possibility to set up the best possible alternative energy systems with the ability to transform environmentally friendly, adequate, and secure solar energy into other forms such as electrical and chemical energy [1].

After Honda and Fujishima demonstrated that water can be split on a TiO_2 electrode into hydrogen and oxygen, over the past few decades. A lot of effort has been put into the development of semiconductor-based photocatalytic materials, especially metal oxides, and metal sulfides. Due to the wide bandgap of metal oxides, their photocatalytic activity is observed in the UV region, which accounts for about 4% of the received solar energy and thus renders the whole process unfeasible [2]. Metal sulfides have conduction bands composed of d and sp orbitals, while the valence bands are composed of S 3p orbitals, which are much more negative than O 2p orbitals. Therefore, the conduction band positions of the photocatalysts in this group are negative enough to reduce water to hydrogen and have narrow band gaps that respond appropriately to the solar spectrum. Despite the photocatalytic activity under visible light, Metal sulfides possess many challenges like degradation and fast recombination of holes and electrons [3] [4].
The photocatalytic performance of metallic sulfides can be improved through more efficient light absorption and reduced hole-electron recombination, both properties dependent on the bandgap energy and the crystal structure [5]. Recently, $Cd_xZn_{1-x}S$ nanocrystals used as the solid solutions of Cadmium sulfide CdS and Zinc sulfide ZnS have aroused interest because of their suitable bandgap, improved stability against photocorrosion, and redox capabilities of charge carrier [6]. However, the photocatalytic performance of pure $Cd_xZn_{1-x}S$ is still limited due to fast charge recombination, which is unfavorable for the more widespread use of this photocatalyst. Therefore, to overcome the above difficulties, wurtzite/zinc-blende (WZ/ZB) homojunction was developed as an alternative to $Cd_xZn_{1-x}S$ solid solutions with higher photocatalytic performance for hydrogen production. By virtue of staggered gab (type II) band alignment between WZ and ZB, bulk photoexcited electrons and holes can be well separated and transported to the photocatalyst surface.

On the other Hand, modulating the photocatalytic properties via defect engineering has been considered an effective approach. Vacancies are intrinsic impurities presented in crystals, perform as adsorption sites to enhance charge transportation and restrain the recombination of photoexcited electrons and holes [7].

In this work, photocatalysts composed of WZ/ZB twinned $Cd_xZn_{1-x}S$ solid solutions with rich sulphur vacancies (TV-$Cd_xZn_{1-x}S$) were synthesized. Compared to non-twined $Cd_xZn_{1-x}S$ and twined without sulphur vacancies (T-$Cd_xZn_{1-x}S$), the TV-$Cd_xZn_{1-x}S$ solid solutions are endowed with enhanced photocatalytic performance under visible light, achieving the optimal photocatalytic performance of 850 μmol/h.g in Na_2S/Na_2SO_3 solution.

MATERIALS AND METHODS

Materials

All the chemicals used in this study were analytical grade with high purity and commercially on hand as follows: Cadmium acetate dihydrate (Alfa Aesar), Zinc acetate dihydrate (ACS reagent), Thioacetamide (Alfa Aesar).

Synthesis of $Cd_xZn_{1-x}S$ solid solution

The $Cd_xZn_{1-x}S$ nanocrystals were synthesized as stated by a previous approach with some modifications [7]. Typically, 50 mmol Cadmium acetate dihydrate and Zinc acetate dihydrate was dissolved in 100 mL deionized water. Then, desired amount of thioacetamide was added to the above mixture and stirred for 20 min. After that, the suspension was further stirred for 20 min before it was transferred to a 200 mL Teflon autoclave and kept at 180 °C for 24 h. After being cooled to room temperature, the product was washed two times with deionized water and once with ethanol. Finally, the obtained product was dried at 75 °C for 6 h in a vacuum oven.

Characterization

The powder XRD patterns were collected on a Rigaku D/Max-2200 diffractometer supplied with a Cu X-ray tube (Cu Kα radiation, λ = 0.154 nm). The data sets were acquired over the 2θ range of 10−80°. The light absorption properties of the samples were conducted on Ocean optics model USB-4000 spectrophotometer. Spectra were recorded in the 280-1000 nm range using halogen and deuterium lamps as light sources.

RESULTS AND DISCUSSION

Fig.1. (a-b) shows the UV-Vis absorption spectra of the prepared $Cd_xZn_{1-x}S$ samples. Since the solid solution of $Cd_{0.1}Zn_{0.9}S$ is in Zinc-blend crystal arrangement, its absorption edge remains in the blue region (<400 nm) in the visible light spectrum. As expected, in the $Cd_{0.9}Zn_{0.1}S$ sample, the absorption edge shifts towards the red region (>500 nm) due to the high content of CdS compounds (Wurtzite/Zinc-blende). It is also seen that the absorption edge of the $Cd_{0.5}Zn_{0.5}S$ sample containing equal molar ratios of Cd and Zn corresponds to ~480 nm in the visible light spectrum. The crystal structure and phase purity of the prepared samples were investigated by X-ray diffraction (XRD). Fig. 1. (c-d) The characteristic diffraction peaks from the CdS are located at 2θ = 24.99°, 26.60°, 28.36°, 36.87°, 44°, 48.19°, 51.68°, 52.29°, 53.29°, 54.83°, 58.73°, 67.33°, 70.50°and 76.18° correspond to the planes (100), (002), (101), (102), (110), (103), (200), (112), (201), (004), (202), (203), (210), and (105) planes of Wurtzite, respectively. It is matched with the crystal structure [ICDD PDF 80-0006]. In addition, the characteristic diffraction peaks of the ZnS are located at 2θ = 28.5, 33.1, 47.4, 56.3, 69.4 and 76.7 correspond to the planes (111), (200), (220), (311), (400) and (331), respectively. It is matched with the crystal structure [ICDD PDF 65-1691]. Characteristic diffraction peaks of $C_{0.5}Z_{0.5}S$ were detected at 2θ = 25.8, 27.5, 29.3, 31.85, 45.6, and 54.185, unlike the characteristic peaks of CdS and ZnS in the literature. The 100's peak at 2θ =27.5 of $Cd_{0.5}ZnS$ has a high angle side (2θ =26.5) with the 100's peak of CdS and a low angle with respect to the 100's peak of ZnS (2θ =28.5) showed slip. With the increase of Cd content, the XRD diffraction peaks of $Cd_xZn_{1-x}S$ gradually and continuously shifted from the dominant of Wurtzite phase to the dominant of Zinc-blende phase. These results show that the synthesized catalysts are not a simple physical mixture of CdS and ZnS, but a solid solution of $Cd_{0.5}Zn_{0.5}S$ is formed.

Solid solutions of $Cd_xZn_{1-x}S$ generally produce much higher photocatalytic H_2 than ZnS and CdS alone. It is predicted that the activity can be improved by varying the Cd/Zn molar ratio of $Cd_xZn_{1-x}S$ (x = 0.1, 0.3, 0.5, 0.7 and 0.9) solid solutions. It can be seen from Fig. 2. that the $Cd_{0.9}Zn_{0.1}S$ photocatalyst provides hydrogen production at a relatively low rate of approximately 50 µmol/h.g. On the other hand, in the $Cd_{0.7}Zn_{0.3}S$ sample, where the Zn molar ratio is 30%, the amount of photocatalytic H_2 production increased significantly and was calculated as 720 µmol/h.g per hour.

In the presence of $Cd_{0.5}Zn_{0.5}S$ photocatalyst synthesized equimolarly, the highest H_2 production rate was reached with 850 µmol/h.g. Afterwards, the photocatalytic activity decreased significantly when the molar ratios of cadmium were less than 50%. In the presence of $Cd_{0.3}Zn_{0.7}S$ photocatalyst, the amount of H_2 production as a result of the photocatalytic reaction was 677 µmol/h.g; In the presence of $Cd_{0.1}Zn_{0.9}S$ photocatalyst, it was determined as 75 µmol/h.g. WZ/ZB twinned $Cd_{0.5}Zn_{0.5}S$ solid solutions with rich sulphur vacancies have the highest photocatalytic performance. Compared to non-twined $Cd_{0.5}Zn_{0.5}S$ with 234 µmol/h.g and twined without sulphur vacancies with 368 µmol/h.g.

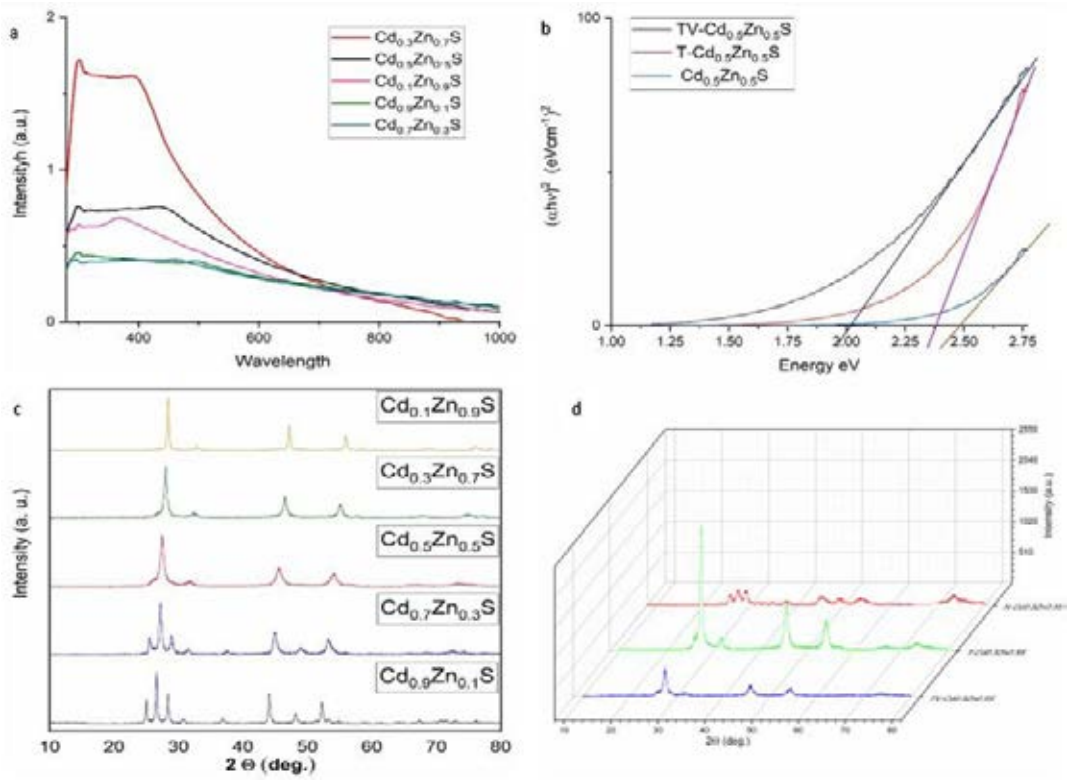

Figure 1 (a-b) UV–vis absorption spectra of $Cd_xZn_{1-x}S$ and Tacu plots of X-$Cd_{0.5}Zn_{0.5}S$ and (c-d) XRD patterns.

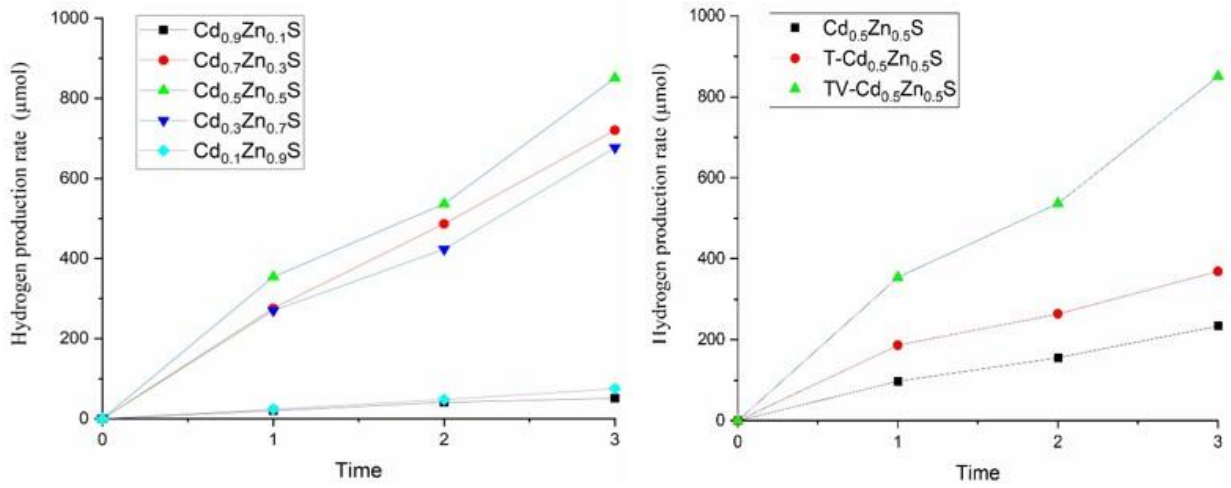

Figure 2 H_2 production rate of $Cd_xZn_{1-x}S$ photocatalysts.

CONCLUSIONS

In summary, the photocatalytic hydrogen production of $Cd_xZn_{1-x}S$ solid solutions can be enhanced by improving optoelectronic properties with binary Wurtzite and Zinc-blende phases obtained by changing Cd/Zn molar ratios and controlling the reaction conditions. Due to the fact that the solid solution of $Cd_{0.5}Zn_{0.5}S$ has an optimum band gap and a middle position of the conduction band, the visible light absorption, photogenerated electron-hole pair separation is improved, resulting in more efficient H_2 production. The enhanced photocatalytic performance of TV-$Cd_{0.5}Zn_{0.5}S$ can be ascribed to the twinned solid solutions and the presence of rich sulphur vacancies.

ABSTRACT

Hydrogen generation through photocatalytic splitting of water, which is known as hydrogen evolution reaction (HER), is an attractive method of converting the solar energy generated from renewable sources into chemical energy stored in molecular hydrogen. perovskite oxides hold promise as functional materials for the water splitting due to its excellent properties as low-cost and high activity. Herein, platinum photodeposited onto $MTiO_3$ (M: Ba and Sr) perovskites ($MTiO_3$-Pt) have been investigated on the photocatalytic hydrogen evolution under solar light irradiation in the presence of triethanolamine (TEOA) and Eosin Y as electron donor and photosensitizer, respectively. Photocatalytic hydrogen evolution activities take place in the order of SrTiO3-Pt> BaTiO3-Pt> SrTiO3> BaTiO3.

Keywords: Photocatalytic hydrogen evolution, Perovskites, Titanates

INTRODUCTION

Hydrogen evolution from water splitting with highest mass energy density and its rich reserves is pursued as an ideal clean energy system due to the lessen the reliance on fossil fuels [1]. Since the pioneering work of photodecomposition of water onto Pt/TiO_2 electrodes by Honda and Fujishima (1972), tremendous efforts have been proposed mostly for the development of photo/catalysts that are activated with UV–visible light spectrum [2]. Besides, proton reduction and water oxidation reactions are required to excess overpotentials; thus, catalysts with appropriate band position and also the bandgap design are major point for overall water splitting systems [3]. $SrTiO_3$ and $BaTiO_3$ perovskite-type oxides can be used as an alternative to mostly used TiO_2 because of suitable band positions, opticaland crystallographic properties for the efficient photochemical energy conversion reactions [4, 5]. These perovskites have been widely used for the photocatalytic hydrogen evolution systems due to their structural flexibility, suppression of photocorrosion and physicochemical stability [4].For example, numerous valuable studies have been recently reported by using different kind of perovskite based catalysts such as NiO-$SrTiO_3$ [6], $BaTiO_3$/ZnO [7], Rh-doped $SrTiO_3$ [8], g-C_3N_4 coated $SrTiO_3$ [9], Cr/N-codoped $SrTiO_3$ [10], Cu–$SrTiO_3$ [11], TiO_2/$BaTiO_3$ [12], $BaTiO_3$/$SrTiO_3$ [13], Co_3O_4/CdS/$SrTiO_3$ [14], $SrTiO_3$/Bi_2S_3 [15], Al/$BaTiO_3$ [16], Mo doped $BaTiO_3$ [17], NiS/g-C_3N_4/$SrTiO_3$ [18], La,Rh-doped $SrTiO_3$ [19].

Herein, we have reported that Pt have been *in situ* generated on the $MTiO_3$ (M: Ba and Sr) by reduction of H2PtCl6 from excited electrons during the photocatalytic reaction. Then, the effect of the photodeposited Pt on $MTiO_3$ (M: Ba,Sr) ($MTiO_3$-MoS_x)were systematically investigated for the photocatalytic HER by using triethanolamine (TEOA) as a sacrificial electron reagent and EY as a sensitizer.

MATERIALS AND METHODS

The photocatalytic hydrogen evolution experiments were performed in a 135 mL sealed tightly with a rubber septum Pyrex flask in the anaerobic glovebox system. Commercially available Eosin-Y dye and triethanolamine were used for photosensitizer and electron donor, respectively. Triethanolamine (TEOA) (5%) and Eosin-Y (0.33 mM) solution (20 mL solution volume) were prepared in the other flasks and bubbled with nitrogen to remove oxygen, then took in the glove-box. Firstly, catalysts were taken Pyrex flask and then, both electron donor solution (TEOA) and dye (EY) were added the flask in the glovebox. Before the photocatalytic experiments, the mixing solution with TEOA, (EY) and $MTiO_3$ were sonicated about 10 minutes to homogenize the solution. After this procedure, well-dispersed mixture was stirred spiritedly under the visible light source at 25±2°C temperature. The headspace gas was analyzed hourly to determine amount of produced hydrogen with gas chromatograph.

RESULTS AND DISCUSSION

The hydrogen production rates of $MTiO_3$ (M= Ba and Sr) by EY sensitization have been investigated in aqueous TEOA solution at pH 9. The HER rate found out as the 0.82 $mmolg^{-1}h^{-1}$ and 0.55 $mmolg^{-1}h^{-1}$ for BaTiO3 and SrTiO3, respectively. No hydrogen production is observed in the absence of dye molecule or sacrificial electron donor.

Photocatalytic hydrogen evolution activities of $MTiO_3$ have also been studied under long time visible light irradiation (8 h) in the presence of EY solution. Figure 1a indicates that the hydrogen production rate for EY/ $MTiO_3$ photocatalytic system shows almost steady increase over 8 h solar light irradiation. The total amount of H_2 after 8 h have been turned out to be 2.16 $mmolg^{-1}$ and 2.24 $mmolg^{-1}$ by using BaTiO3 and SrTiO3, respectively. in the TEOA and EY solutions. The HER rates of $MTiO_3$ (M= Ba and Sr) have been increased by in situ photodeposited Pt co-catalyst reducing H2PtCl6 during the photocatalytic HER. When the effect of Pt co-catalyst loading on $MTiO_3$ have been investigated, the HER activities of $BaTiO_3$-Pt and $SrTiO_3$-Pt were increased about 6.8 and 7.6-fold compared to bare $BaTiO_3$ and $SrTiO_3$, respectively. It can be seen that $SrTiO_3$-Pt was shown the highest photocatalytic HER performance as 16.96 mmol g^{-1}, while $BaTiO_3/MoS_x$ was produced 14.59 mmol g^{-1} hydrogen for 8 hours of photocatalytic reaction. Photocatalytic hydrogen evolution activities were changed in the order of $SrTiO_3$-Pt> $BaTiO_3$-Pt> $SrTiO_3$> $BaTiO_3$.

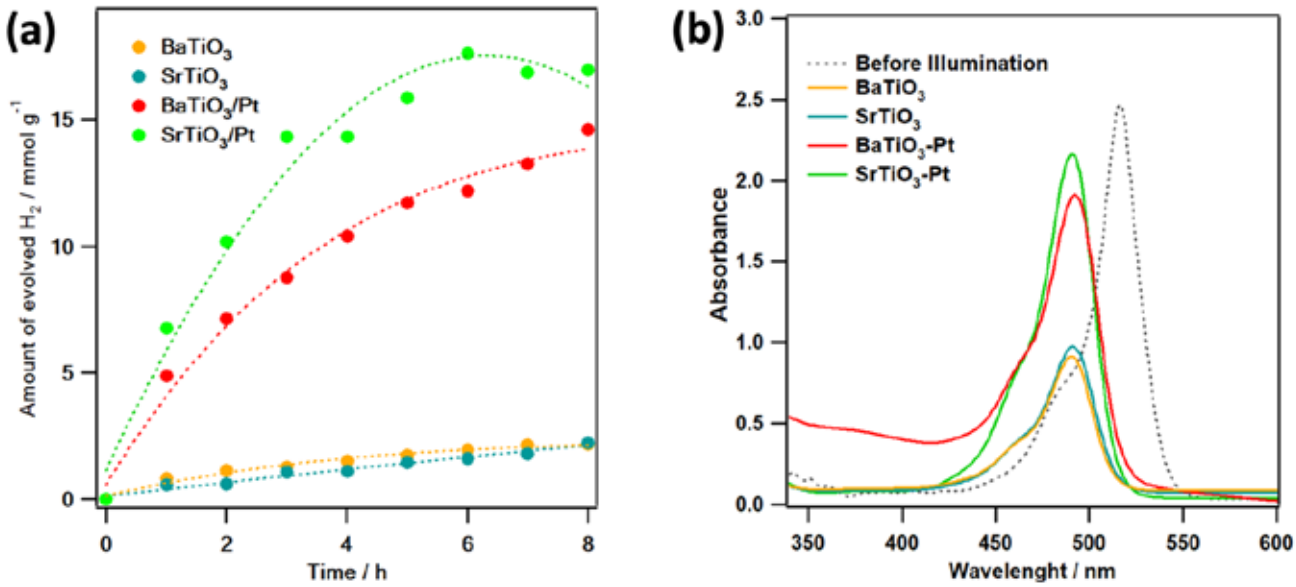

Fig 1. (a) Photocatalytic HER activities of MTiO3 and MTiO3/Pt, (b) UV-Vis absorption spectrums of the EY dye solutions before (black dashed line) and after (black solid line) photocatalytic HER

The photocatalytic stability of HER can be explained by the degradation of the EY dye. The degradation of dye molecule was determined by UV-Vis absorption spectroscopy technique as shown in Figure 1b. Also, the shift of the characteristic absorption peak EY (from 520 nm to 490 nm) with gradually intensity decrease is observed in the UV-Vis spectra after 8 h photocatalytic reaction, indicating that the sensitizer EY could degraded in this photocatalytic system [20, 21]. The peak shift can be explained by the removal of some bromine atoms from EY and the degradation of the dye as a result of possible formation of fluorescein-like species [22-24].

CONCLUSIONS

The highly crystalline perovskite particles $MTiO_3$ are utilized for solar-light-driven photocatalytic hydrogen evolution from water splitting by dye sensitization due to their wide band gaps. Photocatalytic HER activities of $MTiO_3$ are enhanced by loading Pt, which is obtained by photodeposition of H_2PtCl_6 reduction, as a non-noble metal co-catalyst. The HER rates of $SrTiO_3$/Pt and $BaTiO_3$/Pt have been increased approximately 6.8 and 7.6-fold, respectively, when compared to their pristine $MTiO_3$ forms.

ABSTRACT

High-throughput synthesis of Ni-based catalysts was performed by organometallic liquid grafting using a robotic arm. Monometallic catalysts contain Ni, whereas bimetallic catalysts contain a promoter metal such as B, Mg, V, Mn, Fe, Co, Cu, Zn, or Sn, supported on inorganic metal oxides such as magnesia, alumina, titania, silica, or ceria. The catalytic performance results showed that the support-metal-promoter choice affect catalyst activity, stability, syngas composition, and type and nature of carbon species formed under reaction conditions. Among 95 catalysts studied, NiFe/MgO and NiFe/Al_2O_3 catalysts are the most active and stable. In addition, the synthesized catalysts were characterized using several characterization methods including, but not limited to, N_2 physisorption, chemisorption, X-ray diffraction, vibrational spectroscopy, and imaging techniques. Characterization results show that (i) the best performing catalysts have metallic sites that are highly dispersed, uniform, and resistant to sintering at 800 °C, (ii) reduction profile of catalysts supported on alumina exhibits important structure-activity relationships, and (iii) distinct carbon species formed on specific sites, affecting the stability. Our findings demonstrate that organometallic grafting is a successful technique for synthesizing catalytic materials with highly dispersed and uniform sites that lead to promising catalytic performance for dry reforming of methane.

Keywords: Hydrogen, Dry Reforming, Methane, Grafting, Carbon dioxide

INTRODUCTION

Dry reforming of methane, Eq. (1), is a catalytic chemical transformation where CO_2 and CH_4, two greenhouse gases, are converted into CO and H_2, a gas mixture known as syngas, which can be used to produce value-added chemicals and fuels. [1,2] The reaction holds an enormous potential for net positive utilization of CO2 into chemical building blocks through hydrogen economy.

$$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2 \qquad \Delta H^0_{298} = 247\ \mathrm{kJ/mol} \qquad (1)$$

Several precious metals including Ru, Rh, Pd, and Pt and transition metals including Fe, Co, and Ni supported on inorganic metal oxides catalyze dry reforming of methane. Yet, endothermic nature of the reaction and high operating temperatures required for meaningful transformation rates lead to catalyst deactivation due to carbon deposition. Precious metals perform better against carbon deposition; but they are expensive and not abundant. Therefore, Ni emerges as an attractive reforming catalyst owing to its wide availability and low cost. Yet, Ni-based catalysts are prone to deactivation by carbon deposition and agglomeration under the reaction conditions.

It was reported that Ni catalysts with small particles sizes (small nanoparticles to single atom catalysts) [3,4] and easier reducibility [4,5] perform well for dry reforming of methane and alleviate the carbon deposition issue by preventing methane decomposition to carbon [4]. Conventional techniques for synthesizing catalysts such as impregnation lead to ill-defined active sites and large Ni nanoparticles. If a control at the atomic level is achieved, homogeneous distribution of metals in a close proximity to Ni may cause an ensemble effect and result in unique catalytic performance. [6] 30 In addition, presence of a secondary metal helps with some of the catalyst attributes and may enhance the ensemble effect.

Among the techniques for synthesizing catalysts, surface organometallic chemistry (SOMC) is a powerful bottom-up synthesis technique. [7] In SOMC, liquid organometallic precursors can be grafted on dehydroxylated metal oxides creating isolated metal sites or highly-dispersed uniform nanoparticles upon heat treatment. Such nanoparticles lower the energy of the surface and increase their interaction with the support, resulting in enhanced resistance to sintering under reaction conditions. [8]

In this study, by means of high-throughput synthesis and testing, we've [9, 10] synthesized bimetallic catalysts supported on different metal oxides to improve catalytic performance of Ni-based catalysts by grafting a submonolayer of promoters to enhance interactions between the metal and promoter-modified support. Specifically, nickel-containing bimetallic catalysts with different secondary metals (boron, zinc, manganese, cobalt, vanadium, copper, iron, magnesium, and tin) over six different metal oxide supports (silica, alumina, titania, ceria, and magnesium oxide) were synthesized via SOMC. The synthesized catalysts performance was obtained over dry reforming of CH_4.

EXPERIMENTAL

Experimental studies consist of catalyst syntheses, characterization (pre-reaction or post-reaction), and catalytic performance tests. For catalyst syntheses, a high throughput automated synthesis platform placed in a N_2-filled glovebox was used. The robotic arm was programmed to perform basic actions such as dispensing solids and liquids as well as stirring.

Catalysts were synthesized using a stepwise surface organometallic chemistry (SOMC) technique as shown in Fig. 1. After depositing organometallic precursors of promoters to partially dehydroxylated inorganic metal oxide supports to obtain approximately 50% of a monolayer coverage, calcination was performed in static air at 450 °C for 2 h. Then, the resulting solid material was suspended in toluene for grafting of organonickel precursor (bis(N,N'-di-t-butylacetamidinato)nickel(II)) in toluene to obtain sub-monolayer coverage. Before each reaction, samples were reduced under hydrogen at 800 °C.

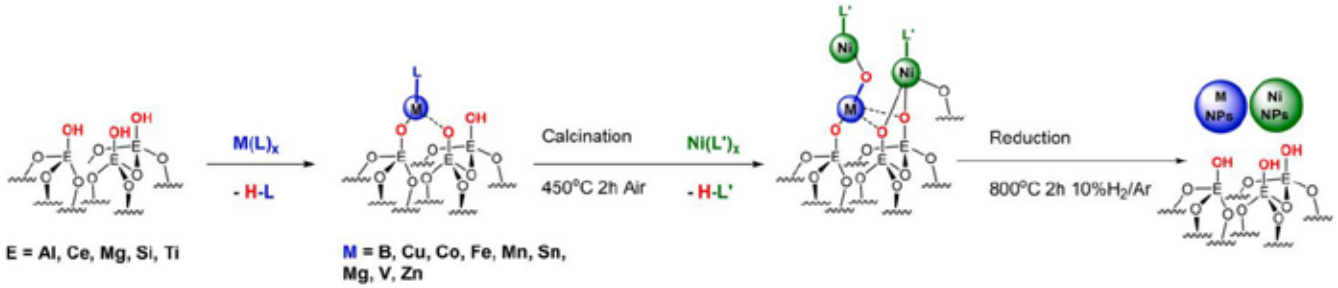

Fig. 1. High-throughput multi-step catalyst synthesis schematic via surface organometallic chemistry (SOMC) process [9]

Catalytic activity experiments were performed using a high-throughput system consisting 16 channels of fixed-bed reactors. Prior to each reaction, catalysts were pre-reduced under H_2 at 800 °C. Activity experiments were performed as temperature scans between 650 – 800 °C, followed by a stability test for 24 h at 800 °C at a gas hourly space velocity (GHSV) of 3200 h^{-1}. The exhaust composition was obtained with a gas chromatography.

The synthesized catalysts were characterized using inductively coupled plasma atomic emission spectroscopy (ICP-OES), X-ray photoelectron spectroscopy (XPS), temperature programmed reduction in H_2 (H_2-TPR), X-ray diffraction (XRD), Thermogravimetric Analyses coupled with a mass spectrometer (TGA-MS), Raman spectroscopy and electron microscopy imaging techniques.

RESULTS AND DISCUSSION

All the samples are first reduced under hydrogen and tested for dry reforming of methane for an equimolar CH_4 and CO_2. To assess the catalytic performance better, conversions obtained over bimetallic catalysts, i.e. NiX/M_2O_3, were divided with that obtained over monometallic Ni/M_2O_3. The top right quadrant of Fig. 1a. shows that bimetallic samples perform much better than their monometallic counterpart. To examine undesired carbon formation on the samples and composition of the reformed gas, Fig. 1b. shows H_2/CO ratio with respect to C balance. The higher H_2/CO ratio was attributed to occurring of methane cracking and Boudouard reactions, whereas the lower ratio was attributed to CO_2 reduction to CO with a subsequent C deposition on the samples. Fig. 1c. shows the stability test of the 10 best performing samples for 25 hours. NiFe/MgO and $NiFe/Al_2O_3$ are the most active and stable catalysts combinations for dry reforming of methane with a conversion very near to the thermodynamic limits. In addition to catalytic activity experiments, the present talk will also discuss characterization results and how they are related to the observed catalytic performance.

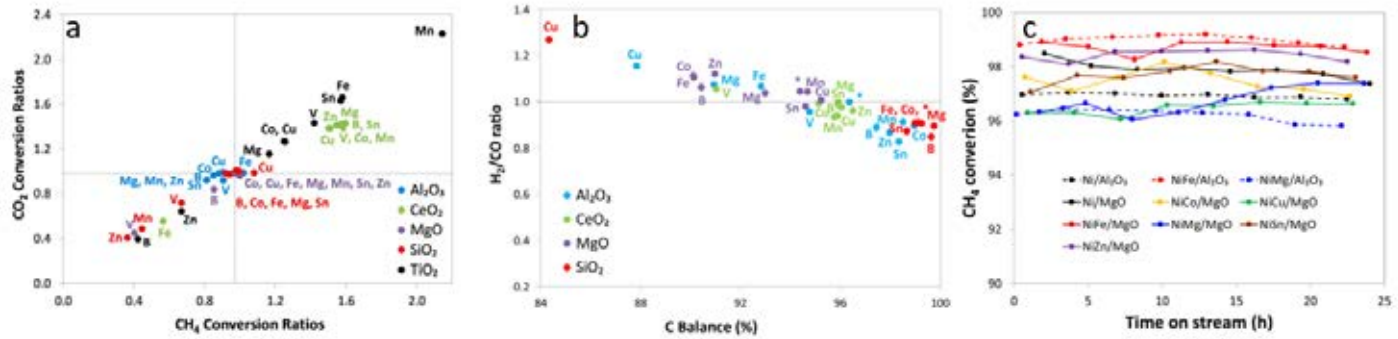

Fig. 2. (a) CO_2 conversion ratio to CH_4 conversion ratio of NiX/M_2O_3 to Ni/M_2O_3, (b) The ratio of H_2/CO to total carbon balance for some of the NiX/M_2O_3 to Ni/M_2O_3 catalyts, and (c) thermal stability runs of selected bimetallic catalysts. Reaction Temperature= 800 °C, CH_4:CO_2 = 1:1, and GHSV = 3200 h^{-1}. [9, 10]

CONCLUSIONS

Through extensive experimental studies including characterization and high-throughput syntheses and catalytic performance testing, $NiFe/Al_2O_3$ and NiFe/MgO bimetallic catalysts were identified to be the best performing samples for dry reforming of methane. The high performance of these samples was attributed to the presence of highly dispersed, uniform, and reducible Ni active sites, formed by the state-of-the-art top-down synthesis technique SOMC. In addition, characterization studies over pristine and post-reaction samples shed a light on the underlying chemistry of the catalytic surface reactions involved in dry reforming of methane and different carbon-induced deactivation modes.

ABSTRACT

Energy need is a major concern than ever before. The increasing demand and developing technology in every field within the industry have increased the demand for energy. Therefore, the gradual depletion of fossil fuels, which has been used as an energy source, pushed people to seek new energy sources. Energy from fossil fuels was polluting the environment depending on the amount reducing the resources since it was consumed from the volume of the limited resource. The energy source of the future is seen as alternative energy sources, as they can be adapted to any area where energy is needed, from transportation to lighting. Among these, gas that contains the highest energy is hydrogen and can be produced by renewal. It comes to the fore in the choice of energy source. As Green Hydrogen, the production of hydrogen with solar energy and the use of the produced hydrogen in heating the Industrial Zone have been studied theoretically. As a result, hydrogen can be produced with zero emission with a solar power plant to be built in the vicinity of the OIZ, which is planned to be built in Eskil, and the heating of the OIZ can be provided with Green Hydrogen.

Keywords: Energy, Green Hydrogen, Solar Energy, Heating, Hydrogen Production

INTRODUCTION

It has been decided to establish an OIZ (Organized Industrial Zone) in 3 more districts of Aksaray, including Eskil [1]. In order to produce the hydrogen that will be used in the heating of the Organized Industrial Zone as "Green Hydrogen" with zero emission, the establishment of a photovoltaic facility in the Eskil salt lake basin has been theoretically foreseen and studied.

MATERIALS AND METHODS

In order to generate electricity from the sun, a region has been selected in the salt lake basin near the Organized Industrial Zone. Konya region and Tuz Gölü basin are in the most productive region class for the production potential in the photovoltaic field [2-3].

RETScreen application is an application where you can simulate the production and management of clean energy on the mapped Earth. The location of the solar power plant planned to be produced for the Organized Industrial Zone is shown in Figure 1. [4]. According to the data received from RETScreen, the amount of sun received by the region is shown in Figure 2. [5]

When we evaluate the data obtained from the RETScreen application on a monthly basis, Table 3 shows values such as air temperature, relative humidity, precipitation rate, amount of sunlight received, and atmospheric pressure of the selected region [5].

There are two methods to produce hydrogen after the energy is produced. These are burning hydrogen or giving electricity. There are four main groups to produce hydrogen with electricity obtained from the sun as a method. There are [6]:

1) photovoltaic (PV)
2) photo electrochemical
3) photo biological
4) solar thermal energy

Figure-3 shows schematically how hydrogen is produced with solar energy. [8-9].The hydrogen that is desired to be produced as Green Hydrogen with zero emission can be produced by the photovoltaic method. The electrical energy obtained from the sun's rays is given to the water and the water is electrolyzed. Thus, the hydrogens in the water can be separated and stored.

Figure-3. Energy Production Scheme of the Designed Solar Power Plant Area

The reaction that takes place at the electrode, that is, the anode, where the oxidation reaction takes place:

$$2H2O+ \rightarrow O2 + 4H+ + 4e- \quad (1)$$

The reaction that takes place at the electrode, the cathode, where the reduction reaction takes place:

$$4H2O+ 4e- \rightarrow 2H2 + 4OH- \quad (2)$$

It separates water into its components by electrolysis with its formulas. In the last step of the plant, hydrogen is transferred in liquid form or directly to the organizing area. Thus, an environmentally friendly and efficient energy source is used for the heating need in the region. [9]

RESULTS AND DISCUSSION

The need for heating of the Organized Industrial Zone, which is planned to be built, can be supplied with alternative energy sources. The need for heating of the region can be met by providing hydrogen production with photovoltaic production with zero emission value as Green Hydrogen. As Green Hydrogen, the need for heating of the region can be met by providing hydrogen production with photovoltaic production with zero emission value.

It is very important for the campus to have open areas exposed to the sun, especially on the Konya-Aksaray border. This indicates that it is convenient and positive to produce hydrogen from the Sun. Possible relocation of the organized Industrial zone will affect the location of the photovoltaic plant to be established around the plant. The plant efficiency will not change significantly due to the high amount of sunshine in the region, but the distance of the suitable land to the Industrial Zone will be an important item for the transportation of hydrogen.

ABSTRACT

Water splitting for hydrogen generation is an interesting strategy in energy technology. Hence, developing cheap and robust electrodes have received great attention in recent years. In this research, we fabricated nickel oxide (NiO) Nanorod Arrays structure coating as an anode that has a strong bonding with the Ni foam (NF) substrate to prepare NiO/NF. The electrode was prepared by using the hydrothermal method (in a temperature of 100°C and reaction time of 12 h) in a solution containing nickel nitrate and urea under the optimized experimental conditions. The electrochemical performance of the fabricated electrode was investigated in alkaline solution of 1 M KOH and revealed that only +450 mV is required to achieve a current density of 100 mA cm^{-2} for water oxidation showing an efficient electrocatalyst. The enhanced performance of the developed electrode for water splitting can be related to the morphology of the nanorod structure, high ordered array structure and high adhesion of NiO nanorod arrays on nickel foam substrate.

Keywords: Water oxidation, NiO, Nanorod array

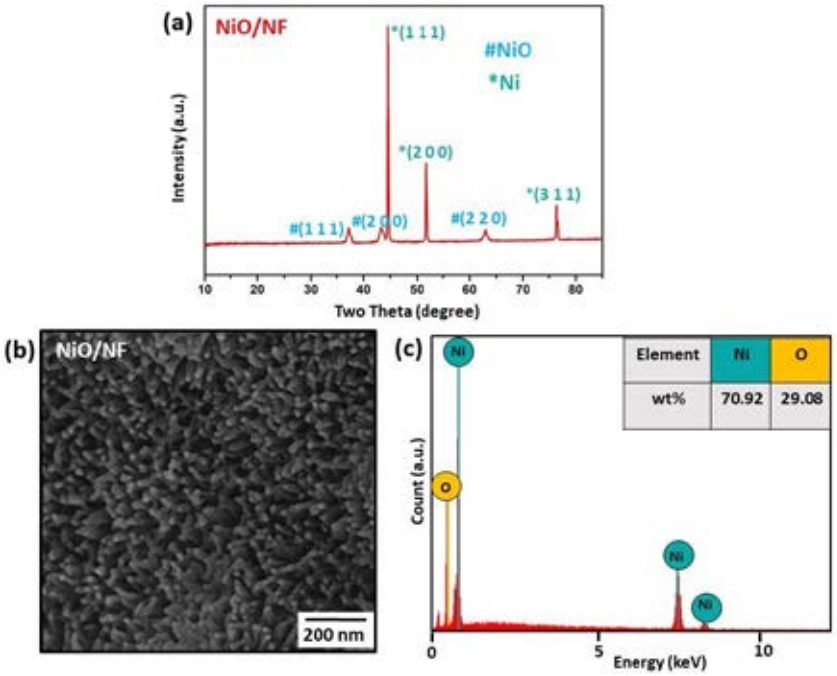
INTRODUCTION

Splitting of water into H_2 and O_2 is one of the most efficient approaches for generation of high-purity H_2 fuel [1,2]. Due to the sluggish kinetics of the oxygen evolution reaction (OER) at the anodic electrode surface in an overall water-splitting cell, which is resulting from the four-step this reaction, the development of effective electrocatalysts for these systems is still considered as a bottleneck [1,3]. Therefore, finding the economical and efficient electrocatalysts with low overpotentials to overcome the sluggish kinetics is necessary to deliver high current density. The electrocatalysts based on precious metal oxides such as IrO_2 and RuO_2 are the best choice for OER [3,4]. Unfortunately, large-scale applications of these materials are limited because of their scarcity and high price. Recently, an attractive alternative to these noble metal materials as OER catalysts is introduced by using nickel-based electrocatalysts in the different forms such as oxides, nitrides, phosphides, etc. [5]. Morphology is an important factor that directly affects the degree of catalytic activity of the compound and is able to create a high surface area with many active sites to expose in the electrolyte that results in high performance in the water-splitting processes [5,6]. Considering this goal, in this work, we report an OER electrode fabricated with a NiO nanorod arrays on nickel foam, in which they have been vertically grown on porous Ni foam as conductive support. The prepared OER electrode exhibits high current density of 100 mA cm^{-2} at overpotential of +450 mV in 1M KOH at the room temperature. Furthermore, the array-nanostructured electrode showed an efficient charge transfer with a small impedance arc and it resulted in the high OER performance.

MATERIALS AND METHODS

The materials nickel nitrate hexahydrate ($Ni(NO_3)_2{\cdot}6H_2O$), urea ($CO(NH_2)_2$) and absolute ethanol were purchased from Merck (Germany). In order to synthesize NiO nanorod arrays on Ni foam, the simple hydrothermal method was applied. Typically, 0.5 g of $Ni(NO_3)_2{\cdot}6H_2O$ and 0.2 g of urea were dissolved in 12.0 mL of di-ionized (DI) water and stirred for 30 min to prepare a clear and homogeneous solution. Ni foam with dimensions of (3 × 1 cm^2) was cleaned via sonication in acetone and ethanol for 15 min and then, it was annealed at 500°C in Ar atmosphere to fully remove the surface native oxide layer. The well-cleaned Nickel foam as substrate and the solution obtained were transferred into a 15 mL cylindrical Teflon located in a stainless-steel autoclave. The autoclave was maintained at 100°C for 12 h and then cooled down to room temperature naturally. After the hydrothermal process, the deposited thin film (green color) was rinsed 3 times with DI water and pure ethanol via sonication and then dried in oven for 6 h at 80°C. Then, the sample was placed at the middle of a tube furnace and annealed at 450 °C under a constant flow of 200 standard cubic centimeters (sccm) Ar for 1 h at a heating rate of 2 °C /min. Finally, the furnace was cooled down to room temperature for removing the sample.

CHARACTERIZATIONS



The morphology and composition of samples were characterized by field emission scanning electron microscopy (FE-SEM) Mira 3-XMU model equipped with an energy dispersive spectroscopy (EDS). In order to study the crystal structure, the X-ray diffraction (XRD) patterns were recorded in a range from 10° to 80° with 0.02° per step using an X'Pert MPD X-ray diffractometer with Copper Kα (λ=1.5410 A˚) radiation at 40 kV and 40 mA.

ELECTROCHEMICAL TESTS

The electrochemical performance was tested by a three-electrode galvanostat/potentiostat (Autolab PGSTAT302). All measurements were carried out in a three-electrode glassy cell which contained with 1 M KOH aqueous solution, the fabricated NiO Nanorod NiO/NF, platinum wire, and an Ag/AgCl electrode as working, counter and reference electrodes, respectively. The effective working electrode area in the electrolyte was approximately 1 cm^{-2}. The working electrode (NiO/NF) was cycled 50 times by CV until reaching a stable polarization curve. OER polarization curve measurements were performed by linear sweep voltammetry (LSV) at a scan rate of 50 mV s^{-1}. Electrochemical impedance spectra (EIS) were measured at an overpotential of +270 mV from 0.1 Hz to 100 KHz frequencies.

RESULTS AND DISCUSSION

A) XRD/SEM/EDS analysis: XRD pattern of NiO/NF nanorod arrays after its annealing at 450°C is shown in Fig. 1a. The peaks at the 2θ= of 37.21˚, 43.23˚ and 62.87˚ were originated from (111), (200) and (220) planes of the prepared NiO structure, respectively. As illustrated in the Figure, all the peaks marked (#) are indexed to NiO (JCPDS 47-1049) and the other peaks which have been marked with (*) are ascribed to Ni metal associated with the Ni foam substrate. The morphology and composition of the NiO/NF nanorod arrays were investigated by FE-SEM and EDS analysis, respectively. According to the FE-SEM image (Fig. 1b), we have found that the array structure with a perfect rod shape was formed during the hydrothermal treatment. The nanorods were typically 100–200 nm in length and their diameters ranging from 10 to 15 nm. The nanorods were vertically aligned on the Ni foam substrate and forming an array structure. EDS analysis (Fig. 1c) of the NiO nanorod arrays only revealed the peaks of Ni and O which further confirms that the as-fabricated NiO nanorod is of high purity. The obtained results by EDS is in good agreement with the XRD result where no other impurity peaks were observed.

. Fig. 1. (a) XRD pattern, (b) FE-SEM image, and (c) EDS analysis of NiO/NF nanorod arrays

B) Oxygen evolution reaction: In order to evaluate the oxygen-evolution reaction performance of the electrode based on NiO/NF nanorod arrays, we first evaluated the OER activity of the as-prepared catalysts in 1M KOH electrolyte at room temperature (25°C) by using electrochemical measurements including LSV and EIS. So, the NiO/NF nanorod arrays electrode and pristine NF (for comparison) were applied as working electrodes. Fig. 2a shows LSV polarization curves of the NF and NiO/NF nanorod arrays electrodes. The NiO/NF nanorod arrays exhibited a good OER activity, requiring overpotential of +450 mV to deliver current density of 100 mA cm^{-2}, which is smaller than that of NF (+839 mV). The whole coverage of the NF and strong adhesive of nanorod arrays on the NF substrate facilitate the charge transfer between the electrode/electrolyte as revealed by the results from EIS measurements (Fig. 2b). EIS curve depicts that the charge-transfer resistance of the NiO/NF nanorod arrays electrode is ~1.0 Ω, which is significantly smaller than that of pristine NF (~80 Ω), confirming its easier charge transfer ability.

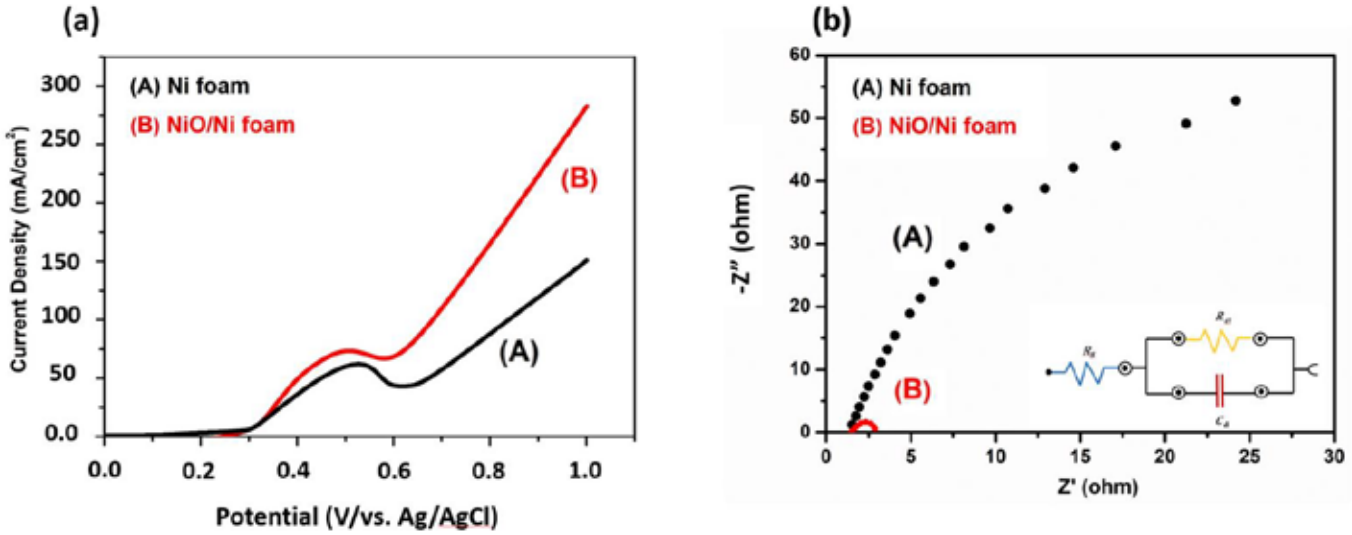


Fig. 2. (a) Polarization curves of the Ni foam (A) and NiO/NF nanorod arrays (B), and (b) EIS Nyquist plots of the Ni foam (A) and NiO/NF nanorod arrays (B) catalyst measured at the potential of 0.5 V vs. Ag/AgCl.

CONCLUSIONS

In summary, this study has developed an economic and simple OER electrocatalyst based on the NiO nanorod arrays deposited on nickel foam (NiO/NF) for efficient and stable water splitting process. The prepared NiO nanorods possess a large surface area, which yields an easier charge transfer and numerous active sites. The NiO/NF catalyst exhibited an excellent electrochemical behavior in water splitting which requires a low overpotential of ~450 mV to deliver a high current density of 100 mA cm^{-2}, in alkaline media at room temperature. The results clearly revealed that the simply prepared of high oriented NiO/NF array structure and low cost with efficient activity can be applied for H_2 production via water splitting, supercapacitors, and other electrochemical devices.

ABSTRACT

Due to its favorable chemical and structural properties, nanostructured nickel-molybdenum oxides produced through an environmentally benign solution combustion method were investigated as possible cathode materials for the hydrogen evolution reaction in an acidic electrolyte. Ni-Mo-oxides of different compositions were employed, leading to the identification of the equiatomic stoichiometric sample ($NiMoO_4$) as the best performing electrode composition for the HER. The promising performance of this material could be linked to the synergistic effect that is induced through the combination of metal oxides in a binary form. While the activity of $NiMoO_4$ is slightly inferior to the state-of-the-art 20% Pt/C, when the cost of the material and the stability aspect are considered, $NiMoO_4$ emerges as the more economically viable option.

Keywords: Hydrogen, mixed-metal oxides, electrocatalysis, synergism, acidic electrolyte

INTRODUCTION

H_2, in combination with renewable energy systems (wind/solar/hydro), is a viable, long-term option to counter the fossil fuel dilemma. Indeed, H_2 can be produced using the surplus of renewable energy in a zero-emission process by water electrolysis. Currently, most industrial applications employing water electrolysis to produce H_2, utilize alkaline electrolyzers since the mild alkaline environment allows the use of cheap electrode materials like Ni and Fe, but they suffer from large power requirements and poor stability [1]. In contrast, polymer-electrolyte-membrane (PEM)-based electrolyzers offer a significantly higher current efficiency, are compact and modular, and enable the internal compression of gases [2]. However, due to the aggressive acidic environment, PEM electrolyzers require expensive metals as electrode materials (e.g., Pt, Ir, Ru, Pd), which limits the widespread use of those electrolyzers.

The goal is to bring the PEM technology closer to commercialization by using inexpensive and durable electrocatalysts. This research seeks to develop bimetallic Ni-Mo-oxide nanostructures to achieve, at a low cost, high electrocatalytic activity and long-term stability that approaches that of Pt. The rationale follows a three-pronged approach: (1) Ni and Mo can induce a synergistic effect, thus enhancing the cathode activity in HER (intrinsic effect), (2) metal oxides have been proven to be stable under extremely acidic conditions in several electrochemical applications and are, thus, excellent candidates for PEM electrolyzers, and (3) nanostructures provide a remarkably high specific surface area and increased surface energy, thus also yielding higher intrinsic and extrinsic electrocatalytic activity.

The $NiMoO_4$ family has been used, traditionally, in industrial catalysis. However, its electrochemical affinity has been, thus far, mainly limited to supercapacitor applications [3]. Also, the harsh, highly corrosive environment of the PEM electrolyte (acidic environment) has discouraged its use in PEM-simulated conditions due to instability concerns and limited conductivity [4]. Different methods can be employed to produce $NiMoO_4$; however, most of the currently used wet chemical methods generate toxic chemical waste leading to environmental toxicity and non-biodegradable products, while physical methods necessitate massive energy requirements. In this study, we propose an environmentally-friendly solution combustion method using agar as a fuel agent.

EXPERIMENTAL

Synthesis of metal-oxides

A stoichiometric amount of nickel nitrate ($Ni(NO_3)_2 \times 6H_2O$) and ammonium heptamolybdate tetrahydrate ($(NH_4)_6Mo_7O_{24} \times 4H_2O$) were dissolved separately in ultrapure water (resistivity >18 MΩ cm). The solutions were stirred for 30 minutes and subsequently mixed together. An appropriate amount of agar was added, at a high temperature, to dissolve agar and induce gelation. After the formation of the gel, the solution-containing beaker was equilibrated at room temperature, after which it was placed in an oven to remove the water content. The dried gel was, then, placed in a preheated furnace at an appropriate temperature to obtain the oxide structures through a

highly exothermic combustion reaction. NiO, MoO_3, and different Ni-Mo-oxide compositions were prepared using the same method except for changing the amount of the precursor salts. A commercial 20% Pt/C was employed as a control HER electrocatalyst in the electrochemical measurements.

Electrochemical measurements

The electrochemical measurements were conducted in 0.5 M H_2SO_4 using a three-electrode electrochemical cell. The working electrode consisted of a glassy carbon electrode (GCE) covered with a thin layer of the electrocatalytic material, while a platinum wire and a saturated calomel electrode (SCE) were used as the counter and reference electrodes, respectively. The working electrode was prepared by mixing the produced electrocatalytic material with an appropriate amount of water and ethanol to enhance dispersion. Subsequently, carbon black was added to the catalyst ink to increase the conductivity of the electrocatalytic layer. Then, a 20 µL aliquot of this suspension was dropped on the mirror-polished GCE (surface area: 0.283 cm^2) and dried at room temperature. The performance of the synthesized electrocatalyst was screened using a short term chronoamperometry (1000 seconds) experiment carried out at an overpotential of -0.55 V. Subsequently, an LTP (linear Tafel plot) was performed in the overpotential range from 0.55-0 V to obtain the Tafel slope and other electrochemical performance indicators. The potentials reported in this study were converted to RHE (reversible hydrogen electrode).

RESULTS AND DISCUSSION

Effect of composition and morphology characterization

The effect of the composition of Ni_xMo_{1-x}-oxide (x = 0.0, 0.2, 0.4, 0.5, 0.6, 0.8, 1) towards the HER is presented in Fig. 1. It is notable that the pure oxides (NiO and MiO_3) exhibit a negligible activity for the HER. As the oxide components are combined, an increase in the hydrogen activity is notable, which reaches a maximum (ca. 190 mA/cm^2) at $NiMoO_4$. The increase in the performance of the material can be attributed to several factors (composition, electrochemical surface area, particle size, electronic configuration, to name a few). The determination of the electrochemical surface area is hindered by using carbon black as a conductive additive, which confounds the computation of a reliable active surface area.

Selected SEM images of the synthesized materials are presented in Fig. 2. Since the HER is a heterogeneous reaction occurring at the surface of the electrocatalyst, a small particle size would, theoretically, entail a higher specific surface area, which would result in improved performance. However, this is not the case here, since the smallest particle size is associated with $Ni_{0.8}Mo_{0.2}$-oxide (2-3 nm) which performs relatively poorly towards the HER, as seen in Fig. 1. The BET surface area and pore volume of the synthesized materials were determined, as shown in Fig. 3. The maximum surface area and pore volume are observed for $Ni_{0.8}Mo_{0.2}$-oxide (110 m^2/g, 0.25 cm^3/g) which is markedly higher than those of the best-performing $NiMoO_4$ (26 m^2/g, 0.10 cm^3/g); however, this sample exhibits comparatively lower electrocatalytic HER performance, indicating that the surface area is not the determining factor in the observed HER activity.

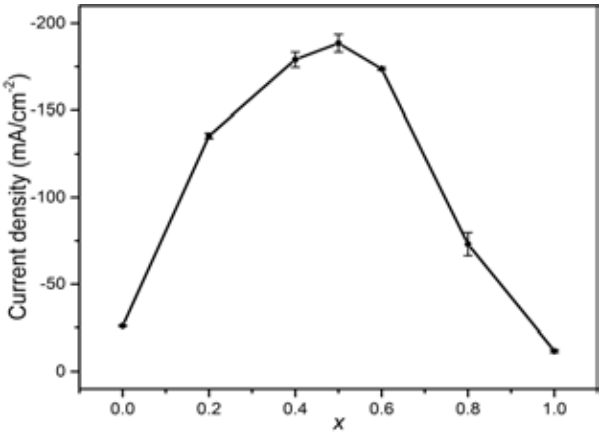

Fig. 1. *Extrinsic* electrocatalytic activity of the Ni_xMo_{1-x}-oxide (x = 0.0, 0.2, 0.4, 0.5, 0.6, 0.8, 1) in 0.5 M H_2SO_4 at an overpotential of -350 mV vs. RHE.

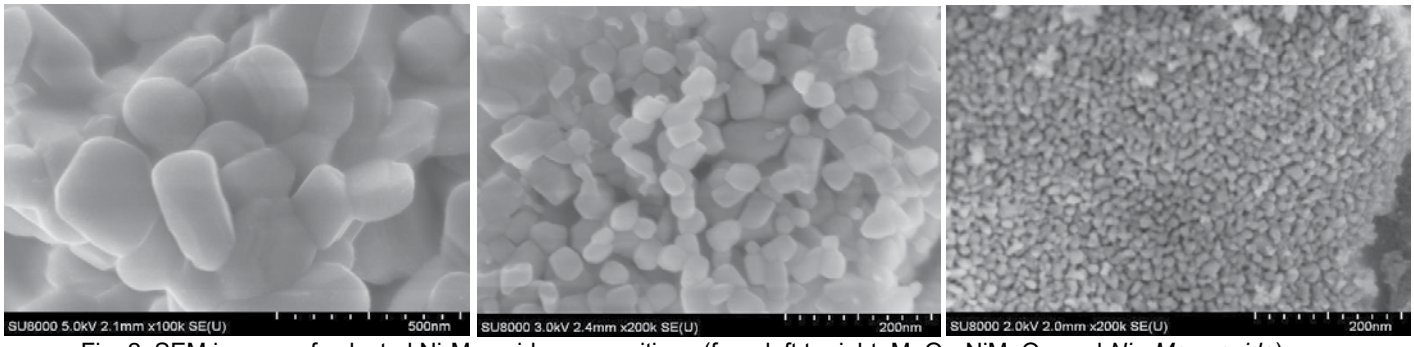

Fig. 2. SEM images of selected Ni-Mo-oxide compositions (from left to right, MoO_3, $NiMoO_4$, and *$Ni_{0.8}Mo_{0.2}$-oxide*).

XRD measurements were also performed (not shown here), illustrating the existence of different phases as a function of compositions. The predominant phase in $NiMoO_4$ is β-$NiMoO_4$, which has been proven to be more kinetically active in various chemical applications, compared to its α-$NiMoO_4$ counterpart. In addition to the positive influence of the β-

phase, it can be purported that the high activity of $NiMoO_4$ is also related to the optimal electrical configuration that stems from the synergistic effect that is elicited upon combining Ni and Mo [5]. Different theories have been proposed to explain this phenomenon, among which the most notable is the spill-over theory.

Long-Term Stability

The long-term stability of the most electrocatalytically active material ($NiMoO_4$) is compared to that of the state-of-the-art 20% Pt/C, as portrayed in Fig. 4. Despite the large overpotential at which the experiment is conducted (-350 mV vs. RHE), the performance of $NiMoO_4$ is stable after 24 h. The satisfactory stability of $NiMoO_4$ can be attributed to the favorable surface chemistry of mixed metal oxides due to their electron-filled *s* shells. On the other hand, the activity of 20% Pt/C drops precipitously in a linear fashion. The decay in performance of 20% Pt/C is likely due to the underpotential deposition phenomenon – commonly observed for bulk Pt [6].

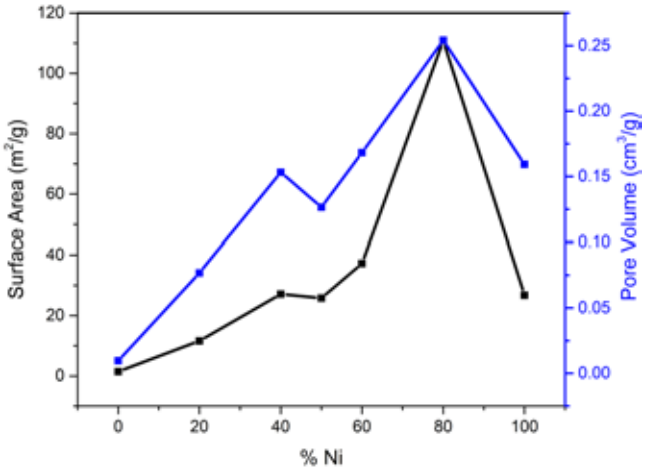

Fig. 3. The variation of surface area and pore volume as a function of nickel content.

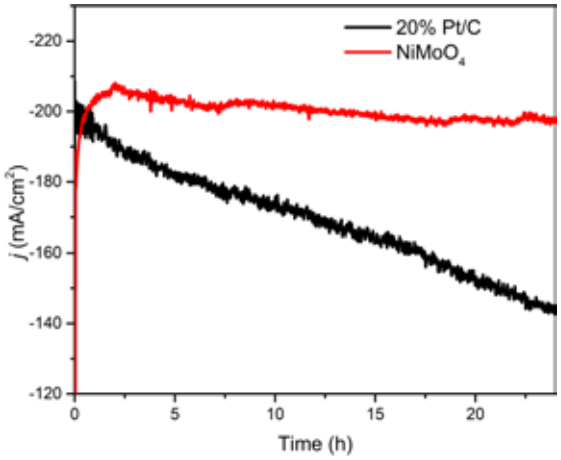

Fig. 3. Long-term stability of $NiMoO_4$ at an overpotential of -350 mV vs. RHE and the commercial 20 % Pt/C recorded at an overpotential of -250 mV vs. RHE.

CONCLUSIONS

Nanostructured Ni-Mo-oxides of several compositions were employed in the hydrogen evolution reaction in the acidic medium. The best-performing oxide composition exhibited a Ni:Mo ratio of 1:1 ($NiMoO_4$), with an HER current density of
190 mA/cm^2 at an overpotential of -350 mV vs. RHE. Different characterization techniques were employed to relate the electrocatalytic activity to the physicochemical properties of the materials, showing that an optimal electronic configuration brought about by alloying Ni and Mo is responsible for the high HER electrocatalytic activity of $NiMoO_4$.

As part of the European project QualyGridS, drafts for standardized testing protocols for electrolyzers to perform electricity grid services are defined and elaborated. These protocols are designed to be used by alkaline and proton exchange membrane (PEM) electrolyzers up to the Megawatt scale. The protocols are being submitted for standardisation. Testing results using these protocols on a state-of-the-art PEM electrolyzer system of 50 kW with 1500 cm^2 area stack are presented with considerations of the influence of balance of plant (BOP) components. System behaviour of 50 kW and Megawatt PEM electrolyzers are compared to determine the influence of their scale in performance and response time. An economic analysis has been conducted in the scope of the project. Today's situation has been analyzed in a first part: the objective was to identify the best way to combine H_2 supply for a primary value stream and provision of grid services. A second part of the analysis studied the potential future evolutions that could change the current picture.

Keywords: PEM electrolyser, grid service, dynamics

INTRODUCTION

The potential of water electrolyzers (WE) to provide different services to the grid has been widely discussed in the literature [1-3] as well as initially demonstrated in pilot projects in the EU [e.g. 4]. The electrolysers are capable to generate hydrogen for different applications, as flexible loads are connected and disconnected when demanded by electricity distributors (Transmission System Operators (TSO), Distribution System Operators (DSO) and peer-to-peer operators) and gas grid operators. Thus, flexibility is defined as the modification of injection (through generation) to the grid and/or withdrawal (through consumption patterns) from the grid, in reaction to an external signal in order to provide a service within the energy system [5]. For electric grids, it implies covering certain parameters like amount of power modulation, duration, rate of change or response time. Flexibility is going to be increasingly needed in the EU due to widespread introduction of renewable energy sources (RES) in the electric grid in such a way that non-dispatchable generation will replace the traditional generation. In this context, the benefits from flexibility in the demand side may lead to key achievements such as: (i) being able to increase the amount of RES in the system, (ii) avoiding or delaying network reinforcement; (iii) systems operators being able to successfully match generation and demand.

Some of the gaps for further market penetration of electrolyzers operating on renewable electricity are the precise analysis of performance requirements, definition of standardized tests for qualification of electrolysers and development of business models combining various electrolyzer uses. These issues are addressed throughout the QualyGridS project [6].

SCIENTIFIC APPROACH

Based on existing electricity grid services in the European countries with the published prequalification procedures and typical operation patterns testing protocols for electrolysers were worked out. The grid services are grouped based on the recommendations of ENTSO-E, however there are still differences between the countries. Recently some changes of the services were seen based on the EU Commission Regulation 2017/1485 [8] giving guidelines for transmission system operation.

Testing protocols from our project QualyGridS try to unify the variations in the grid services throughout Europe to make sure that an electrolyzer passing these tests will be capable of doing grid services in all countries that offer this service. With specific tests for given grid services as well as basic characterizations identifying the most relevant capabilities for this application parameters like dynamics and stability are tested.

An example of such a unified testing protocol for FCR (Frequency control reserve) is given in Figure 1. FCR requires the fastest power variations of the different services available in many countries and can achieve interesting remuneration rates.

The testing protocols were applied to a 50 kW electrolyzer operated at DLR (Fig. 2). This PEM electrolyzer manufactured by Hydrogenics uses a 6-cell 1500 cm^2 area stack and can be run up to 2 A/cm^2. Stack and system concept are built in an equivalent way as for the 1.5 MW PEM electrolyzer operated at Uniper in Reitbrook, Hamburg. However, the 50 kW electrolyzer can be considered rather as a test bench for the large area short stack and it is by no way an optimized system for an electrolyzer with 7.5 Nm^3/h hydrogen production.

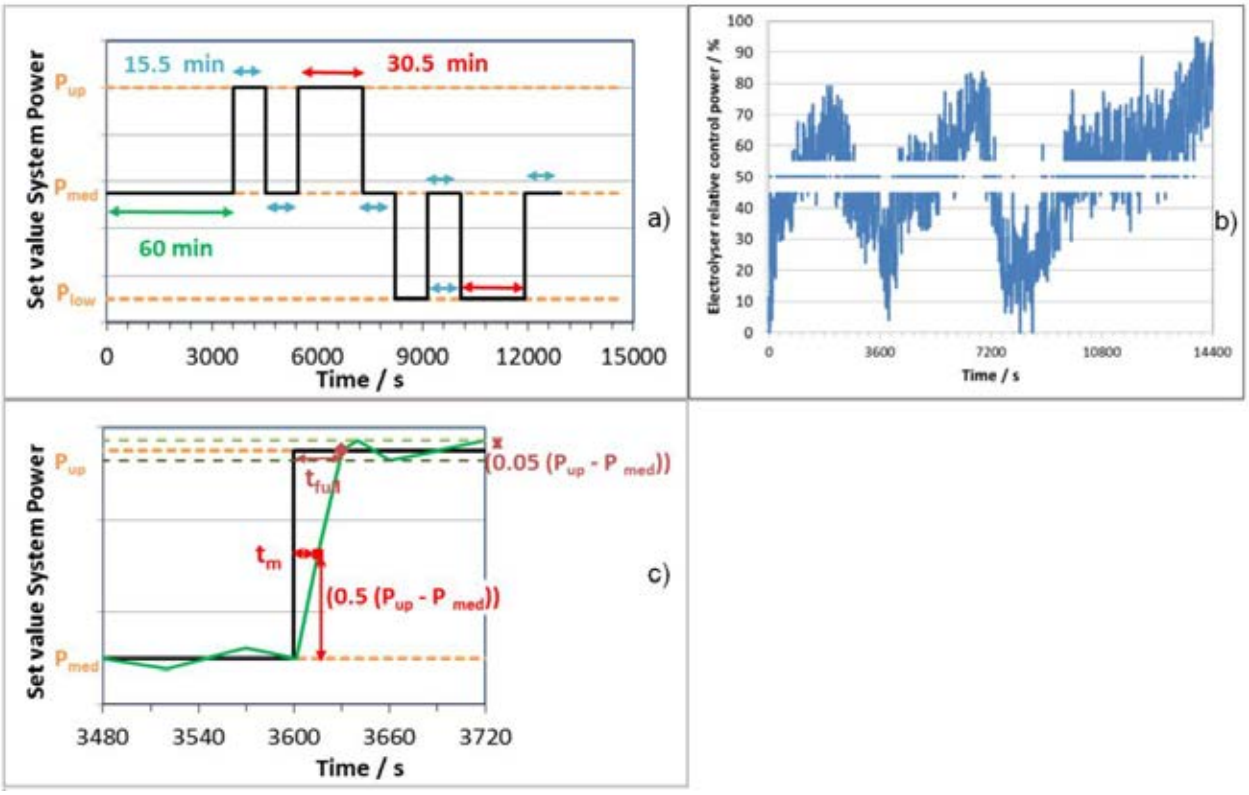

Fig. 1: QualyGridS suggested unified FCR testing protocols and evaluation. a) Testing protocol part 1 derived from prequalification procedures; b) Testing protocol part 2 derived from a real case of grid frequency input; c) Evaluation of activation times and stability. Pass criteria: t_m. ≤ 15 sec, t_{full} ≤ 30 sec, stability ≤ 0.05 (P_{up}-P_{med})).

Fig. 2: process room (left) with stack and operation room (right) with HMI (Human machine Interface) and DI water processing of 50 kW experimental electrolyser used at DLR

RESULTS AND DISCUSSION

The reaction of the stack power to the step power change request will be given in the presentation. While the stack behaviour is comparable at all scales and highly dynamic the system architecture, control strategies, volumes and dynamics of components have a strong influence on the ramping rates and the stability of the total power consumption. In comparison a startup ramp from hot standby of the 1.5 MW electrolyzer is shown. FCR requests a maximum duration of the ramp of 30 seconds. This is achieved by the full size electrolyzer but not by the experimental smaller electrolyzer. The reason for the slower behaviour of the smaller system is the setup of the BOP components: pressure control is slower, ramp speed of the rectifier is limited and the safety conditions for the system prevent it from faster changes. However the 1.5 MW system is not designed for very fast changes of power. Hydrogenics has with the same stack technology also set up a 2.5 MW electrolyzer in Markham, Canada, that follows the grid's power request within seconds [7].

Similarly alkaline electrolyzer systems are tested in the project and it could be shown that with the right systems setup they can just as well achieve the necessary dynamics and stability to perform grid services.

The economic analysis of electrolyzers performing grid services was set up in several stages: in a first stage 2017 economic data of grid services in Europe were collected and a few attractive grid services were selected. An assessment of the potential revenue for a water electrolyzers that could come from the participation to grid services was made considering the situation of today with the best way to combine H_2 supply for a primary value stream and to provide grid services [9]. Dynamic simulations with optimization of the operating strategy and of the size of the system were performed.

A second part of the analysis studied the potential future evolutions that could change the current picture. Simulations were done on prospective scenarios, highlighting notably the potential impact of electricity prices evolution on the results.

CONCLUSIONS

Similar grid services can be characterized by a generic testing protocol that should qualify an electrolyzer for a given grid service in most European countries trading this service. The requirements about dynamics of power ramping, stability and precision of reaching a given power, duration of keeping the new power level as well as power capacity if no aggregation is possible are characterising the different services. PEM and alkaline electrolyser systems have shown the capability of fulfilling the requirements of the services with proper adaptation of the system BOP. More services for which there is no clearly defined market and no prequalification procedures available will request similar performances of the electrolysers so that with the test results on the most popular services and some basic characterisation data of the system one can decide on the electrolyzer's capability. Providing grid services can contribute to an increased income of the electroyzer.

NICKEL COBALT OXIDE NANOCUBES AS AN EFFICIENT ELECTROCATALYST FOR HYDROGEN EVOLUTION IN ALKALINE SOLUTION

ABSTRACT

The use of hydrogen as a promising approach to meet the impending climate change and global warming has attracted a lot of attention. Electrolysis of water is one of the best ways to produce pure H_2. However, implementing water electrolysis for large-scale applications requires robust and efficient electrocatalysts that can sustain water splitting without corrosion. Here, we reported 3D nanocubes grown on Nikel foam ($NiCo_2O_4$/NF) by a hydrothermal method that can act as an efficient hydrogen evolution reaction (HER) electrocatalyst in alkaline solution (1M KOH). We have achieved a unique structure that exhibits exceptional HER activity (overpotential of 38 and 166 mV to drive current densities (j) of 10 and 100 $mA.cm^{-2}$). Such superior HER catalytic performance can be derived from the rough feature of the edges and synergistic effect between Ni and Co atoms and exposure to many active sites on the nanocubes. This discovery significantly helps us to design and synthesize low-cost and highly efficient electrocatalysts for large-scale hydrogen production from water electrolysis.

Keywords: $NiCo_2O_4$/NF, Nanocubes**,** Hydrothermal, Hydrogen Evolution Reaction.

INTRODUCTION

Hydrogen is considered as one of the most promising energy carriers due to its applications in reducing the global energy crisis [1]. Some methods to produce hydrogen are coal gasification, steam reforming methane, electrochemical water-splitting, etc [2]. Hydrogen generated by water electrolysers with renewable energy inputs, like wind and solar power, is a clean energy carrier due to no harmful by-products and zero-pollution emission [3]. Electrochemical water-splitting reaction ($2H_2O \rightarrow O_2 + 2H_2$) consisting of two half-reactions (oxygen evolution reaction (OER) anode $2H_2O\ (l) \rightarrow O_2(g) + 4H^+\ (aq) + 4e^-$ and hydrogen evolution reaction (HER) cathode $2H^+\ (aq) + 2e^- \rightarrow H_2\ (g)$) [4]. The benchmark and commercially electrocatalysts are platinum group metals (PGMs) with high catalytic activity, leading to low overpotentials to derive high current densities. However, using these materials at an industrial scale is not cost-effective due to their scarcity and high cost [5]. In recent years, significant research has been done to design and development of Earth-abundant-based electrocatalysts with good catalytic performance. Among many nonprecious metal alloys, sulfides, selenides, oxides, and phosphides, Ni and Co-based oxides are highly desirable in developing of efficient HER electrodes for the realization of hydrogen economy [6].

MATERIALS AND METHODS

In this work $NiCo_2O_4$/NF nanocubes have been developed by hydrothermal method. To gain more insight in the characterization of the developed electrodes, ex-situ studies of the catalyst were performed by using X-ray diffraction (XRD), field emission scanning electron microscopy (FE-SEM). All electrochemical characterizations were investigated by a standard three-electrode system in 1M KOH.

RESULTS AND DISCUSSION

FESEM images demonstrated the uniform formation of 3D nanocubes of Ni and Co on Ni foam with highly rough edges. (Fig. 1a and 1b). Such unique homogeneous nanocubes structure provides a large surface area and thereby enabling an outstanding electrocatalyst performance [7, 8]. The X-ray diffraction (XRD) analysis revealed the product is the phase of cubic $NiCo_2O_4$ (JCPDS 00-020-0781) (Fig. 1c). To determine the electrocatalytic performance, we used the Linear Sweep Voltammetry (LSV) technique with a scan rate of 20 mV s^{-1}. (Fig. 2a) exhibits a superior catalytic activity of 3D nanocubes $NiCo_2O_4$/NF compared to previous work, only requires an overpotential of 36 mV to achieve current density of 10 $mA.cm^{-2}$. For more evaluate the electrocatalytic activity of electrode, electrochemically active surface area (ECSA) (Fig. 2b) was assessed by the measuring double-layer capacitance (C_{dl}). The Nyquist plots (Fig. 2c) from Electrochemical impedance spectroscopy (EIS) measurement shows the charge transfer resistance (R_{ct}) for the prepared electrode is small and indicated the fast reaction kinetics for HER.

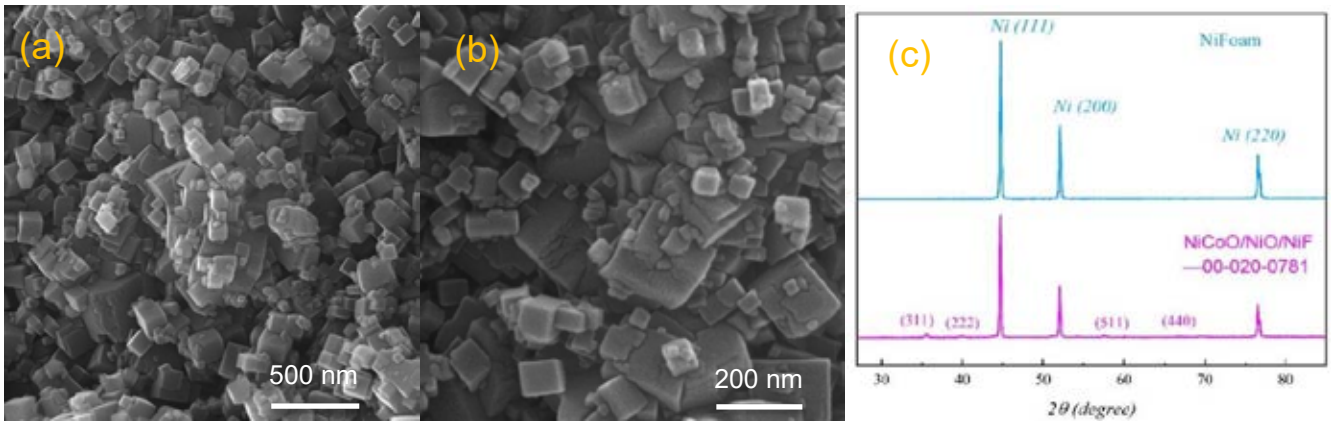

Fig. 1. (a, b) FE-SEM images of $NiCo_2O_4$/NF and (c) XRD patterns of $NiCo_2O_4$/NF and Ni Foam

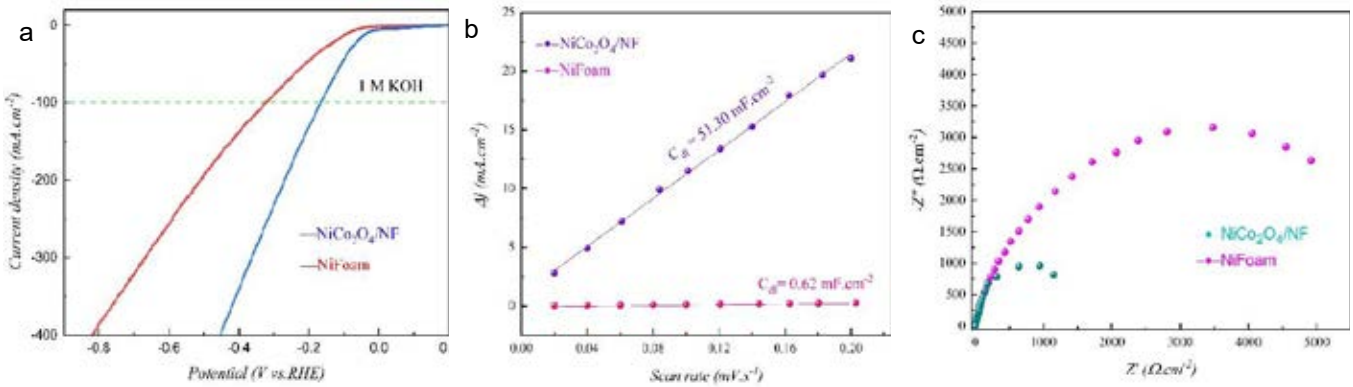

Fig. 2. (a) HER polarization curves in 1 M KOH, (b) ECSA value and (c) EIS Nyquist plots of $NiCo_2O_4$/NF and Ni Foam.

CONCLUSION

In summary, we have demonstrated a significant electrocatalytic HER activity of $NiCo_2O_4$/NF (overpotential of 38 mV to deliver current density 10 $mA.cm^{-2}$) could be ascribed to the 3D nanocubes unique structure. Nanocubes presence significantly reduces the interfacial resistance to accelerate the charge-transfer kinetics of H_2 evolution.

ABSTRACT

The reversible operation as an electrolyzer of a commercialized molten carbonate fuel cell for the generation of syngas (H_2 & CO) has recently provoked the interest of researchers. In general, Electrolyzers have the benefit of storing the surplus of renewable energy. This type of electrolyzer can additionally transform CO_2 into valuable fuel due to its unique properties at dissolving and reducing carbon dioxide in its molten carbonate electrolyte. The capability of such electrolyzer represents a conceptual revolution in the energy sector with a wide range of applications. This work presents the co-electrolysis of CO_2 and H_2O model of the Molten carbonate electrolyzer (MCEC). The one-dimensional steady-state model was created by making some changes to previously published work to introduce CO_2 electrolysis. To some extent, the model findings matched the previous model, which only took H_2O electrolysis into account. The discrepancies are driven by the chemical extent of the CO_2 electrolysis reaction in conjunction with the chemical reverse water gas shift reaction. These discrepancies highlighted the necessity of considering CO_2 electrolysis as the obtained cell voltage and temperature exhibited a higher value at the limiting current density by about 65% and 40%, respectively, than when CO_2 electrolysis is ignored.

Keywords: Molten carbonate Electrolysis cell, numerical modeling, co-electrolysis, Syngas production

INTRODUCTION

The molten carbonate electrolysis cell (MCEC) is a technology that may be utilized in power-to-gas systems. Its electrolyte's ability to trap large amounts of CO_2 offers an interest in reducing carbon dioxide within it to generate syngas (H_2 & CO) via a co-electrolysis process. The co-electrolysis of CO_2 and H_2O in molten carbonate electrolysis cells is being investigated to demonstrate the molten carbonates' capacity to electrolyze CO_2 into CO. Some studies were performed to examine the electrochemical conversion of CO_2 into CO in the MCEC. Peelen et al., 1998 [1] studied the electrochemical reduction of CO_2 into CO on a gold flag electrode in 62/38 mol % Li/K carbonate mixture in the temperature range 575–700 °C. Also, Kaplan et al., (2010,2012) [2], [3] reported the conversion of CO_2 to CO by using a cell with a molten electrolyte mixture of lithium carbonate and lithium oxide at 850-900 °C. The electrodes were graphite (anode) and titanium (cathode) and not conventional MCFC electrodes (Ni-based materials), and the working temperature was much higher than that of the MCFC system. All these studies proved the electrochemical conversion of CO_2 using flag electrodes instead of the conventional MCFC electrodes (Ni-based materials). Recently, Meskine et al., 2020 [4] have verified the electrochemical production of CO through CO_2 electrolysis with a limited maximum cell potential of 1.3 V to avoid the production of C instead of CO in the cell. Despite all of the research that has confirmed the CO_2 electrolysis inside the MCEC, no MCEC model study has considered CO_2 electrolysis. To date, all models assumed that CO is only generated chemically via the reverse water gas shift process. In this work, a developed model that considers only H_2O electrolysis, presented in [5], is adjusted to cover both H_2O and CO_2 electrolysis in the MCEC.

MODEL

In this model study, both H_2O and CO_2 electrolysis are considered assuming that the total current is divided between the two electrolysis according to the following equation Eq. (1) and Eq.(2).

$$I_{H2O} = \beta . I \quad (1)$$

$$I_{CO2} = (1 - \beta) I \quad (2)$$

The parameter β refers to the repartition of the electrode active sites between both electrochemical reactions [6]. It can be expressed by the relative percentage of inlet H_2O (Y^{in}_{H2O}) and CO_2 (Y^{in}_{CO2}) at the electrode interface (Eq. (3)).

$$\beta = \frac{Y^{in}_{H2O}}{Y^{in}_{H2O} . Y^{in}_{CO2}} \quad (3)$$

Based on this assumption, the developed model in [5] consisted of a material balance, energy balance, and electrochemical model is modified accordingly. The material balance involves both the electrochemical reactions (CO_2 and H_2O electrolysis) taking into account the current density split for determining the amount of H_2O and CO_2 reacted electrochemically, and the chemical reaction (the reverse water gas shift (RWGS) reactions), stated in [5]. The energy balance in [5] is generally unchanged; however, the heat of the reaction includes an additional term referring to the heat generated or consumed by the CO_2 electrolysis. As for the electrochemical model, the cell potential equation remains unchanged whereas the Nernst voltage (V_{nernst}) and reversible voltage (V_{rev}) are modified to consider the CO_2 electrolysis, as presented in Eq. (4) and Eq. (5), respectively.

$$V_{nernst} = V_{rev} - \frac{RT}{n_e F}\ln\left(\frac{P_{H2O}}{P_{H_2}.P_{CO}.P_{O2}}.\frac{P^3_{CO2,fe}}{P^2_{CO2,oe}}\right) \quad (4)$$

$$V_{rev} = \frac{\Delta G^0_{H2O\ electrolysis} + \Delta G^0_{CO2\ electrolysis}}{4F} \quad (5)$$

RESULTS AND DISCUSSION

The model results demonstrate the impact of the current density on the cell potential, the outlet composition of the cell, and the stream outlet temperature of the cell. In Fig. 1, the outlet composition of the H_2O, CO_2, H_2, and CO gases with the change in current density is depicted. The graph showed that the outlet H_2 gas composition (grey dotted line) increases in line with the decrease in the outlet H_2O gas composition (yellow dotted line), supporting the involvement of water in hydrogen production. However, the outlet CO gas composition (orange-solid line) drops with the increase in current density until reaching a specific current density (-0.2 A/cm^2), then suddenly increases. In parallel, the outlet CO_2 gas composition (blue-solid line) gradually decreases before falling rapidly to zero after a current density of -0.2 A/cm^2.

This discrepancy in the CO and CO_2 curves is better understood in Fig. 2, which explains the relationship of the outlet CO composition trend with the evolution of the CO_2 electrolysis and RWGS reactions. From this curve, two different sources can be extracted that define the cause of the deviation. The first source is the state where the RWGS equilibrium is not reached, which indicates that the RWGS reaction is not occurring in the cell, and CO is only

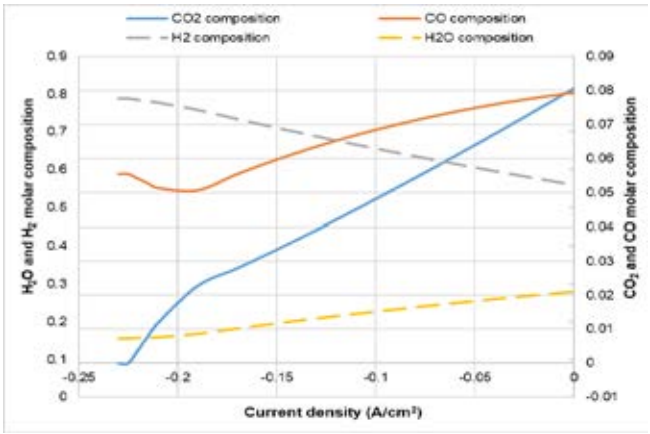

Fig. 1 : Gas Outlet Composition change with the current density (A/cm^2)

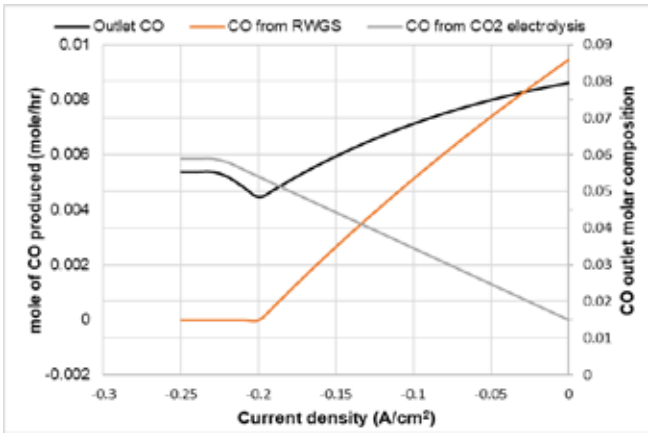

Fig. 2 : Outlet CO composition change and the mole of CO produced (mole/hr) from CO_2 electrolysis and RWGS versus current density (mA/cm^2)

produced by electrolysis process. From Fig. 2, it can be observed that at a current density -0.2 A/cm^2, the mole of CO produced by RWGS is zero, which means that the RWGS is not occurring. This state causes a deviated increase in the outlet CO trend, following the increasing trend of the CO produced by CO_2 electrolysis. The second source is the state where the limiting current density is reached by which CO_2 is totally consumed. It can be noticed in the CO_2 composition curve in Fig. 1 that after a certain current density (-0.23 A/cm^2), the outlet CO_2 composition reaches zero, which implies that the CO_2 is totally consumed. At this stage, the cell operation is at the limiting current density of -0.23 A/cm^2, and it can't function at a current density above this limiting one. This situation is also represented by a sudden increase in cell potential (Fig. 3) when approaching the limiting current density due to higher concentration losses created by the low CO_2 reacting agent. Besides, the outlet gas temperature sharply increases from 850°C (-0.225 A/cm^2) to 1060 °C (-0.23 A/cm^2) as the cell potential when reaching the limiting current density, as illustrated in Fig. 4. These outcomes of the cell potential and cell temperature in the case of limiting current density were corroborated by A. Szczęśniak et al., 2020 [7] when they investigated the impact of different malfunctions on the

molten carbonate fuel cell's operation. Low feed gas flow was one of these malfunctions that led to a drop in cell voltage during fuel cell operation and a significant increase in cell temperature. In the reverse mode, this malfunction reflects the sharp increase in cell voltage and temperature.

In comparison with the results of the previous model in [5], both models are comparable before reaching the state of deviation in the co-electrolysis case. This similarity can be explained by two factors. The first one is that the total current density applied to the cell is the same for both models, where this current is only employed for H_2O electrolysis in the previous model while it is split between H_2O and CO_2 electrolysis in the current model. The second one is the equilibrium balance of the reverse water gas shift reaction with the CO_2 electrolysis reaction, which results in a similar gas composition between the two models.

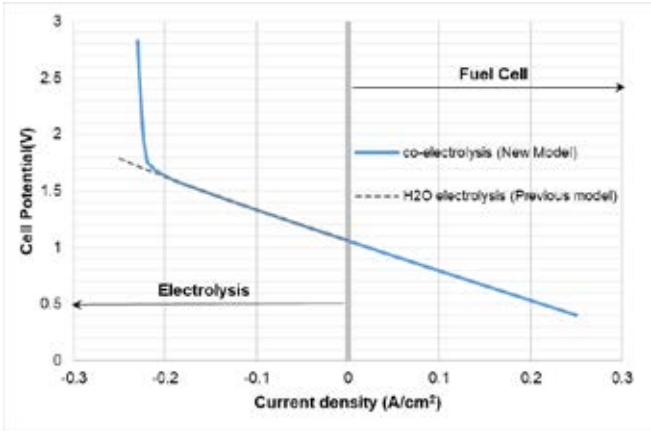

Fig. 3 : Cell potential versus the current density (A/cm^2) during electrolysis operation and fuel cell operation

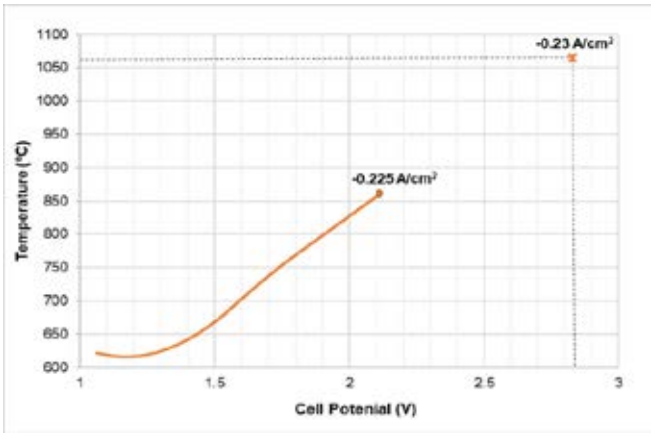

Fig. 4 : Gas outlet Temperature as a function of the cell potential (V)

CONCLUSION

The co-electrolysis model provides a helpful foresight on the operating conditions of the cell. The occurrence of the CO_2 electrolysis limits the current density for a safe cell operation. If the limiting current density is reached when considering CO_2 electrolysis, the cell voltage and temperature will be higher than the values obtained when neglecting CO_2 electrolysis ([5]) by around 65% and 40%, respectively. This state can be problematic for the safety of the cell operation as high cell voltages and temperatures can cause cell degradation.

ABSTRACT

In this study, sustainable portable renewable energy generation system with hydrogen production and desalination of sea water is proposed. For this purpose, a wind turbine, photovoltaic panels (PVs), parabolic through solar collectors (PTSCs), flash turbine, organic Rankine cycle (ORC), water electrolysis system, reverse osmosis unit (RO) and storage tanks are constructed on a ship. This system is suitable for coastal settlements with high solar and wind potentials which are short of drinking water and electrical energy. It is an advantageous system in that going to a place where it is needed and meet the demand there. This integrated system is conceptually modeled and simulated using Engineering Equation Solver (EES) software. Thus, the system produces 5947.20 MJ electric energy and 468.56 g of hydrogen with 38.06% and 38.87% maximum energy and exergy efficiencies, respectively.

Keywords: Wind Turbine, Photovoltaic Panels, Parabolic Collectors, Hydrogen Production, Desalination.

INTRODUCTION

In recent years, the cost of electricity generation has been reduced by the use of wind turbines. The wind turbines have high efficiency and they can play an active role to meet the world's energy need. [1]. So, using wind turbines reduce the energy cost for desalination of sea water for the coastal settlements. The minimum energy needed for ideal desalination is the Gibbs free energies difference of the seawater and freshwater. The results show that the minimum energy consumption for the ideal desalination process increases with increase of the salinity of seawater and operation temperature [2]. The specific purpose of this study is to assist the studies that can be carried out in order to provide quick service to coastal settlements experiencing freshwater and electricity problems in certain time intervals.

MATERIALS AND METHODS

The proposed integrated system consists of a wind turbine which has a 34 m blade radius, PVs which has an area of 128 m^2, PTSCs which has an area of 200 m^2, a flash turbine, an ORC, a water electrolysis unit, a RO system and storage tanks. Fig.1 illustrates the overall system schematic. The integrated system is built on a ship for taking it to the other coastal places with high solar and wind potentials. It is aimed to meet the energy and potable water needs of people elsewhere. The output powers of the wind turbine and the PVs are integrated via wind-solar hybrid charge controller and connected to a power controller unit to deliver the city grid. In addition, the generated power by the flash turbine is also connected to the power controller unit. On the other hand, produced potable water and hydrogen are stored in suitable tanks.

Analyses of the system

This hybrid system generates electricity through wind turbine, PVs and PTSCs. The efficiency of the system is highly dependent on the generated electricity. Finding the performance of the hybrid system is extremely important for evaluating the system as thermodynamically. The energy and exergy efficiencies of the hybrid system are found as follows, respectively:

$$\eta_{sys} = \frac{\dot{E}_{U,sys}}{\dot{E}_{in,sys}} \quad (1)$$

$$\psi_{sys} = \frac{\dot{E}x_{U,sys}}{\dot{E}x_{in,sys}} \quad (2)$$

The net power is obtained for Fig.1 as follows:

$$\dot{W}_{net} = \dot{W}_{wind} + \dot{E}_{PV} + \dot{W}_{turbines} - \left(\dot{W}_{pump1} + \dot{W}_{pump2} + \dot{W}_{pump3} + \dot{W}_{pump4} + \dot{W}_{pump5}\right) \quad (3)$$

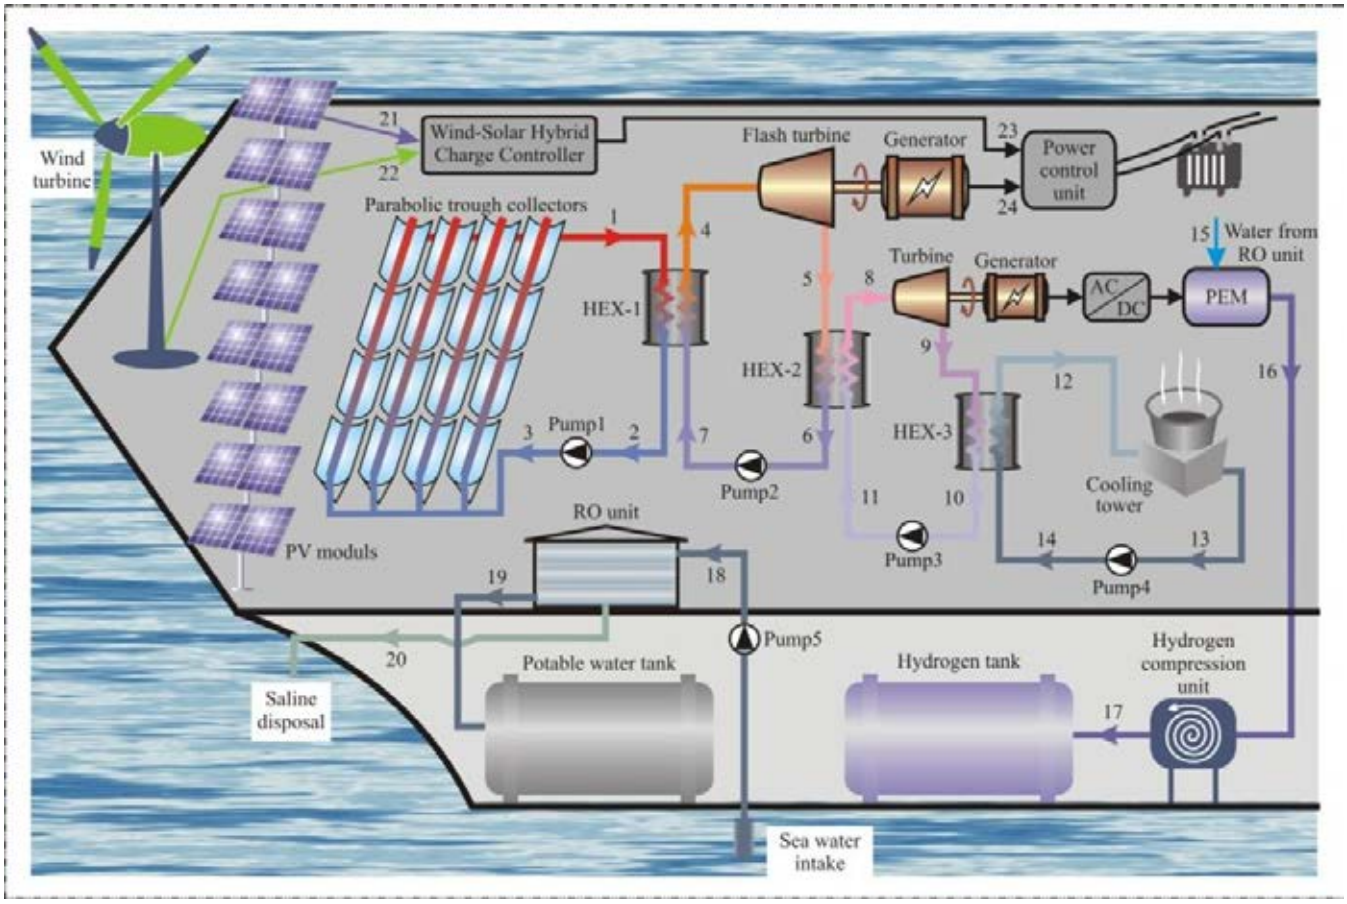

Fig. 1. Schematic of the proposed system harvesting wind and solar energy.

RESULTS AND DISCUSSION

The performance of the hybrid system was investigated under daily solar radiation and average wind speed for selected day in August. Fig. 2 shows the average energy on the wind turbine, PVs and PTSCs between 8:00 a.m. and 5:00 p.m. The maximum solar radiation on the PVs was found as 125.13 kW between 11:00 a.m. and 13:00 p.m. for the selected day in August. The minimum solar radiation on the PVs was found as 60.67 kW between 16:00 p.m. and 17:00 p.m. The maximum direct solar radiation on the PTSCs was found as 162.36 kW between 11:00 a.m. and 13:00 a.m. for the selected day in August. The minimum solar radiation on the PTSCs was found as 78.02 kW between 16:00 p.m. and 17:00 p.m. Wind speed was taken as constant at 5.3 m/s and the wind turbine generates 329.64 kW of energy for a day. Fig. 3 shows energy and exergy efficiencies of the overall system. The maximum and minimum energy efficiencies of the overall system were found as 38.06% and 29.94%, respectively. The maximum and minimum exergy efficiencies of the overall were found as 38.87% and 30.95%, respectively.

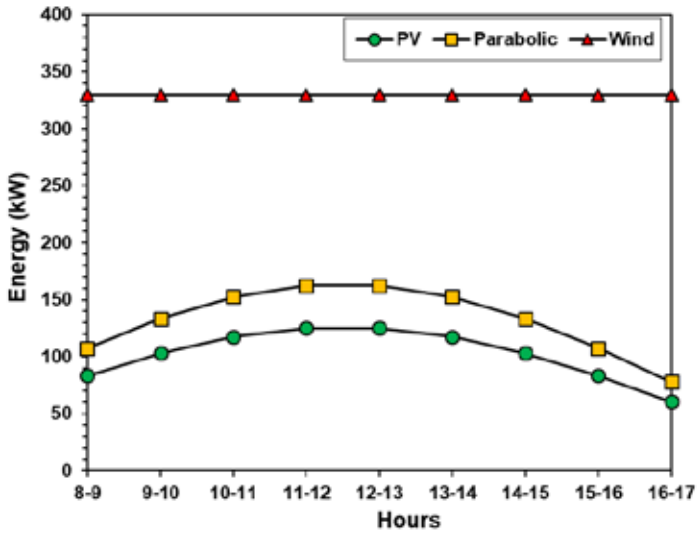

Fig. 2. Average energy on the wind turbine, PV and parabolic solar collectors

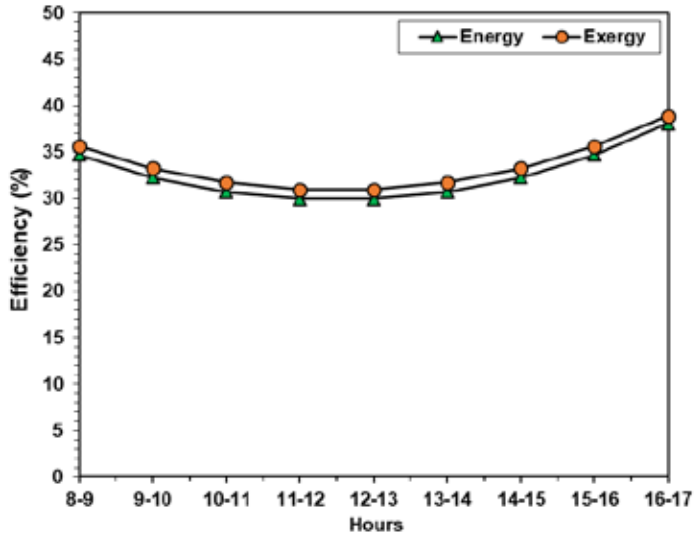

Fig. 3. Energy and exergy efficiencies of the overall system.

CONCLUSIONS

In this study, energy and exergy analyses and electricity and hydrogen production of the hybrid system were investigated. So, a total of 5947.20 MJ electric energy and 468.56 g of hydrogen were produced by hybrid system for a daylight selected in August.

ABSTRACT

In this work, electricity, hydrogen production performance of parabolic trough solar collectors (PTSCs) integrated with a solar pond is researched. The system consists of the PTSCs with the surface area of 100 m^2, a solar pond with the surface area of 100 m^2, an Organic Rankine Cycle (ORC) which is operated with n-butane for electricity production, and a proton exchange membrane (PEM). In order to improve the overall system performance, n-butane is selected as working fluid in the ORC and the waste heat of the ORC is used in the mushroom production unit. In addition, the low-temperature water coming from the solar pond was circulated to the PTSCs via a pump and the temperature of the water was increased by the PTSCs. Thus, the temperature of this preheated water is upgraded by the PTSCs, and it increase the electricity performance of the ORC. The electricity is used to produce hydrogen by PEM. The analyses of the integrated system are determined with Engineering Equation Solver (EES) for a daily solar energy in July. So, an integrated energy generation system is simulated and it is occurred entirely of renewable energy systems. As a result, it has been found that if the integrated system components are improved, the heat, electricity and hydrogen production can be increased considerably.

Keywords: Solar pond, Parabolic trough solar collectors, Organic Rankine Cycle, Hydrogen production, Exergy

INTRODUCTION

One of the most important renewable sources is solar energy. It uses for producing heat, electricity and hydrogen by solar energy technologies. One of the important solar technologies is solar pond. It is converted to solar energy to store as heat in the storage zone (HSZ) [1]. The stored thermal energy can be transferred to another technology to increase the heat performance in the integrated systems [2]. One of the systems producing thermal energy by using solar energy is parabolic trough solar collectors (PTSCs) that is known one of the most solar technologies to harvest solar energy [3]. High-grade thermal energy sources are already used for generating electricity. However, to generate electricity from low-temperature energy sources is also essentially important. ORC is one of the most important systems that produce electricity from low-grade sources. If the ORC is integrated with the solar energy technologies, electricity production of the ORC can be improved [4].

In this study, an integrated solar energy system for multiple energy generation based on solar energy was simulated by using the engineering program to solve with EES and the daily energy production performance of the system was tried to be improved. The inlet water of the parabolic solar collector was preheated through the solar pond and maximum outlet water was obtained in a sunny day in July. The maximum output of ORC with daily hot water is increased. At the same time, PEM was operated with this electricity and hydrogen was produced from water in it. In addition, the waste heat from the ORC was used in a mushroom production facility. Thus, this new integrated system was operated from 9 am to 3 pm for a sunny day in July to determine heat, electricity and hydrogen production performance of the system.

MATERIALS AND METHODS

The Fig.1 shows that the integrated energy system which occurs of solar pond, PTSCs, an ORC and electrolysis system. The purpose of the system is to generate high amounts of electricity and hydrogen and also to heat a mushroom production unit with waste heat. The role of the PTSCs is to provide the hot water for pumping the ORC. The temperature of the water coming from solar pond is upgraded by the PTSCs. Thus, the hot water is pumped the ORC to produce significant amount of electricity for hydrogen production as a final output. In Fig. 1 initially, the water transferred by a pump1 from the solar pond, it enters in the PTSCs from point 2. In a short time, the temperature of the water can reach up to higher than heat storage temperature of the solar pond and it enters the evaporator from point 3. A lot of the energy of water transfers to the evaporator to increase the temperature of working fluid (n-butane) in the ORC. Thus, n butane exits the evaporator from point 6 and it expands throughout the turbine to produce electricity. The electricity is transferred from point 12 to the PEM for hydrogen production. At the end of the process,

hydrogen is generated by electrolysis system from point 13 for storing in a tank. And also, n-butane come out of the turbine to enter the condenser from point 7 where it is condensed and the waste heat in the condenser is transferred for heating a mushroom production unit. Thus, the energy and exergy efficiencies of the overall system can be significantly increased.

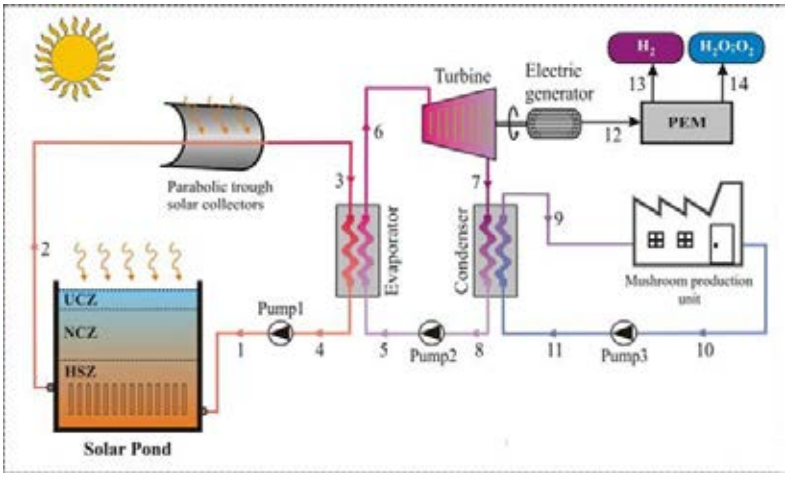

Fig. 1. Parabolic trough solar collectors integrated with solar pond for hydrogen production based on solar energy

Analyses of the integrated system.

Solar pond stores solar energy as thermal energy in the storage zone of it. Finding the performance of HSZ is extremely important for the solar pond. The energy efficiency of the HSZ is obtained as follows:

$$\eta_{HSZ} = \frac{\dot{E}_{HSZ}}{\dot{E}_{in,solar\ pond}} \quad (1)$$

Besides, another one of the solar energy technologies is the PTSC that converts solar energy into thermal energy. PTSC upgrades temperature of the inlet fluid from low-grade to high-grade to exit it. Energy efficiency of the PTSC is found as follows:

$$\eta_{PTSC} = \frac{\dot{E}_U}{\dot{E}_{PTSC}} \quad (2)$$

Thus, hot water is circulated to the ORC by a pump for producing electricity. The ORC operates the thermal energy that is transferred from low-middle grade sources for electricity production at. The net power is obtained for Fig.1 as follows:

$$\dot{W}_{net} = \dot{W}_G - \left(\dot{W}_{pump1} + \dot{W}_{pump2} + \dot{W}_{pump3}\right) \quad (3)$$

RESULTS AND DISCUSSION

In this study, performance of the integrated system was investigated under daily solar radiation for selected a day in July.

The integrated system produced a lot of electricity and hydrogen from solar energy. Fig. 2 shows the average solar radiation on the solar pond and parabolic solar collectors from 9 a.m. and 3 p.m. The maximum solar radiation on the solar pond was found as 890.6 W/m^2 and 890.6 W/m^2 between 11-12 hrs and 12-13 hrs for the selected day in July, respectively. The minimum solar radiation on the solar pond was found as 756.2 W/m^2 between 9-10 hrs and 14-15 hrs.

PTSC is geometrically different from the solar pond. Therefore, the solar radiation reaching on the surface of the PTSCs could be found different. The maximum solar radiation on the PTSCs was found as 795.4 W/m^2 and 795.4 W/m^2 between 11-12 hrs and 12-13 hrs for the selected day in July, respectively. The minimum solar radiation on the PTSCs was found as 663.8 W/m^2 between 9-10 hrs and 14-15 hrs. Fig. 3 shows that the hourly electricity and hydrogen production of the ORC and electrolysis system. The maximum hourly electricity production of the ORC was found as 10.16 MJ between 12-13 hrs for the selected day in July, respectively. The minimum hourly electricity production of the ORC was found as 7.63 MJ between 9-10 hrs. ORC produced total electricity via hot water that is produced in the integrated system. One of the best ways to store electricity in the system is to convert it to hydrogen. Therefore, the electricity produced by ORC is transferred to the electrolysis system. The electrolysis system was

operated in 80% efficiency. The maximum hourly hydrogen production of the electrolysis system was found as 54.02 g between 12-13 hrs for the selected day in July, respectively. The minimum hourly hydrogen production of the electrolysis system was found as 40.57 g between 9-10 for the selected day in July, respectively.

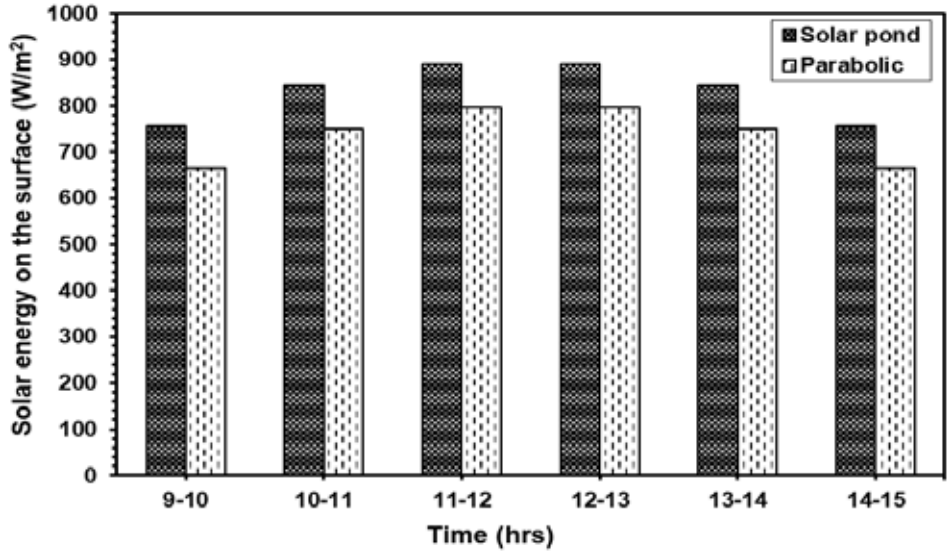

Fig. 2. Average solar radiation on the solar pond and parabolic trough solar collector

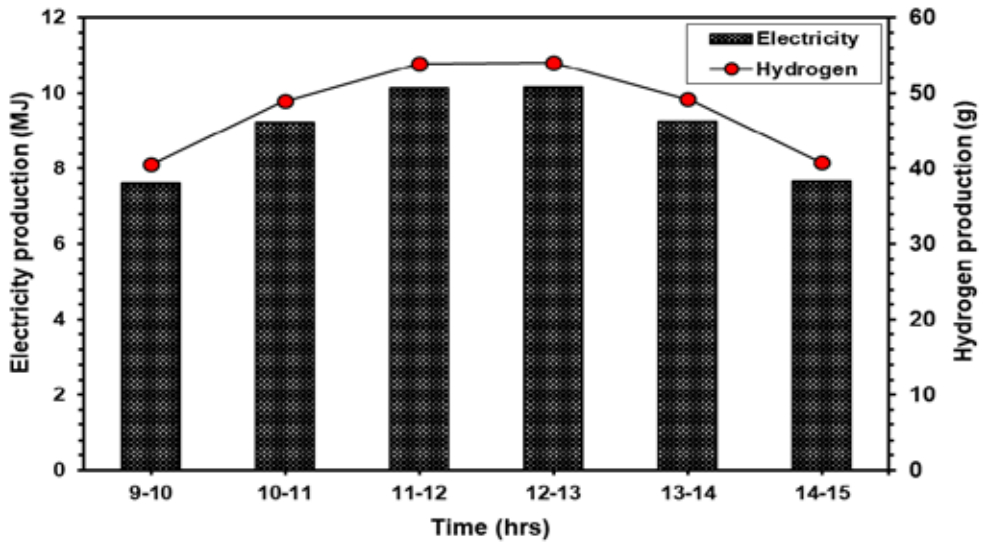

Fig.3. Hourly electricity and hydrogen production of the ORC and electrolysis systems

CONCLUSIONS

In this study, heat, electricity and hydrogen production of the integrated system were examined. The low temperature heat stored in the HSZ of the solar pond was increased to high temperature by means of PTSCs and then in the ORC was converted at high power electricity. Finally, the generated electricity by the ORC was used hydrogen production by the electrolysis system. As a result, 54.083 MJ of electricity and 287.56 g of hydrogen were produced for a selected day in July.

ABSTRACT

In this work, the electricity and hydrogen production performance of an integrated system is investigated. The system includes a flat plate solar collector (FPSC), a photovoltaic thermal (PV-T) panel, an Organic Rankine Cycle (ORC), a proton exchange membrane (PEM) and a building for fungus production. In order to improve electric production performance of the ORC is worked with n-butane. The FPSC and PV-T has 6.48 m^2 and 2.16 m^2 area for capturing efficiently solar energy. The analyses of the integrated system are found by employing Engineering Equation Solver (EES) under daily solar energy in July. So, the low-temperature water coming from the PV-T to FPSC via a pump is upgraded to higher degree. The heated water is transferred to ORC for generating electricity. Besides, electricity is produced by the PV-T. Thus, a lot of electricity is produced in the overall system, efficiently. Moreover, overall performance of the system is found for under daily solar radiation. As a result, it was found that integrated system generated much more thermal energy, electricity and hydrogen.

Keywords: Photovoltaic thermal panel, Flat-plate solar collectors, Organic Rankine Cycle, Hydrogen production, Energy and exergy analyses

INTRODUCTION

Solar energy is one of the most important clean and renewable sources that can be used instead of fossil sources. Technologies that generate electricity or thermal energy by using solar energy are solar collectors. One of the solar technologies is photovoltaic solar cell (PV) which directly generates electricity through solar energy [1]. Thus, PV can produce electrical and thermal energy through solar energy in a system that is known as photovoltaic thermal (PV-T). The waste thermal energy is transformed into beneficial shape by employing the heat exchanger through air or water [2]. One of the systems producing thermal energy by using solar energy is flat-plate solar collector (FPSC) [3]. One of the systems that produce electricity by utilizing the obtained thermal energy is ORC [4]. There has not been a study on the electricity and hydrogen production of FPSC integrated with PV-T for under daily solar energy. This work aim to analyze electricity and hydrogen production of new integrated system. For this purpose, a sunny day is selected in July. Thus, the system is investigated for electricity and hydrogen production in one of the warmest month of the year. System is operated under daily solar energy from 8 a.m. to 4 p.m. This case study is operated for Adana that one of the cities of Turkey.

MATERIALS AND METHODS

The system is seen Fig. 1 that consists of a PV-T, a FPSC, greenhouse and an ORC contains n-butane as an operating fluid for producing electricity, building for fungus production and a hot water storage tank. The system works as follows. Initially, fresh water is pumped to the PV-T by pump1 from point 1 to reach high-grade temperature by using waste heat energy in the PV-T via exchanger. The hot water is transferred from the PV-T to FPSC from point 2 to reach a higher degree than point 2. In a short time, the temperature of the water is increased to high-grade by the FPSC for pumping to the evaporator from point 3 and then water exits the evaporator from point 4 to enter the insulated hot water tank. While PV-T produces electricity, PV cells generate waste thermal energy which is extracted by water via exchanger to pump the FPSC. Also, the hot n-butane is pumped to the turbine by pump2 from point 5 for electricity production by using hot water in the system. Also, n-butane leaving the turbine from point 6 is condensed in the condenser and exits from point 7. Also, water is transferred from the fungus production building to the condenser by pump 3 from point 11, and the water enters from point 9 to the greenhouse for cooling and then it exits from point 10. Finally, the electricity is transferred from point 12 to the PEM for hydrogen production. At the end of the process, hydrogen is generated by the PEM electrolysis system from point 15 for storing in a tank.

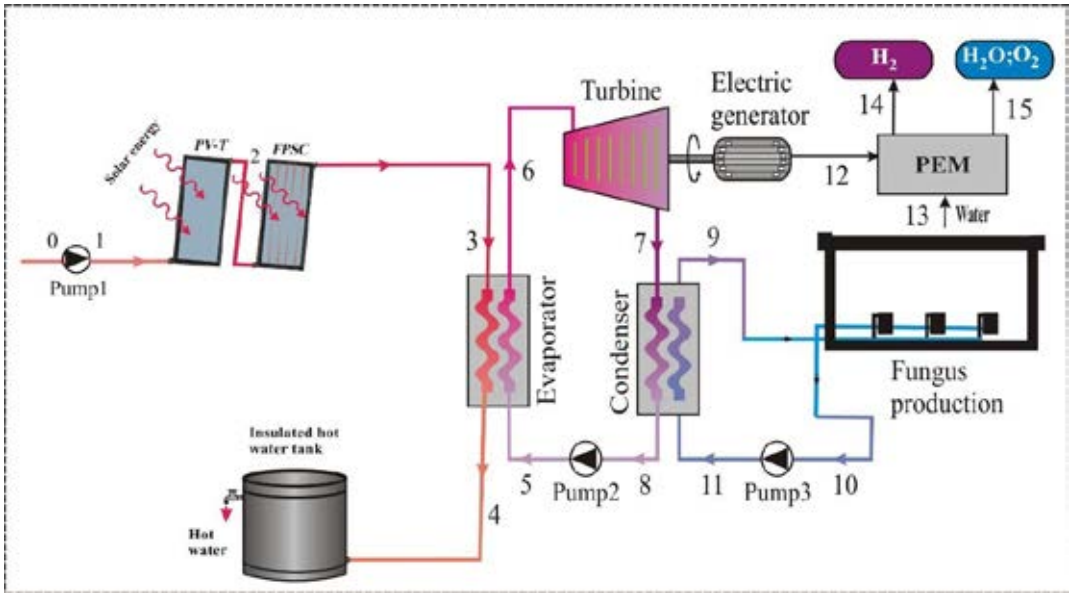

Fig. 1. A PV-T panel integrated with a FPSC for hydrogen production based on solar energy.

Energy analyses and electricity and hydrogen production off the system.

PV-T solar technology produces electrical and thermal energy by harvesting solar energy. While PV-T is converting solar energy into electricity, it also produces waste thermal energy. Electricity efficiency of the PV-T depends on the temperature of the PV which is given as follows [5]:

$$\eta_{el} = \eta_0[1 - \beta_{PV}(T_{PV} - T_0)] \quad (1)$$

One of the solar energy technologies is the FPSC that converts solar energy into thermal energy. FPSC upgrades temperature of the inlet water from low-grade to high-grade. Energy efficiency of the FPSC is found as follows:

$$\eta_{FPSC} = \frac{\dot{E}_U}{\dot{E}_{FPSC}} \quad (2)$$

The ORC operates the thermal energy that is transferred from the integrated system for electricity production at low-middle-high grade. The net power is obtained for Fig.1 as follows:

$$\dot{W}_{net} = \dot{W}_G - (\dot{W}_{pump1} + \dot{W}_{pump2} + \dot{W}_{pump3}) \quad (3)$$

RESULTS AND DISCUSSION

In this study, performance of the integrated system was investigated under daily solar radiation for selected a day in July. This integrated system produced a lot of electricity and hydrogen. Fig. 2 shows hourly electricity production of the PV-T and ORC from 8 a.m. and 4 p.m. for a day selected in July. The maximum hourly electricity production of the PV-T was found as 0.8997 MJ between 11-13 h for the selected day in July, respectively. The minimum hourly electricity production of the PV-T was found as 0.6551 MJ between 8-9 h and 15-16 h. ORC generates electricity with the help of hot water that is produced in the system from PV-T and FPSC. The maximum hourly electricity production of the ORC was found as 0.7075 MJ between 12-13 h for the selected day in July, respectively. The minimum hourly electricity production of the ORC was found as 0.4028 MJ between 8-9 h. One of the best ways to store electricity generated in the system is to convert it to hydrogen. Fig. 3 shows hourly hydrogen production of the electrolysis that is used electricity which was transferred from ORC and PV-T in the integrated system. The maximum hourly hydrogen production of the electrolysis (electricity was transferred from the PV-T) was found as 5.036 g and 5.036 g between 11-12 h and 12-13 h for the selected and the minimum hourly hydrogen production of the electrolysis was found as 3.667 g between 8-9 h and 15-16 h. The maximum hourly hydrogen production of the electrolysis (electricity was transferred from the ORC) was found as 3.762 g between 12-13 h for the selected and the minimum hourly hydrogen production of the electrolysis was found as 2.142 g between 8-9 h. The maximum hourly hydrogen production of the integrated system was found as 8.798 g between 12-13 h for the selected day in July, respectively. The minimum hourly hydrogen production of the system was found as 5.809 g between 8-9 h.

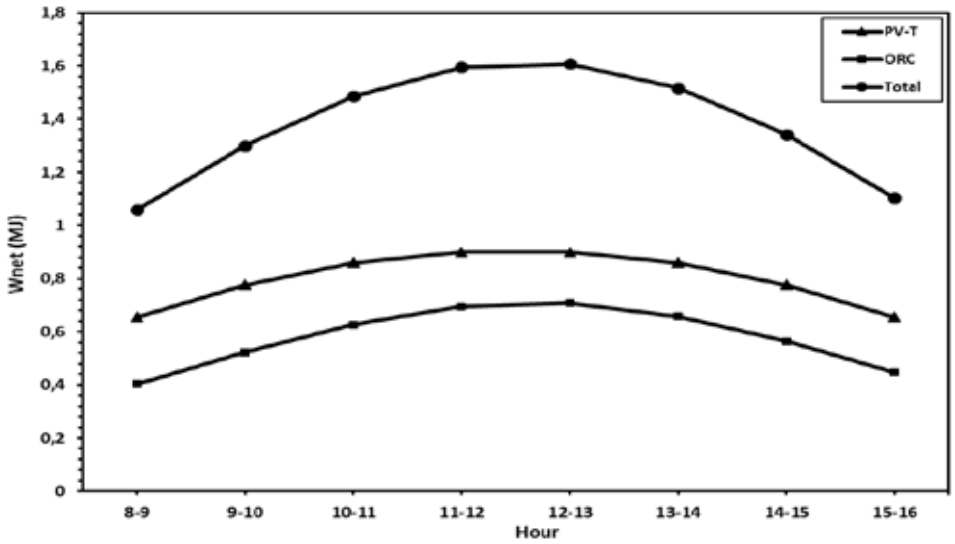

Fig.2 Hourly electricity production of the PV-T and ORC for a day selected in July.

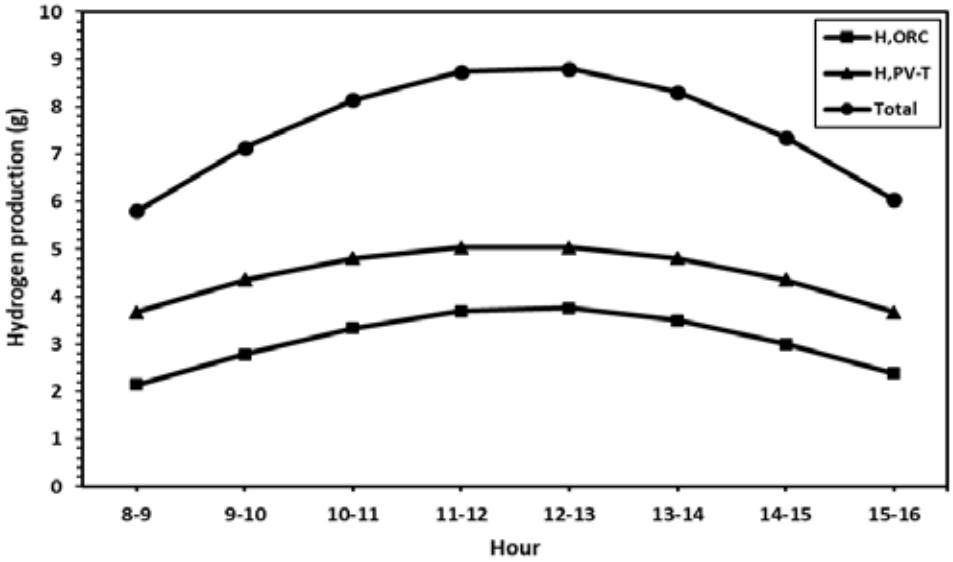

Fig.3 Hourly hydrogen production of the ORC, PV-T and integrated systems

CONCLUSIONS

In this study, electricity and hydrogen production of the integrated system were investigated. In this system, PV-T produced thermal and electrical energy under daily solar energy. If waste thermal energy of the PV-T is extracted by cold water, performance of the PV-T is increased. The waste thermal energy was transferred to the FPSC by means of cold water. Thus, the hot water coming from the PV-T was pumped to the FPSC and the temperature of the water in n the FPSC was upgraded from low-grade to high-grade via solar energy for pumping to the ORC to produce electricity. Finally, produced electricity in the ORC was transferred to electrolysis system for generating hydrogen to store a tank. A total of 11.0063 MJ and 60.314 g of electricity and hydrogen were produced by integrating for a day selected in July.

CRITICAL ASSESSMENT OF THE PRODUCTION SCALE REQUIRED FOR FOSSIL PARITY OF GREEN ELECTROLYTIC HYDROGEN

*Joris Proost
Université catholique de Louvain, Division of Materials and Process Engineering, 1348 Louvain-la-Neuve, Belgium

*Corresponding author e-mail: joris.proost@uclouvain.be

ABSTRACT

Hydrogen produced from renewable electricity through Power-to-Hydrogen can facilitate the integration of high levels of variable renewable electricity into the energy system. An electrolyser is a device that splits water into hydrogen and oxygen using electricity. When electricity is produced from renewable energy sources, electrolytic hydrogen can be considered to be green. Key green hydrogen production technologies, mostly PEM and alkaline electrolysers, are still further maturing, both in technical (efficiency), economical (CAPEX) and durability (lifetime) performance. Nonetheless, we will show in this contribution how fossil parity for green hydrogen, i.e. a Total Cost of Ownership (TCO) similar to grey H_2 coming from CO_2 intensive SMR processes, can already be achieved today. Moreover, this can be realised at a scale which corresponds to the basic units of renewable electricity generation, i.e. a few MW.

Keywords: power-to-hydrogen, electrolyser, renewable electricity, fossil parity

INTRODUCTION

Although water electrolysis as such is already a well-established H_2 production technology for almost a century, its large-scale implementation for the production of green H_2 has been hampered mainly by cost issues. In this respect, the current price of fossil SMR-based H_2 provides a very challenging benchmark. According to [1], the global hydrogen feedstock market represented in 2015 a total estimated value of 115 billion $, corresponding to a hydrogen demand of about 56 Mton/yr. From these numbers, the average market price for fossil H_2 can be estimated as 2.0 $/kg. In the current paper, we aim at critically assessing the production scale required to reach such fossil parity for electrolytic hydrogen.

RESULTS

Hydrogen production today

As of today, hydrogen is mainly being used as a specialty chemical in a number of applications. These are generally classified into 4 main categories : (1) the chemical industry, where H_2 is a basic building block for the synthesis of ammonia, methanol and a number of technical polymers; (2) a number of downstream refining processes, like hydro-cracking and hydro-treating; (3) iron, steel and glass manufacturing, where H_2 is the preferred reducing gas during annealing, blanketing and forming processes ; (4) other specialty applications, like the semiconductor industry, the use as a propellant fuel or the cooling of generators. As of today, the great majority of all of the above H_2 is being delivered by a centralised, off-site hydrogen production, dominated by 2 large-scale chemical processes: steam methane reforming (SMR) and coal gasification. Unfortunately, both of these processes are heavily CO_2 intensive, SMR emitting upto 8 tons of CO_2 per ton of H_2 produced. Therefore, with the objective of reaching the CO_2 emission targets also in todays fossil-based H_2 production, the part of green electrolytic hydrogen production from renewable electricity (which represents less than 4% today) can be expected to significantly increase over the coming years. However, in order to meet the current global H_2 demand of around 70 Mton/year, a total of 300 GW installed electrolyser capacity would be needed. As this represents already about 20% of the total installed renewable power capacity today, such massive electrolyser deployment is currently not very realistic. As a result, a selection of technologically feasible market penetrations for electrolytic H_2 needs to be made. Such selection then also implies that todays local H_2 consumers, besides becoming local (on-site) producers of renewable electricity, also need to become local (on-site) producers of electrolytic H_2, at a production scale which still allows to meet the stringent requirement of fossil parity at about 2.0 $/kg.

Green hydrogen production scale-up

Contrary to the intrinsically large-scale SMR, water electrolysis is intrinsically small-scale. Both the geometrical area of the electrodes (a few m^2 at most) and the number of electrodes that can be compiled in series in a single stack is relatively limited. As a result, the unit size of water electrolysers has long been limited to the kW-range, a typical on-site containerized production unit being a few 100 kW at most. However, in order to be able to realize the mandatory coupling to renewables, mainly wind and solar, the power scale of water electrolysers needs to become of the same order of magnitude as the renewable electricity source itself. This requires a major scale-up from the kW-scale, typical for state-of-the art electrolysers about a decade ago, towards the multi-MW scale typical for state-of-the art on-shore

wind turbines. Such an electrolyser scale-up is typically being realised by increasing the number of cells per stack. However, from the state-of-the-art data that we recently collected from a number of electrolyser manufacturers [2], such a "keep-on-stacking" approach seems to have an intrinsic limit at around 100 cells/stack. Beyond that number, other balance-of-plant issues come into play, including the risk of electrical shorts and the technological complexity of a safe large-scale gas collection. Therefore, for multi-MW applications, multi-stack electrolyser systems are typically being used.

DISCUSSION

The cost of electrolytic hydrogen

While it is technically feasible to produce green electrolytic hydrogen with such multi-stack systems at the multi-MW scale (even > 100MW), the critical question still remains at what price/cost. In this respect, the 3 major parameters affecting the electrolytic H_2 production cost are the operational time of the electrolyser, the cost of renewable electricity, and the electrolyser CAPEX [3]. Hence, before becoming a realistic alternative production technology, there is a need for cheap(er) renewable electricity (well below 70 Euro/MWh), the investment cost of electrolysers needs to be brought down (well below 1000 Euro/kWh), and there should also be a clear industrial commitment to CO_2 reduction. Luckily, with respect to these parameters, significant progress has been made over the past years. First of all, a significant price reduction for renewable electricity has already been realised for both solar PV and on-shore wind, with prices on the order of 30-40 $/MWh becoming realistic by 2025. Moreover, for alkaline systems, a CAPEX of 750 Euro/kW is already realistic today for a single stack 2 MW system. Moreover, as seen in Fig. 1, a significant further reduction in CAPEX as low as 450 Euro/kW is currently being projected for multi-stack systems when scaling up to 50-100 MW. Also note from Fig. 1 that single stack electrolysers are much more susceptible to CAPEX reduction than multi-stack systems.

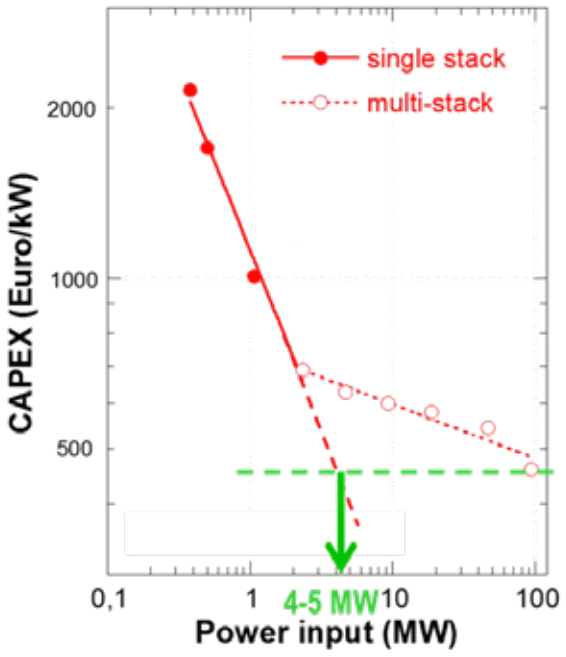

Fig. 1. State-of-the-art CAPEX data for alkaline electrolysers as a function of power input. The change in slope for alkaline electrolysers corresponds to the use of multi-stack systems.

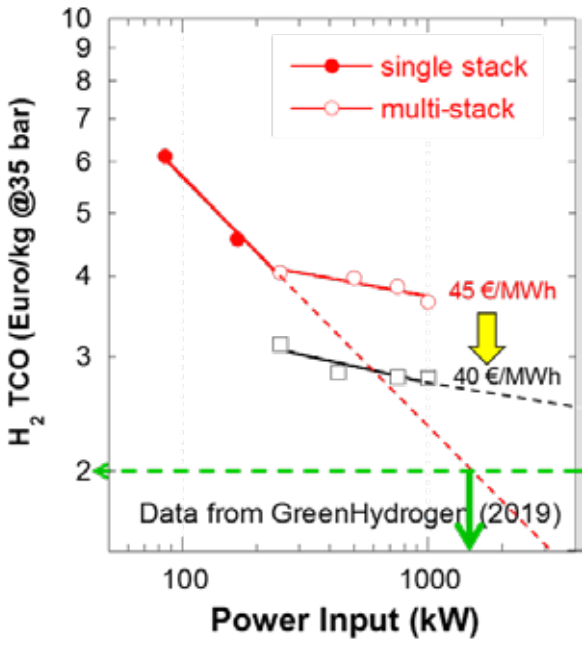

Fig. 2. Total Cost of Ownership (TCO) of electrolytic H_2, delivered at 35 bar, as a function of power input. OPEX includes the use of electricity, water and nitrogen (for purge), assuming a renewable electricity price of 40 and 45 €/MWh, respectively.

Based on the above updated numbers, a recent study from the International Energy Agency [4], allows to anticipate a significant reduction in the electrolytic H_2 production cost as a function of the available renewable electricity price, assuming the most favorable (but still realistic) CAPEX value of 450 Euro/kW. It shows that for a combination of high load factors and a non-zero but relatively low electricity cost, on the order of 30 $/MWh, the electrolytic H_2 production costs can be competitive with SMR.

The scale of fossil parity for green hydrogen

A final issue then relates to the production scale required for obtaining such fossil parity with electrolytic H_2. Indeed, from Fig. 1, one could wrongly conclude that reaching the required reduction in electrolyser CAPEX down to 450

Euro/kW would require very large-scale electrolytic H_2 production units, on the order of 50-100 MW. However, Figure 1 also suggests that there might still be a much smaller production scale for reaching such low CAPEX values. Indeed, based on an extrapolation of the currently available CAPEX data for single-stack alkaline electrolysers in Fig. 1, the level of 450 Euro/kW (dashed horizontal green line) can already be reached around 4-5 MW. Such a significant reduction in the scale required for fossil parity is directly related to the much steeper reduction in CAPEX that can be realised for single-stack as compared to multi-stack electrolyser systems.

Even more direct corroborating evidence for this relatively small scale fossil parity for green electrolytic H_2 is given in Figure 2. The latter represents state-of-the-art industrial data for the Total Cost of Ownership (TCO) of electrolytic H_2 as a function of power input. Values are based on a 10 years operation, including a 10 years' service & maintenance agreement, for a complete turnkey, containerized alkaline electrolyzer unit (including inverter and water treatment), delivered and installed in Europe. The electrolyser efficiency is guaranteed at 46.7 kW/kg at 100% load, and delivers H_2 at 35 bar. Until now, it was commonly agreed that the only option to decrease the electrolytic H_2 production cost towards fossil parity was to increase the capacity of the (multi-stack) system upto 50-100 MW, as already discussed in Fig. 1. However, as suggested by the dashed red line in Fig. 2 through the TCO data for single stack systems, there is yet another technological alternative. It consists in extending the power input that can be taken up by a single-stack electrolyser upto a few MW (2-4 MW, the exact number depending on the electrolyser technical characteristics like electrode size). This then also corresponds to the scale of the basic units of renewable electricity generation. The (only) remaining technological challenge on the electrolyser level would then be to try to increase the number of cells/stack for such a single stack system, or to increase the specific area of each individual electrode (e.g. by replacing classical 2-D plates by 3-D electrodes [5]).

CONCLUSIONS

In this paper, we have addressed the question what would be an economically viable (minimum) production scale for green hydrogen, produced from water electrolysis using renewable electricity. A realistic benchmark to do so is to take the current price of grey hydrogen (the so-called fossil parity), currently estimated at 2.0 $/kg and produced by fossil-based and thus CO_2 intensive processes. Using the most recent TCO values for electrolytic hydrogen, it was concluded that fossil parity could already be reached at a production scale on the order of a few MW. Although this might still require a further intensification of the water electrolysis process, e.g. by extending the power range of a single-stack electrolyser, such small-scale fossil parity provides an important paradigm shift. Indeed, with respect to the current, large-scale unit size fossil fuels (SMR) based centralised hydrogen production, it has the important advantage of allowing a decentralised local H_2 production. Renewables can then be harvested anywhere, and used directly for the local production and consumption of green electrolytic hydrogen, fully in line with the small-scale local H_2 demand.

ACKNOWLEDGEMENTS

We cordially thank Eric Dabe from NEL and Henrik Steen Pedersen from GreenHydrogen for providing their state-of-the-art CAPEX and TCO data on electrolytic hydrogen. This paper also benefited from a number of insightful discussions at the International Energy Agency with Uwe Remme and Cédric Philibert, respectively at the IEA's Energy Technology Policy Division and the Renewable Energy Division. Finally, financial support from the Public Service of Wallonia – Dept. of Energy and Sustainable Building is gratefully acknowledged as well for allowing these fruitful interactions with the IEA.

ABSTRACT

This paper deals with the influence of magnetic filed on water electrolysis for green hydrogen production. Experimental setup was design and experimental research conducted. Results of influence of magnetic filed on the energy efficiency of the alkaline electrolyzer is analysed. Average energy efficiency for three cases is calculated and compared. In the first case, water electrolysis was conducted without application of the magnetic field. In the second case, magnetic filed is created with one pair of permanent neodymium magnets and applied on the electrolyzer, while in the third case the same experiment is repeated, but with stronger magnetic filed created by two pairs of neodymium magnets. Each type of the experiment is repeated several times and average values are calculated. Results indicated that magnetic filed is having positive impact on the energy efficiency of the process, and that with application of stronger magnetic field, the increase of energy efficiency is higher.

Keywords: green hydrogen, water electrolysis, alkaline electrolyzer, magnetic filed, permanent neodymium magnets

INTRODUCTION

In a world that is steaming towards a carbon-neutral society, hydrogen technologies are recognized as an essential part of the global energy transition. In the combination with renewable energy sources (RES), hydrogen can serve as a long-term energy storage solution with zero carbon dioxide (CO2) emissions. Hydrogen produced with the utilization of RES is generally known as green hydrogen, while grey and blue hydrogen are produced from fossil fuels [1]. Although the advantages of green hydrogen are well known, its ecological potential is not yet completely utilized, mainly due to economic reasons. The production of the components and equipment used in hydrogen production, storage, and utilization of hydrogen in fuel cells is still not large enough, so the production costs are too high. To reduce the costs, and make the technology economically viable, the production must scale up. This process is already happening by itself since the demand for hydrogen grows every day [2].

To speed up the process, ongoing research that are in progress in the world, must result in improvement of quality of the product. One way to do so is to increase the efficiency of the processes that occur in the application of hydrogen technologies, such as the process of hydrogen production, i.e., water electrolysis. One of the interesting solutions that can have positive effects on the process is the application of the magnetic field. The magnetic field is set in the inter-electrode space between two electrodes which results in the creation of the Lorentz force that accelerates the process of separation of bubbles of hydrogen from the electrodes [3]. Experiments were conducted with both smooth solid electrodes and porose electrodes, resulting in positive effects on the process [4]. Research shows that the application of foam electrodes combined with the influence of a uniform magnetic field results in energy consumption reduction by about 3.4% [5]. The next step for further research is a combination of both numerical and experimental approaches [6].

EXPERIMENTAL SETUP

The alkaline electrolyzer is the main part of the experimental setup (Figure 1.). Its construction is divided into two main parts: the upper tank where electrodes are placed, and the lower tank which is open to the atmosphere. Tanks are connected with the thin tube, ensuring that electrolyte can be transported from one tank to another. The upper tank is closed to the atmosphere because previous experimental research showed that bubbles of oxygen and hydrogen upon reaching the surface of the electrolyte splash the drops of the electrolyte out of the electrolyzer, that way disabling accurate measurement of the produced hydrogen. The housing of the electrolyzer is made of polymethyl methacrylate, commercially known as plexiglass. Sides of the upper tank are connected with epoxy adhesive resistant to alkaline solutions since 25% potassium hydroxide (KOH) water solution is used as the electrolyte in the experiments. Before the start of the experiment, the upper tank is filled with the electrolyte. The lower tank is filled as well, to the level above the end of the tube that is connecting both tanks. When the electrical circuit is closed, the process of water electrolysis begins, and bubbles of oxygen and hydrogen are starting to generate on electrodes. Produced gas is then accumulating

at the top of the upper tank as bubbles go up and the electrolyte is pushed down, raising the level of the electrolyte in the lower tank.

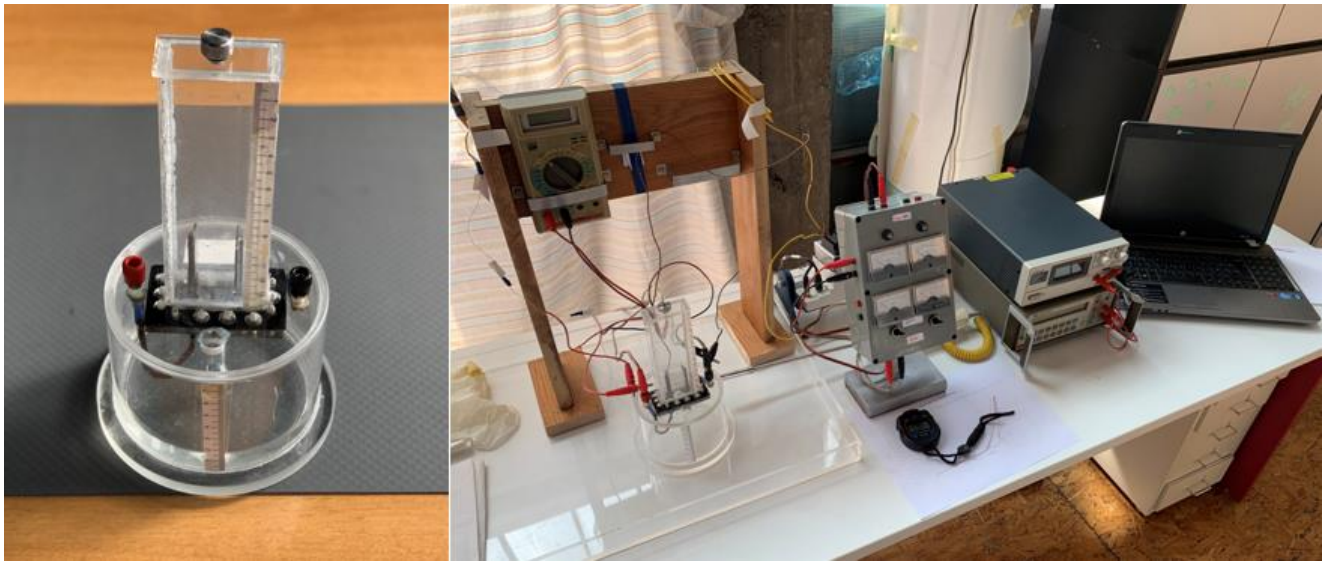

Fig.1. Alkaline electrolyzer (left) and complete experimental setup (right)

For the research, permanent neodymium magnets were used. Magnets are cubes, dimensions 25x25x25 mm. In the first case with magnets, magnetic field is created by a couples of magnets. They are placed on the magnet-holding device into positions where opposite poles are facing each other. That way, a stabile inhomogeneous magnetic field is created between magnets. In second case, another pair of magnets is added to the existing pair, therefore increasing the magnetic flux density in the filed. They are set in the same position. Magnets in both cases are presented in Figure 2. Distance between magnets can be manually adjusted. In this research the distance between magnets was 25 mm for both cases.

Since the magnetic filed in presented case depends on the distance between surfaces of two opposing magnets, the magnetic flux density was measured and mapped with the Hall sensor in both cases. The magnetic flux density at the surface of the magnets for the first case with one pair of magnets was approximately 610 mT at, at the middle of the side where the magnetic flux density is highest. Further away from the surface of the magnet, towards the middle of the field, the value of the magnetic flux density is dropping towards the minimum of approximately 350 mT. In the second case with two pairs of magnets, the magnetic flux density was approximately 630 mT at the surface of the magnets, with values dropping towards the minimum of approximately 380 mT in the middle of the field. Overall, for the same distance of 25 mm between surfaces of the opposing magnets, with addition of one extra pair of the magnets, the magnetic flux density of the field increased between 3% and 7%. The increase in magnetic flux density was not equal or proportional in all parts of the filed. Therefore, the middle of the filed and the middle of the surface were taken as the referent points.

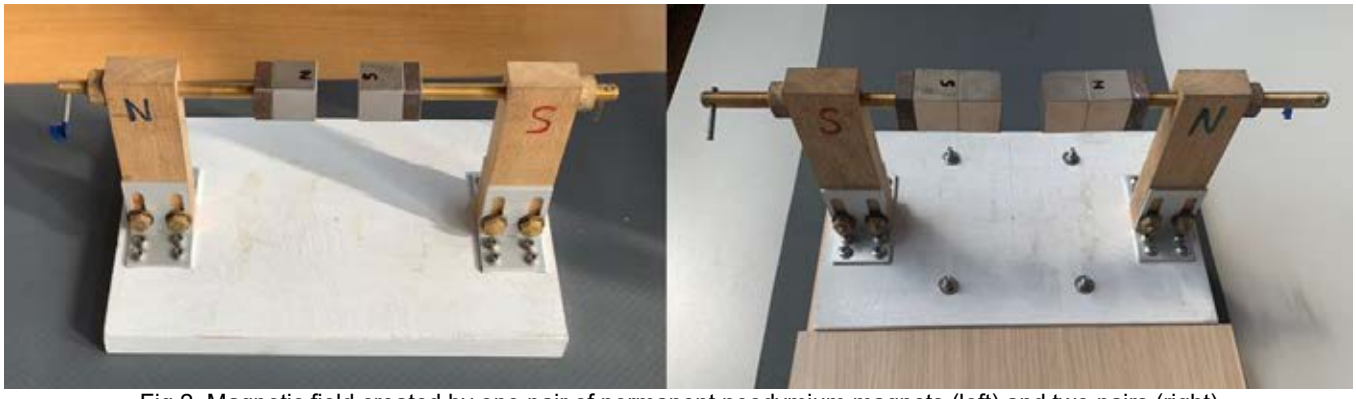

Fig.2. Magnetic field created by one pair of permanent neodymium magnets (left) and two pairs (right)

RESULTS AND DISCUSSION

The energy efficiency calculated for the experimental research was ratio of output energy in form of chemical energy stored in the hydrogen and input energy in form of the electrical energy used for the creation of the hydrogen. It was calculated for each and every experiment in the research. Since all experiments vary among themselves in the calculated energy efficiency due to any number of reasons, experiments are divided in three types, and average energy efficiency for each type is calculated. Three types of experiments, whit average energy efficiencies calculated are presented in Table 1.

Table 1. Comparison of the efficiencies of the processes in the dependence of the magnetic field

Magnetic field	Magnetic flux density on the surface of the magnets	Average efficiency of the process	Increase of efficiency compered to case without magnetic field
Without magnetic field	0 mT	65,95 %	0,00 %
One pair of magnets	610 mT	67,26 %	+ 1,98 %
Two pairs of magnets	630 mT	67,57 %	+ 2,46 %

The results of the experiment conclude that the application of one pair of magnets increased energy efficiency by 1,98% compered to the case without application of the magnetic field. With stronger magnetic filed of two pairs of magnets the energy efficiency increased for the 2,46% compared with the case without application of magnetic filed. Furthermore, Results show that the average energy efficiency of stronger magnetic filed yields in 0,46% increase of energy efficiency compered with the weaker magnetic filed.

CONCLUSIONS

Results of the research point out the increase of energy efficiency of the process when magnetic filed is applied. They also indicate that with the stronger magnetic filed that effect is stronger. In the experimental research, stronger magnetic filed was created by addition of extra pair of permanent neodymium magnets. This resulted with only slight increase of magnetic flux density for the same distance between magnets. This would indicate that with further addition of magnets the magnetic filed wouldn't get significantly stronger, which means that for further research different kind of experimental setup and magnets are needed.

AISI 442 AND 446 FERRITIC STAINLESS STEELS AS A SUPPORT FOR BIPOLAR PLATES IN PROTON EXCHANGE MEMBRANE WATER ELECTROLYZERS

ABSTRACT

This paper presents the results obtained in the study of corrosion resistance of ferritic steels AISI 442 and AISI 446 with the objective of using them as substrate material for bipolar plates (BPPs) in proton exchange membrane water electrolyzers (PEMWEs). The overall objective is to reduce the cost by replacing titanium BPPs with cheaper steel alloys. Corrosion current and corrosion potential of AISI 442 and 446 steels have been determined by potentiodynamic polarization in solutions having a similar composition to the fluid from the anodic side of PEMWEs. Furthermore, to evaluate the corrosion resistance at anodic potentials, AISI 442 and 446 were subjected to a voltage stress test (VST) where the current is monitored while the samples are maintained at constant potentials of 1.5, 1.75 and 2.0 V for 8 hours. Both samples showed good corrosion resistance at 1.5 V, as indicated by the low current densities, but the current densities increased significantly at 1.75 and 2.0 V. This shows that the surface of the ferritic steels must be protected with a corrosion-resistant coating, which should also have high conductivity. After the VST the samples have also been investigated by electrochemical impedance spectroscopy (EIS) and scanning electron microscopy (SEM).

Keywords: Proton exchange membrane, Water electrolyzer, Bipolar plate, Voltage stress test, Tafel plots.

INTRODUCTION

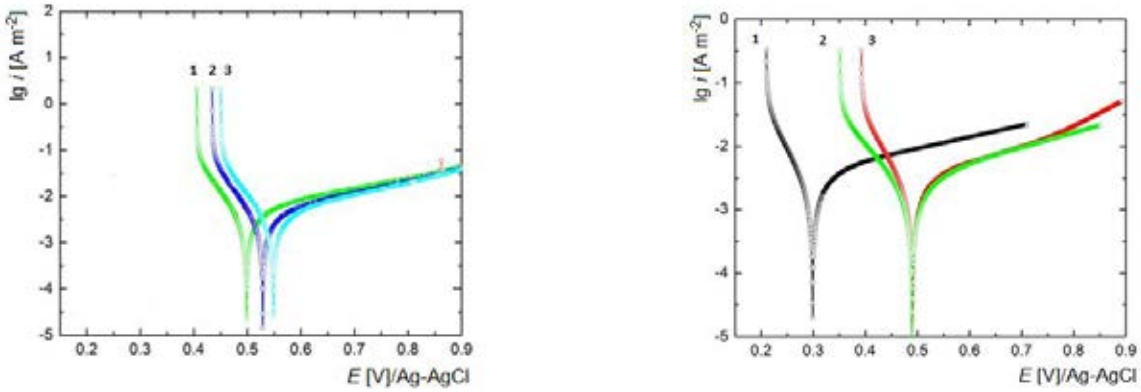
In order to make the production of electrolytic hydrogen profitable, research has focused on the PEMWEs, which have several advantages over alkaline water electrolyzers: high energy efficiency, high current densities, as well as pressures more than 100 bar. Moreover, PEMWEs can operate at variable current densities, making them suitable for connection to wind and solar renewable energy sources [1-2].

One of the most important components of PEMWE stacks is the Bipolar Plate. In addition to separating single cells in a stack, the BPP also conduct electricity and heat away from active areas. The use of cheap metallic materials for BPPs is limited by the aggressiveness of the environment. In addition to a good mechanical strength, BPPs have to be corrosion resistant and electronic conductors. Moreover, the interfacial contact resistance needs to be low [3]. The costs of BPPs are very high, accounting for about 50% of the total costs of a PEMWE stack. The causes that lead to such high costs are the use of high purity Ti, difficult processing of the Ti plates, the need to plate Ti with noble metals to prevent surface anodizing, which would lead to an increased interfacial contact resistance [4]. Research have thus been focused on the use of austenitic stainless steels protected with highly conductive and corrosion resistant coatings. However, austenitic steels are expensive due to their high nickel content, and our research approaches the use of high chromium ferritic stainless steels as a support for BPPs.

MATERIALS AND METHODS

The anticorrosive properties of the AISI 442 and 446 were determined in 0.1 mol L^{-1} Na_2SO_4 solution, acidified with H_2SO_4 up to *pH* = 5. In order to simulate the working environment, KF was added to the solution so that F^- concentration reached 0.1 ppm. The solution was saturated with O_2 (3.5 degree - 99.5%) and the samples tested were made of AISI 442 and 446 sheets, having 1 cm^2 active area. The composition of the AISI 442 and 446 is given in Table 1.

Table 1. Elemental composition of the ferritic stainless-steel samples.



Element		C	Cr	Mn	Si	Al	Mo	P	S	N	Fe
Concentration % mass	AISI 442	0.12	22.1	0.79	0.82	0.72	0.18	0.031	0.028	-	rest
	AISI 446	0.14	24.90	1.08	0.72	-	-	0.032	0.026	0.18	rest

To investigate the anticorrosive characteristics of AISI 442 and 446 samples, potentiodynamic polarization method was used and the corrosion parameters (corrosion current density i_{corr} and corrosion potential E_{corr}) were determined from the Tafel plots. The polarization resistance R_p was calculated using the Stern-Geary relation [5]. The steel samples were subjected to VSTs at 1.5; 1.75 and 2.0 V/NHE for 8 h. Furthermore, the EIS spectra were plotted, in

the frequency range of 100 kHz - 10 mHz, using a sinusoidal signal of 5 mV amplitude. In all experiments, the temperature was 25°C.

RESULTS AND DISCUSSION

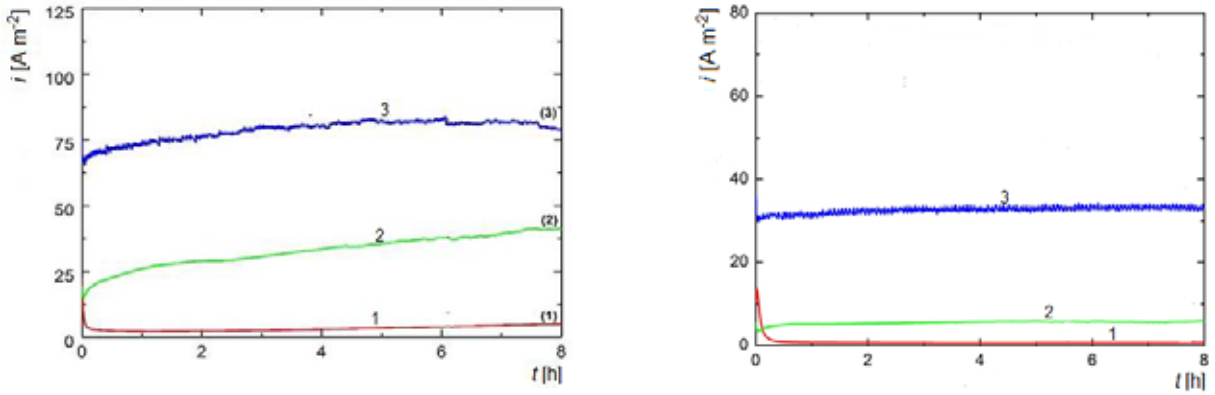
Figure 1a and b shows the polarization curves obtained on the AISI 442 and 446 ferritic stainless steel in the test solution. To verify the reproducibility of the results, three measurements were performed under the same conditions.

(a) (b)

Fig. 1. Linear polarization curves on AISI 442 (a) and AISI 446 (b).

Based on the linear polarization curves, parameters that characterize the corrosion process in the given environment have been calculated: corrosion current density i_{corr}, corrosion potential E_{corr}, cathodic- and anodic Tafel slopes (b_c, respectively b_a), as well as polarization resistance R_p. The results obtained are shown in Table 2.

Table 2. Corrosion parameters for AISI 442 and AISI 446 in 0.1 M Na_2SO_4 (pH = 5; 0.1 ppm F^{-1}).



Sample	Experiment no.	i_{corr} [μA cm^{-2}]	E_{corr} [mV/Ag/AgCl]	$-b_c$ [mV dec^{-1}]	b_a [mV dec^{-1}]	R_p [kΩ cm^2]
AISI 442	1	0.190	468	119	58.7	90
	2	0.179	528	124	60.7	99
	3	0.178	548	127	61.0	101
AISI 446	1	0.145	294	56.1	150	122
	2	0.136	486	64.6	159	147
	3	0.134	489	97.5	173	202

Corrosion current density i_{corr} values show that both AISI 442 and 446 have a good corrosion resistance in the test solution. There are no official targets imposed for the corrosion current of BPPs in PEMWE, but it is meaningful to compare this value to the target imposed by the U.S. Department of Energy for BPPs in proton exchange membrane fuel cells (< 1 μA cm^{-2}). Corrosion currents decrease over time as the surface of the metal changes by thickening the oxides layer. In fact, due to the passivation, the polarization resistance R_p changes with the increase of the oxide layer thickness. Both i_{corr} and R_p values show that AISI 446 is more corrosion resistant than 442.

Voltage stress tests were performed at different values of potential, for several hours, to monitor the current density through the interface between stainless steel and the electrolyte. Figure 2 shows the evolution of the current versus time on AISI 442, respectively AISI 446, at different constant values of the potential: 1.5 V (1), 1.75 V (2) and 2.0 V (3).

From Figure 2a and 2b it can be seen that if the studied steels are polarized at 1.5 V, the current density shows an exponential decay in time and stabilizes at a low value, corresponding to the formation of a passive oxide layer. If the potentials are increased to 1.75 and 2 V, the current density increases significantly, due to both the oxygen evolution reaction and the corrosion process. Unlike AISI 442, on AISI 446 the current densities are stabilized at significantly lower values, effect caused by the higher stability of the protective oxides layer.

Electrochemical impedance spectroscopy measurements were performed after the VST and the results obtained by fitting the impedance data are summarized in Table 3. The Rp values obtained by EIS are higher than those obtained by potentiodynamic polarization, as they are measured after VSTs, when the surface is covered with an appreciable layer of oxides.

(a) (b)

Fig. 2. Current transients of AISI 442 (a) and AISI 446 (b) during polarization at constant potentials (1.5; 1.75 and 2.0 V) at 25°C.

Table 3. Calculated data of the circuit elements and experimental errors (between brackets) for AISI 442 and AISI 446.

Sample conditioning	R_s [Ω cm^2]		R_p [kΩ cm^2]		$C_{dl} \cdot 10^5$ [μF cm^{-2}]	
	AISI 442	AISI 446	AISI 442	AISI 446	AISI 442	AISI 446
After 8 h VST at E_1 = +1.5 V	32.9 (1.91%)	33.2 (1.73%)	1410 (1.63%)	980 (1.63%)	2.58	1.48
After 8 h VST at E_2 = +1.75 V	34.1 (1.08%)	39.7 (1.29%)	760 (2.76%)	775 (1.73%)	6.33	6.82
After 8 h VST at E_3 = +2.0 V	38.1 (0.99%)	41.6 (0.71%)	410 (1.91%)	395 (1.49%)	8.87	18.2

As expected, the polarization resistance decreases as the potential in VSTs increases as the alloy surface changes. In fact, the significant increase in the capacity of the double layer at the metal-solution interface indicates that over time, at extreme potentials, the actual surface area of the metal increases.

CONCLUSIONS

The obtained results show that the corrosion resistance of AISI 442 and 446 ferritic steels is high enough to be used as a support for BPPs in PEMWEs. As the corrosion resistance at higher potentials is not good enough, it is necessary to plate the surface of the steels with a thin layer of metal or alloy which additionally ensures a low interfacial resistance. Due to its higher chromium content, AISI 446 is more resistant to corrosion than AISI 442, as evidenced by SEM images (here not shown), which is why it is preferable as a support for BPPs in PEMWEs.

ABSTRACT

Membrane-electrode assemblies based on chemically stabilised short-side-chain proton exchange Aquivion® membranes, prepared by extrusion or recast methods, have been investigated for operation at high current density (3 - 4 A cm^{-2}) in water electrolysis cells. A thickness of 90 µm was selected for these perfluorosulfonic acid membranes in order to provide proper resilience to hydrogen crossover under differential pressure operation while allowing operation at high currents. The membranes showed proper mechanical strength for high pressure operation and suitable conductivity to reduce ohmic losses at high current densities. Both membranes showed excellent performance in electrolysis cells by achieving a voltage efficiency better than 85% and 80% (1.85 V) at 3 and 4 A cm^{-2}, respectively, in polarisation curves at 90 °C.

Keywords: Electrolysis, Polymer electrolyte membrane, Hydrogen, Extruded membrane, Recast membrane

INTRODUCTION

One of the most advanced processes to produce highly pure “green” hydrogen from renewable energy is based on the polymer electrolyte membrane (PEM) water electrolysis [1]. PEM water electrolysers operate at high pressure to reduce down-stream gas compression thus allowing efficient hydrogen storage. A key aspect of this technology is its excellent dynamic behaviour for proper interfacing with intermittent renewable power sources and its suitable application in grid-balancing service [1]. However, the cost of the hydrogen produced from PEM electrolysis is still high compared to competitive technologies like central steam reforming of natural gas [1].

To allow for a widespread utilisation of the PEM electrolysis technology, a significant reduction of the capital costs is strongly necessary [1]. This will make the hydrogen produced from electrolysis competitive with respect to the currently used organic fuels thus favouring the diffusion of fuel cell vehicles. To achieve such objective, precious metal catalysts used in the electrolysis systems should be minimised and titanium bipolar plates possibly replaced by stainless steel treated with cheap coatings. These strategies are currently addressed, but probably they may not be sufficient because it is still needed to take into consideration the cost of the balance of plant of the PEM electrolyser. This cost is strongly influenced by the hydrogen production rate [1].

On the other hand, it is widely recognised that the most relevant effect on decreasing the cost of PEM electrolysers will be played in the future by the increase of the operating current density while keeping the system efficiency at suitable levels [2-3]. When an electrolyser is operated in a high current density regime, the efficiency losses associated to the ohmic drop play a relevant role. In this regard, the proton transport in the polymer electrolyte membrane is producing a major contribution to the ohmic losses at high current density. Electronic percolation in the catalytic layers, diffusion media and bipolar plates contributes to ohmic losses in a lower extent [4].

Beside a high proton conductivity, proper mechanical strength and low gas-cross over under differential pressure operation are important characteristics that govern the reliability of the membrane separator between the anode and cathode compartments in PEM cells [1].

MATERIALS AND METHODS

In this work, we have investigated Aquivion® membranes with equivalent weight of 980 g eq^{-1} and thickness of 90 µm, produced by extrusion or casting methods, with regard to their electrochemical performance and gas crossover characteristics in electrolysis cells. These membrane-electrode assemblies contained low precious metal loadings in accordance with the trend of decreasing the impact of critical raw materials on the overall cost of the PEM electrolysis system [3]. Interestingly, it was observed that the membrane fabrication method influences significantly the interfacial properties with the electrodes affecting the polarisation resistance and degradation rate in durability studies.

Electrolysis cells have been compared for operation at high current density (3-4 A cm^{-2}) as required to decrease significantly the capital costs of the electrolysis systems [2-3] while gas crossover was investigated during high differential pressure operation to examine the impact of the membrane fabrication method on the system safety

RESULTS AND DISCUSSION

In-plane conductivity has been measured at 80°C and in the relative humidity range from 20% to 120% R.H. (Fig. 1). Both membranes, having the same equivalent weight (980 g/mol.), show a similar trend. As expected, proton conductivity increases by increasing relative humidity. Both membranes reach the same value of 130 -140 mS cm^{-1} under full humidification. This result clearly show that the manufacturing process does not affect the ion conduction properties of Aquivion ® membranes under full humidification which are determined by the amount of $–SO_3H$ functional groups and their dissociation. At low R.H. values (20%) the extruded membrane shows larger conductivity.

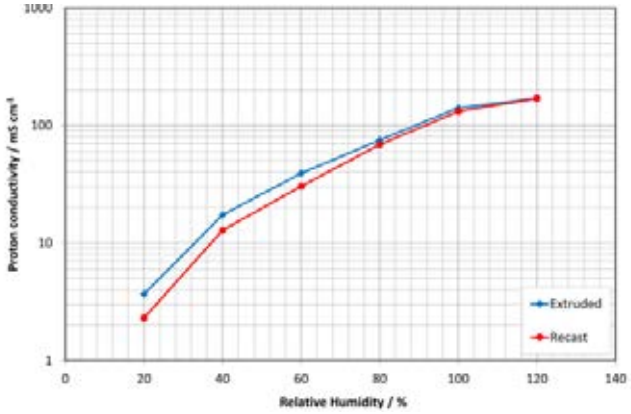

Fig. 1. In-plane proton conductivity at 80°C vs. relative humidity of extruded (E98-09S) and recast (C98-09S) membranes.

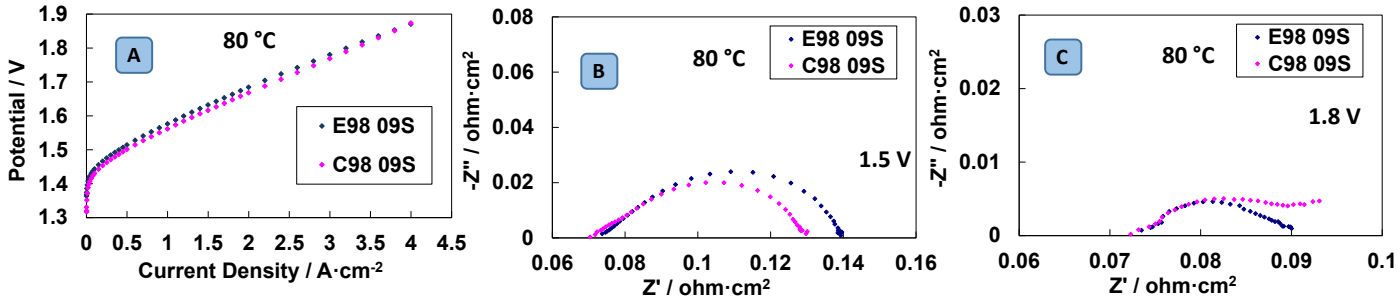

Fig. 2. Polarisation curves (a) and ac-impedance spectra at 1.5 V (b) and 1.8 V (c) at 80 °C of the MEAs with extruded and casted membranes.

A comparison of the polarisation curves at 80 °C for the two MEAs (Fig. 2a) shows a small but evident activation enhancement in the case of the recast membrane resulting from a lower polarisation resistance at 1.5 V (Fig. 2b). A very good reproducibility was observed for these initial polarisation curves by investigating different sets of the same MEAs. This indicates that the observed differences are specifically related to the membrane used in the MEA. The series resistance is just slightly lower for the recast membrane according to the fact that both membranes are based on the ionomer and have the same thickness. At 1.8 V (Fig. 2c), it seems that some small additional low frequency contribution is present in the case of the recast membrane as envisaged from the presence of the onset of a low frequency semicircle or possibly a Warburg-like diffusion-related contribution. As consequence of the different differential resistances, the extruded membrane recovers the performance gap with the recast membrane at 4 A cm^{-2} showing the same voltage efficiency.

CONCLUSIONS

Extruded and recast short-side chain proton exchange Aquivion® membranes have been assessed in membrane-electrode assemblies with regard to their operation at high current density in water electrolysis cells. The membranes were characterised by proper mechanical strength for high-pressure operation and good conductivity to minimise ohmic

losses at high current densities. Both membranes have shown a similar voltage efficiency (> 80%) at temperatures of 80–90°C and high current density (3-4 A cm^{-2}); whereas the recast membrane was slightly better performing in the activation region of the polarisation curves.

ABSTRACT

H2BASQUE is a strategic project funded by the Basque Government for developing innovative technologies (and their key components) for cost-competitive green hydrogen production. The green production technologies that will be developed in H2BASQUE are AEM electrolysis, PEM electrolysis and thermochemical cycles. In addition, this project at improving the scientific-technological and commercial positioning of the Basque Network of Science, Technology and Innovation and Basque companies in the hydrogen sector and in particular in green hydrogen generation technologies.

Keywords: Green Hydrogen production, Electrolysis, Thermochemical cycles

INTRODUCTION

Hydrogen will play a crucial role in the energy transition due to its high potential to contribute to the decarbonization of the economy. Green hydrogen, produced using energy from renewable sources, will serve as a raw material for the chemical industry, particularly in carbon dioxide-emitting industrial sectors (steel plants, refineries, cement plants), for mobility applications, for the residential and tertiary sectors, and for massive energy transportation or long-time energy storage. This last point is especially important since energy generation, in the case of renewables, does not always match in time with its demand.

Due to its characteristics, hydrogen is expected to be a fundamental energy vector in the energy transition, especially in sectors or processes that are difficult to electrify.

PROJECT DESCRIPTION

Hydrogen will play a crucial role in the energy transition due to its high potential to contribute to the decarbonization of the economy. Green hydrogen, produced using energy from renewable sources, will serve as a raw material for the chemical industry, particularly in carbon dioxide-emitting industrial sectors (steel plants, refineries, cement plants), for mobility applications, for the residential and tertiary sectors, and for massive energy transportation or long-time energy storage. This last point is especially important since energy generation, in the case of renewables, does not always match in time with its demand.

Due to its characteristics, hydrogen is expected to be a fundamental energy vector in the energy transition, especially in sectors or processes that are difficult to electrify.

A major challenge of the deployment of this promising energy vector is the generation of low-carbon or carbon-free hydrogen on a large scale and at a competitive cost. The H2BASQUE project will focus on the development of three innovative technologies for this purpose:

- Green hydrogen production by anion exchange membrane electrolysis (AEM)
- Green hydrogen production by proton exchange membrane electrolysis (PEM).
- Green Hydrogen production through thermochemical cycles.

Although the electrolysis process for green hydrogen generation is a known process, it is necessary to advance technologically to make it more efficient and reduce hydrogen generation costs. H2BASQUE contemplates the development of innovative components (membranes, catalysts, MEA ...) that reduce costs, decrease the use of critical materials and improve the performance of the hydrogen production process with respect to the state-of-the-art.

In addition, the project aims at developing three thermochemical cycles; the study of these cycles in custom-designed reactors and the conceptual process design for scaling them up to industrial scale.

Furthermore, the project will investigate the integration in industrial processes of the different green hydrogen generation technologies that will be developed in the project, and it will define the most suitable industrial uses for the implementation of each of them.

The project aims at improving the scientific-technological and commercial positioning of the Basque Network of Science, Technology and Innovation and Basque companies in the H2 sector and in particular in green H2 generation technologies.

H2BASQUE project is coordinated by TECNALIA and also has the participation of TUBACEX INNOVACIÓN, CIDETEC, CIC ENERGIGUNE, UPV / EHU, TEKNIKER, PETRONOR INNOVACIÓN and BASQUE ENERGY CLUSTER.

In this work, the progress made in the different activities of the project will be presented.

ACKNOWLEDGEMENT

ABSTRACT

In order to develop non-platinum group metals anode electrocatalyst for the proton exchange membrane water electrolysis, the catalytic activity of Ta and Mo oxide-based electrocatalyst with Mn addition for the oxygen evolution reaction (OER) have been investigated. The Ta and Mo oxide-based electrocatalyst with Mn addition (Mn-TaO_x and Mn-MoO_x) has increased current density than that Ta oxide-based electrocatalyst with Mn addition in our previous study (Mn-TaO_x(Pre)). From the slow scan voltammogram of Mn-TaO_x and Mn-MoO_x, the redox peak of Mn species was detected in both samples. Though the electric charge of redox peak and the OER current density was independent relation in Mn-TaO_x and Mn-MoO_x, the Mn content is affected on the enhancement of electrical conductivity in Mn-TaO_x and Mn-MoO_x compared to Mn-TaO_x(Pre).

Keywords: Oxide-Based Electrode, Oxygen Evolution Reaction, PEM Electrolyzers, Green Hydrogen

INTRODUCTION

It is not enough to install the hydrogen all over the world and the CO_2-free–hydrogen society, especially “Green Hydrogen[1]” society should be required for sustainable future. As is well known, water electrolysis is essential technology to produce “Green Hydrogen” from renewable energies. Proton exchange membrane water electrolysis (PEMWE) is one of promising water electrolysis to expand production and installation. In Japan, the High-purity Hydrogen Oxygen Generator(HHOG) and hydrogen-based autonomous energy supply system whose nick name is “H_2One^{TM}” have released from Kobelco Eco-Solutions and Toshiba Corp., and both system uses for distributed power supply. The PEMWE is used for the essential device installed in above systems. However, the conventional electrocatalysts for PEMWE are precious metal materials, and especially, the iridium oxide (IrO_2) uses as anode. As the iridium is by-product of platinum, its resources is very poor, and it is afraid that the cost will be higher with installation PEMWE system. Moreover, it is reported that the IrO_2 is easy to cause the degradation under dynamic operation condition which is simulated variable renewable energy (VRE) and the catalytic activity of oxygen evolution reaction (OER) became lower by dynamic operation[2-3]. Therefore, the non-platinum group metals (PGM) oxide anode should be required for Green Hydrogen production. We focused on group 5 and 6 metal oxide, such as tantalum (Ta) and molybdenum (Mo) oxide. In our previous results, Ta oxide-based electrocatlyst with Mn addition has OER activity in sulfuric acid. However, it does not have significant activity for the OER[4]. In this study, we have prepared not Ta oxide-based electrocatalyst with Mn addition but also Ta oxide-based electrocatalyst with Mn addition, and investigated its catalytic activities for the OER in acidic solution.

EXPERIMENTAL

Ta or Mo compound films were formed on Ti rods as a base material, using the R.F. magnetron sputtering. Target was Mn, Ta or Mo disks. Gas atmosphere in the chamber was a mixture of Ar and O_2 gas. After polishing and washing, the Ti rods were heated from 300 °C (TaO_x) or 400 °C (MoO_x). The flow rates of Ar and O_2 during the sputtering were kept at constant. Ta- or Mo-based thin film catalysts prepared by Mn target with Ta or Mo piece of plate are expressed as TaO_x or Mn-TaO_x, respectively. In the case of formation of binary electrode such as Mn-TaO_x, it is considered the difference of sputtering rate between Mn and Ta. Mn addition was varied from 0 to 80 at%. Partial pressures of Ar (p_{Ar}) and O_2 (p_{O2}) were calculated by multiplying the ratio of the flow rate of each gas by the total pressure in the chamber. Sputtering power and sputtering time were fixed at 150 W and 20 min, respectively. To compare with another oxide-based electrocatalyst, we also prepared Ti compound films with Mo addition of 10 at% formed on Ti rods (Mo-TiO_x) by the sputtering under at 0.23 Pa of p_{Ar} and p_{O2} at 100 °C of substrate heating temperature for 20 min of formation time.

All electrochemical measurements were carried out using a three-electrode cell at 30 °C in 1 M H_2SO_4. A reversible hydrogen electrode (RHE) and a carbon plate were used as a reference and a counter electrode, respectively. Ta compound films with and without addition formed on Ti rod used as working electrode. In order to evaluate the catalytic activity for the OER, slow scan voltammetry (SSV) was performed under N_2 atmosphere. Current density

was based on the geometric surface area of the working electrode. The resistance of the film (R_{film}) and charge transfer (R_{ct}) was evaluated by AC impedance spectroscopic measurements in the frequency range from 10^5 to 10^{-1} Hz.

RESULTS AND DISCUSSION

Fig. 1 shows the Tafel plots of Ta and Mo oxide-based electrocatalyst with Mn addition. The horizontal axis is based on geometric current density (i_{geo}). For the comparison, the results of IrO_2 film on Ti rod (IrO_2) which was fabricated thermal decomposition from iridium chloride and Mn-TaO_x which was prepared in our previous study (Mn-TaO_x(Pre))[4] are also shown in Fig. 1. Both Mn-TaO_x and Mn-MoO_x have higher OER activity than Mn-TaO_x(Pre). The Tafel slope of Mn-TaO_x and Mn-MoO_x are 76 and 73 mV dec^{-1}, respectively. Since the Tafel slope of Mn-TaO_x(Pre) was 105 mV dec^{-1}, the OER of both sample have improved compared to that of Mn-TaO_x(Pre). However, the OER activity of both Mn-TaO_x and Mn-MoO_x has lower than that of IrO_2.

From EIS results, both R_{ct} of Mn-TaO_x and Mn-MoO_x was drastically decreased than that of Mn-TaO_x(Pre). In addition, both R_{film} of Mn-TaO_x and Mn-MoO_x was also decreased than that of Mn-TaO_x(Pre). Therefore, the reason why the i_{geo} of Mn-TaO_x and Mn-MoO_x was much larger than that of Mn-TaO_x(Pre) is that both improvements for the catalytic activity for the OER and the electrical conductivity then that of Mn-TaO_x(Pre).

According to Fig. 1, both polarization curves of Mn-TaO_x and Mn-MoO_x have redox peak of Mn(III)/Mn(IV)[5] over 1.4 V as same as Mn-TaO_x(Pre). In the case of Mn-TaO_x(Pre), there was linear relation between the i_{geo} for the OER and the electric charge (Q) of redox peak of Mn species, but it does not show any relationship between i_{geo} for the OER and Q in the case of Mn-TaO_x and Mn-MoO_x. It means that Mn species including in Mn-TaO_x and Mn-MoO_x does not contribute on the OER activity.

From XPS analysis, the certain amount of Mn species has still remained in Mn-TaO_x after electrochemical measurement. It was greatly different from result of Mn-TaO_x(Pre) that the peak which was identified Mn oxides was completely disappeared. Thus, it is suggested that Mn species including in Mn-TaO_x and Mn-MoO_x enhances the electrical conductivity compared to Mn-TaO_x(Pre) from EIS and XPS results.
The chronopotentiometry of Mn-TaO_x for 1 mA cm^{-2} was also evaluated for 120 h. Though the Mn-TaO_x became higher potential in 10 h, the potential was keep constant after 10 h. Compared to the result of IrO_2, it was found that the Mn-TaO_x has relatively high stability in this condition.

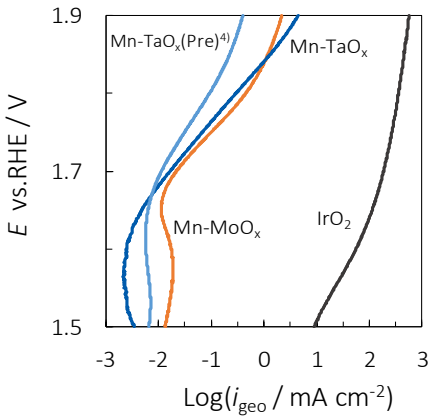

Fig. 1 Tafel plots of Ta and Mo oxide-based electrocatalyst with Mn addition in 1 M H_2SO_4 at 303 K.

CONCLUSIONS

In order to develop non-PGM anode electrocatalyst for proton exchange membrane water electrolysis, the catalytic activity of Ta and Mo oxide-based electrocatalyst with Mn addition for the oxygen evolution reaction (OER) have been investigated. According to results from electrochemical measurement, Ta oxide-based electrocatalyst film with Mn addition (Mn-TaO_x) and Mo oxide-based electrocatalyst film with Mn addition (Mn-MoO_x) have larger geometric current density (i_{geo}) than Ta oxide-based electrocatalyst film with Mn addition in our previous study (Mn-TaO_x(Pre)). According to EIS results, the reason why the i_{geo} of Mn-TaO_x and Mn-MoO_x was much larger than that of Mn-TaO_x(Pre) is that both improvements for the catalytic activity for the OER and the electrical conductivity then that of Mn-TaO_x(Pre). In addition, both polarization curves of Mn-TaO_x and Mn-MoO_x have redox peak of Mn(III)/Mn(IV) as same as Mn-TaO_x(Pre). It does not show any relationship between i_{geo} for the OER and Q in the case of Mn-TaO_x and Mn-MoO_x. It is suggested that Mn species including in Mn-TaO_x and Mn-MoO_x enhances the electrical conductivity compared to Mn-TaO_x(Pre).

ABSTRACT

Production of green hydrogen from renewable sources shows a promising pathway for the long-term de-fossilization, now adopted by many countries in their national strategic vision. The business case hinges on widespread application in transport, stationary and industrial sectors. Cross-sectoral approach is critical, interconnection user profiles to guarantee energy security, despite intermittency. Energy efficiency of the hydrogen production process is of utmost importance to achieve hydrogen cost which are required for industry and energy applications. SOEC represents a particularly interesting technology to improve the production efficiency of hydrogen and e-fuels. This paper will discuss the technology advantages and potentials for improvement.

Keywords: SOEC, hydrogen, e-fuel, production

HYDROGEN PRODUCTION VIA ELECTROLYSIS FROM RENEWABLES

Green hydrogen production via electrolysis shows the lowest carbon footprint among the H2 production pathways. Several Electrolyzer technologies are available, which differ in technical parameter and maturity.

In the time range of 2030 SOEC H_2 production cost estimated to be 15-25% lower compared to PEM electrolysis. Approximately 70% of cost are OPEX and 30% are CAPEX. In the future SOEC has the potential to reach lower CAPEX than PEM electrolysis.

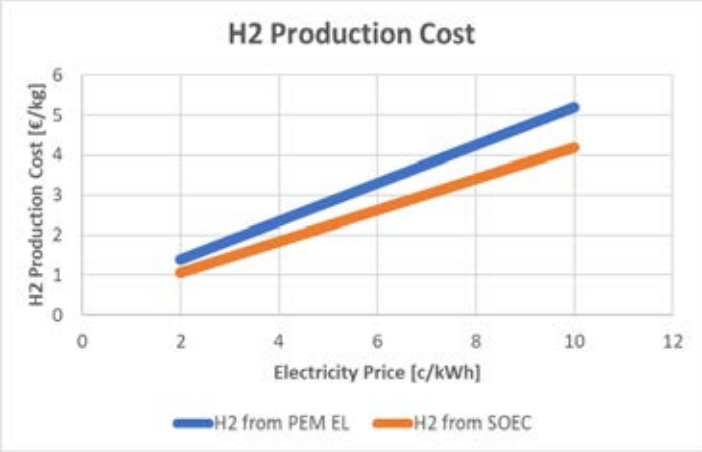

Fig. 1. Hydrogen production cost with PEM EL and SOEC – 2030 Technology scenario

SOEC is still in R&D phase with some pilot plants in the 100kW range in operation. With its working temperature between 600 and 800°C, SOEC has the potential to reach highest efficiencies due to thermodynamic characteristics with lower electricity demand at elevated temperatures for the splitting process of molecules like water into hydrogen and oxygen. Further advantages of this technology include the usage of non-precious catalysts at higher temperatures, the ability to operate the stacks reversibly and the possibility to convert carbonaceous feed gases directly and in combination with water.

AVL is at the moment with various partners developing industrial scale 1MW SOEC modules where the first systems will be deployed already in 2022. A design study of such a modular 1MW system is shown in Fig.2. The overall 1MW system contains of smaller Electrolyzer modules which are connected in series. Each module includes the required number of individual SOEC stacks and all hot balance of plant components. The overall plant will reach about 80% efficiency of hydrogen production based on liquid water input and up to 88% based on steam input.

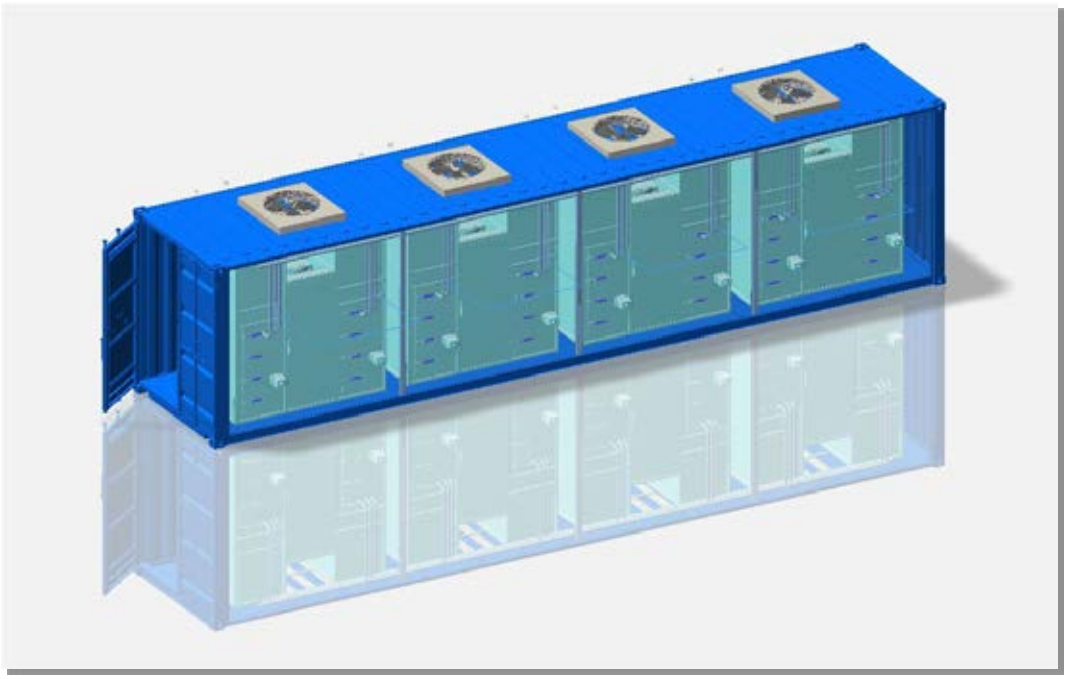

Fig. 2. AVL 1MW SOEC system design concept

E-FUEL PRODUCTION BASED ON THE SOEC PROCESS

As discussed above, SOEC has the ability to convert also carbonaceous feed gases. The conversion of water together with CO_2 is called “co-electrolysis”. Thereby, syngas consisting of hydrogen and carbon monoxide can be produced directly, which can, in addition, serve as a feedstock for various synthesis processes.

Existing PtG plants [1] that combine electrolysis and downstream synthesis like methanation, or Fischer-Tropsch, operate in two separated process steps using solely CO_2 methanation. These concepts still face challenging issues with respect to load flexibility, material degradation and high costs. However, the concept of co-electrolysis of steam and CO_2 in the Co-SOEC stack offers significant benefits. The overall system as well as the round-trip efficiencies for a closed circle system can be significantly improved. The reason for this is that the synthesis process is a stronger exothermal reaction, which positively affects the possibilities of heat recirculation and overall heat management in the system. Moreover, the chemical conversion of CO_2 to CO in the Co-SOEC stack is far more efficient due to the higher temperatures and the associated decrease in the Gibbs free energy of the electrolysis reactions. Furthermore, compared to conventional methods, enhanced conversion rates and reaction kinetics reduce the need for gas upgrading downstream after the methanation and increase power densities. This consequently reduces space and material requirements, which also have the potential to reduce the system costs. Improvements are under development for SOEs to overcome challenges like low dynamic responsiveness and to increase cell lifetime.

AVL has developed a complete Power-to-Liquid plant concept, where the SOEC process is thermally coupled to the Fischer-Tropsch process. Via this thermal coupling the production efficiency can be increased by roughly 30% compared to route via PEM or AL electrolysis. At the moment, AVL and IWO are building up the “IFE – Innovation flüssige Energie” demonstration plant in Austria based on this technology to proof the feasibility and efficiency of this process. The demonstration plant is planned to start operation in early 2023.

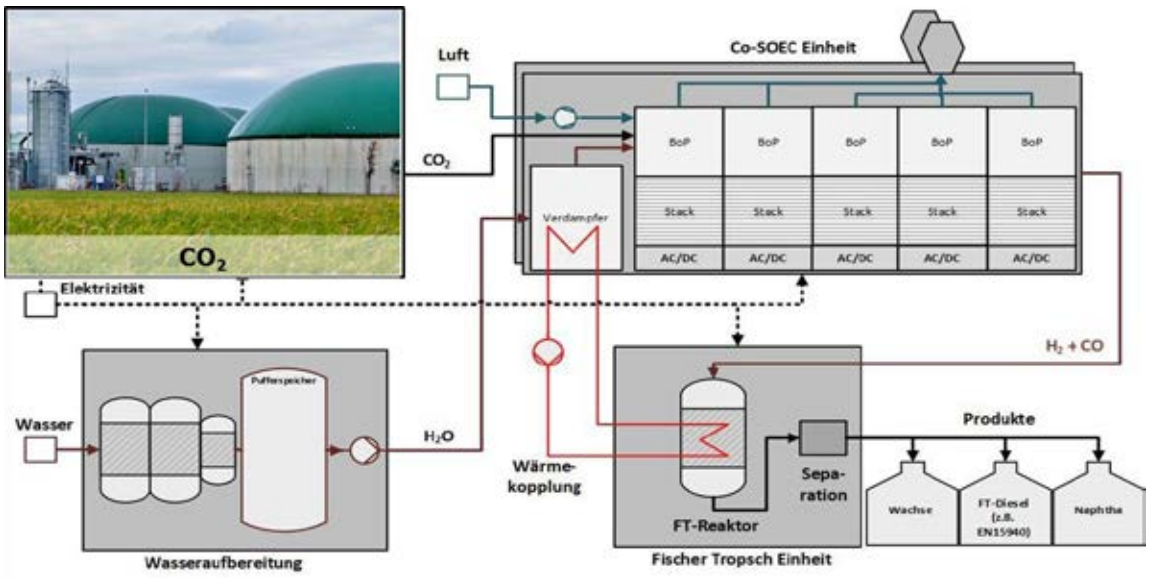

Fig. 3. AVL IWO PtL demonstration plant process

CONCLUSIONS

Optimizing hydrogen production efficiency is key to lower down the price of green hydrogen and to deal with mid-term scarce renewable electricity. AVL is developing hydrogen and e-fuel production technology based on an innovative SOEC process which enables an efficiency improvement by 15-30% compared to PEM and AL electrolyses. For both approaches - hydrogen & e-fuel production - industrial relevant technology demonstrators will be deployed in the timeframe 2022/23.

ABSTRACT

The availability of water for hydrogen production is a fundamental challenge threatening water security and its economic sustainability. This work addresses this by focusing on the design, performance and economic estimation of a novel, highly efficient and environmentally benign hydrogen production process which can be integrated with several power production units, including coal, natural gas-fired power plants and renewable energy sources. The system uses flue gas from coal power plants and various wastewater sources as the process's feedstock to generate steam for the SOEC unit. The SOEC and the balance of plant components are designed, simulated, and integrated using Aspen Hysys Software. The SOEC model is experimentally and numerically validated, and a piece-wise performance evaluation of the system is carried out. The result of this innovative system shows high system efficiencies, which can be improved depending on the energy source and by full energy Integration. The techno-economic analysis of the system gives a Levelized hydrogen cost of $2.99/kg, which can be improved to meet the U.S. Department of Energy (DOE) targets. The study offers insights into water-energy nexus for the researchers and policymakers for decision making and technology development.

Keywords: Solid Oxide Electrolytic Cell (SOEC), Hydrogen Production, Flue Gas, Water-Energy Nexus, Techno-Economic Analysis (TEA)

INTRODUCTION

The production of hydrogen from renewable and sustainable sources is a key to the green hydrogen economy. Water electrolysis has gained attention and looks promising as the process is greenhouse gas-free and yield 100% pure hydrogen. Even though water is abundant, its accessibility is a great challenge, and its use for this process will undermine water security for domestic and agricultural use. One of the major crises faced in this generation due to its increasing population is the availability of clean drinking water, particularly in developing countries. Even the developed ones can only access 2% of the available water[1]. China, most especially its coal-rich region, is faced with water scarcity[2] and projected to be severe in 2050 and the arid and semi-regions like the Middle East and the western U.S. [3].

There are three major commercialized and conceptualized water electrolytic cells for the generation of hydrogen in recent times [4] which include alkaline electrolytic cell (AEC), the most matured technology [5], polymer electrolyte membrane (PEM) electrolytic cell (PEMEC) and solid oxide electrolytic cell (SOEC). The AEC challenges range from low current density to low operational pressure, which aimed to be solved with the advent of PEMEC[6]. Likewise, the PEMEC suffers from high capital cost, pure water requirement, and increased system complexity, stemming from its operational pressure [6, 7]. However, the SOEC is an evolving and promising technology that is anticipated to overcome the setbacks plaguing these two electrolyzers [8, 9]. Solid ion-conducting ceramics are used as electrolytes in the SOECs, which operate at high temperatures ranging from 650-1000 ℃ [9]. Several works have been done on this technology both in the laboratories [8] and industries to commercialize it [9]. Kazempoor and Braun[10] modeled and evaluated a SOEC system to serve as a primary system-level performance prediction tool. Several contemporary studies on SOEC focused on hydrogen production directly from water and steam [11-13]. For better system optimization high round-trip efficiency, SOEC has been designed and studied alongside its reverse counterpart, solid oxide fuel cell (SOFC), to form regenerative solid oxide cell (rSOC) [14-16]. To eliminate the uncertainty concerning future cost and high capital cost of this technology, recent literature evaluates its techno-economic viability to encourage investments[17-19].

This work is distinctive in its water electrolysis in that it explores the flue gas from power plant and wastewater as a feedstock into the hydrogen production unit integrated with a different energy source. The net energy and techno-economic analyses are carried out on the entire system for performance evaluation and sensitivity analysis on the system's critical parameters.

SYSTEM AND MODEL DESCRIPTION

The proposed system is shown in fig. 1. It comprises two sections, namely the upper steam generating section and the high-temperature SOEC unit- hydrogen production unit.

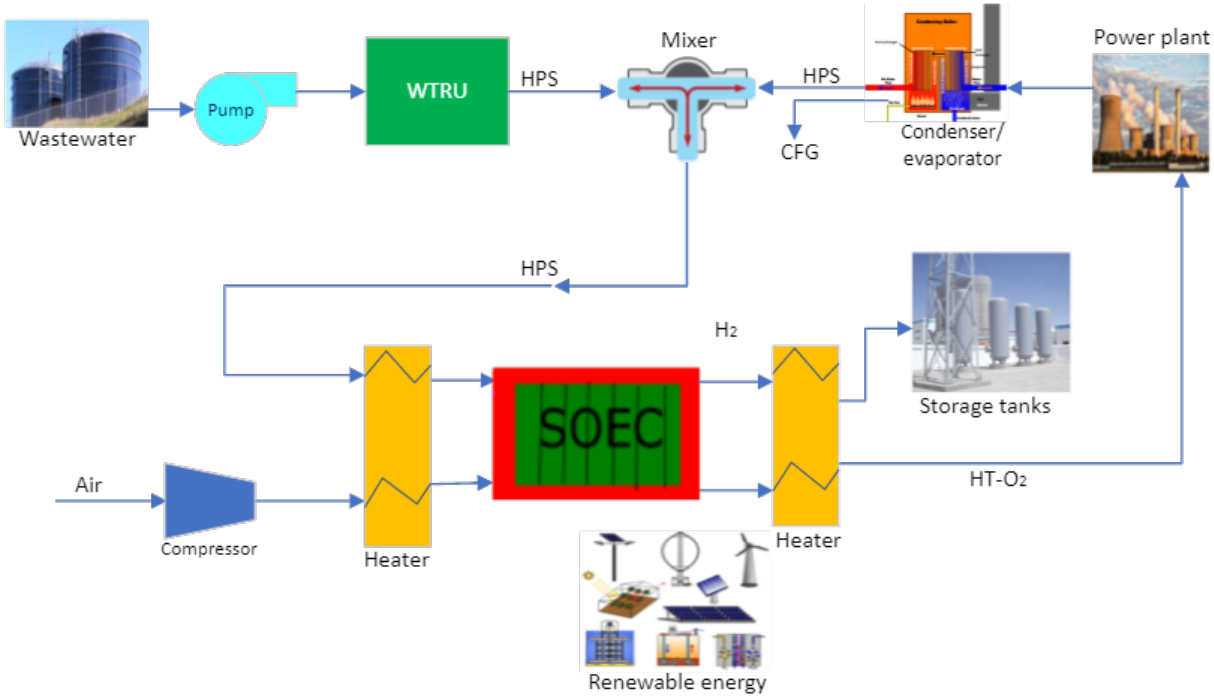

Fig 1: Water-energy integrated system for hydrogen production

In the upper section, high pressurized steam is generated from the wastewater reservoir after it is pumped to the water treatment and recovery unit (WTRU) where it is evaporated at atmospheric pressure and 101 ℃. This is mixed with the steam, which is concurrently generated from the power plant flue gas. The flue gas is cooled to 25℃ in the condenser for moisture recovery, and the heat regained is used in the WTRU. The recovered water is immediately evaporated and combined with the steam from the WTRU. The mixed stream is sent to the pre-heater to elevate its temperature to 750-850℃ before being fed into the SOEC to lower the required entropic heat for decomposition. Air from the ambient environment is compressed, preheated, and supplied to the system to flush out the produced oxygen from the electrolysis reactions in the SOEC. The exiting hydrogen product is stored in a compressed hydrogen tank.

The water decomposition reaction taking place in the SOEC is represented by the anodic oxidation and cathodic reduction reaction below

$$Anode: O^{2-} \rightarrow \frac{1}{2}O_2 + 2e^-$$

$$Cathode: H_2O \rightarrow H_2 + O^{2-}$$

$$Overall: H_2O \rightarrow H_2 + \frac{1}{2}O_2$$

Planar model configuration was used in the SOEC design with the system comprising of the balance of plant (BoP) such as condenser, heater, compressor, mixer, evaporator, separator, pump, heat exchanger to finally actualize a working model which are thermodynamically model using hysys. All other model assumptions are similar to that of Kazempoor and Braun[10].

RESULTS AND DISCUSSION

This section summarizes some of the important results of this work. The SOEC is in the developing stage, and this novel work is evaluated and validated. The system generated 242400 kg/day of hydrogen from the flue gas from a power plant with a capacity 333.7 MW. The voltage efficiency of the SOEC system is 92.9% at 850 ℃, and the overall thermal efficiency of the designed plant is 61.97%, which seems to be very prosperous compared to other plants of the same size. Even though it is shown from hysys that is potential to save over 25% of the utilized energy in the

system which reduces cost of production and optimize productivity. To live up to the progressive development in different sources of energy, the model is designed to be integrated with several energy sources. The Levelized cost of hydrogen (LCOH) production with some of these energy sources is evaluated and has shown in fig. 2. The LCOH ranges from $2.99-5.96/ kg hydrogen with the solar photovoltaic (P.V.) given the cheapest cost assuming the U.S. Department of Energy (DOE) target of 3 cent/kWh by 2020 and beyond. As such, the life cycle analysis (LCA) from cradle to gate for the plant is performed in SimaPro using the solar P.V. and the coal power plant to measure the severity of the environmental impact. Obviously, the COx emission with the coal power plant is higher. However, SimaPro revealed the higher effects of some other critical parameter factors like the human health, ecosystem and particulate matter formation associated with it. This puts solar P.V. and other renewable energy sources in the limelight.

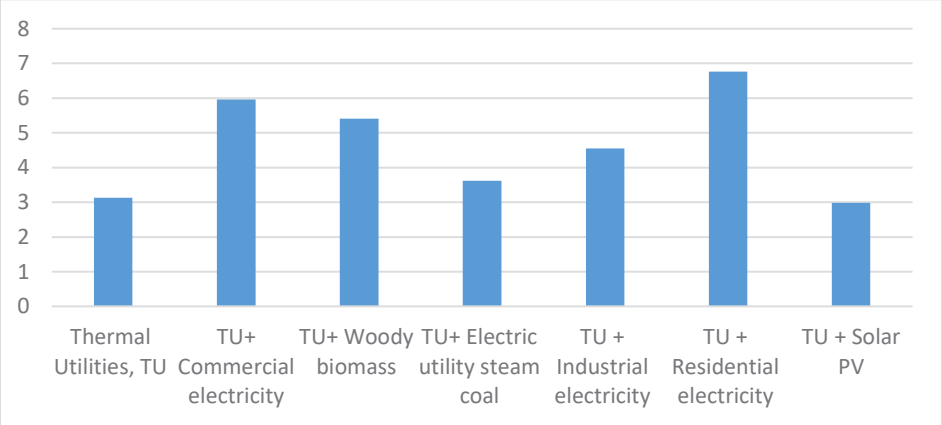

Fig. 2: Levelized cost of hydrogen with different feedstocks

CONCLUSIONS

The novel model designed in this work shows the possibilities of different energy integrations for hydrogen production and redefined a new approach to water-energy nexus. The LCOH of hydrogen can be as low as $2.99 per kg hydrogen, and this is a close route to meeting the DOE target for the cost of hydrogen for distribution and as potential energy storage. Further work needs to be embarked on to establish the exact environmental impact of large-scale hydrogen production to meet up the global requirement for sustainability and a green economy.

ABSTRACT

One of the promising ways for green hydrogen production is polymer exchange membrane water electrolysis (PEMWE). To this day, precious metal electrocatalysts are necessary for high production rates in PEMWEs. Catalysts such as Ir/IrO_2 have been extensively studied for the oxygen evolution reaction, but their high costs and the scarcity of resources hinder their use on a large scale. In this work, we focussed on IrO_x nanoparticles produced by pulsed laser ablation as an electrocatalytic material with the potential of a low-cost production in large scale. Furthermore, we studied B-doped Si structures as promising support material for the IrO_x particles to enhance the precious metal utilisation. The laser-generated IrO_x and B-doped Si nanostructures were ultrasonically sprayed to achieve a homogeneous coating, that builds up the anode catalyst layer, showing a high catalytic activity and promising kinetic parameters. In-situ analysis performed in a self-developed PEMWE are planned to validate the electrochemical results.

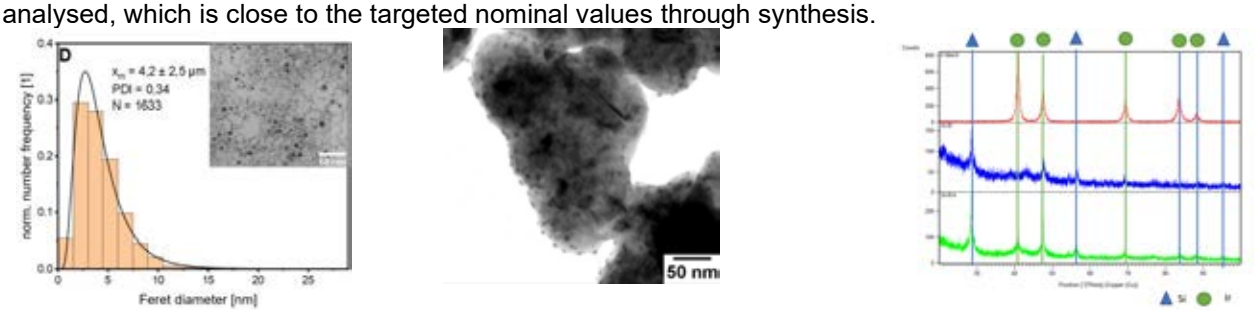
Keywords: polymer exchange membrane, electrolysis, synthesis, IrO_x, Si:B

INTRODUCTION

Electrocatalysts will play an important role in energy conversion processes as they increase the efficiency, production rate and selectivity of the involved transformation [1]. Electrocatalytic water splitting through oxygen evolution reaction (OER) and hydrogen evolution reaction are a promising technique to trigger the penetration of green technologies into the everyday life. Catalysts based on precious metals like Ir or its alloys are needed for the acidic environment and high anodic potentials have been extensively studied for the OER in PEMWEs [2]. The state-of-the-art Ir loadings in the range of 1-3 mg cm^{-2} need to be reduced due to the high costs and the limited availability of these materials.

Chemical reduction techniques are a common way to produce Ir nanoparticles for the later application as catalysts in PEMWE. Such materials are commercially available and being used for both the preparation of anodic catalyst layers (ACLs) and the membrane electrode assemblies (MEAs). In order to reduce costs by reducing noble metal loadings in PEMWE, recent studies report on e.g. increasing the utilisation of Ir due to advanced ACL architectures. Much like the carbon supported platinum catalysts which are state-of-the art in PEM fuel cells, one promising way to design elaborated ACLs is to favor Ir nanoparticles on support structures like e.g., SnO_2-Sb that were reported to be stable in PEMWE anodes [3]. By this, it is possible to enlarge the mass specific electrochemical active surface area and, thus, enable more active sites for the OER compared to unsupported catalyst nanoparticles. Nevertheless, as tin oxide is an n-type semiconductor, it as a low conductivity at room temperature and a relatively low anodic stability.

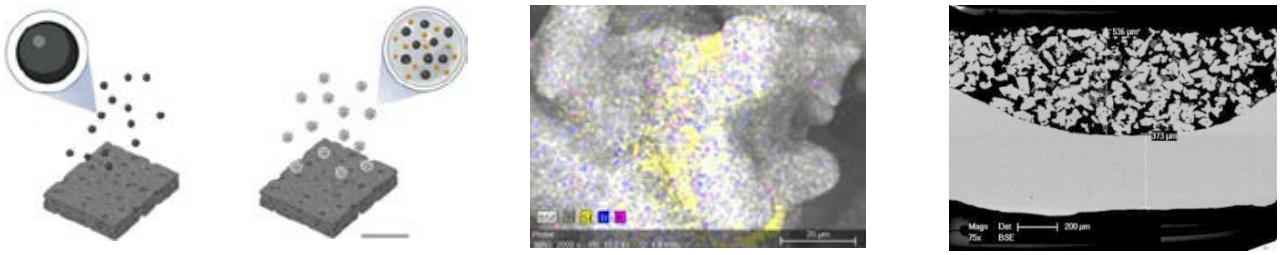
In this work, we report ACL for PEMWE based on laser generated Ir nanoparticles supported on boron-doped Si nanoparticles synthesized in a hot-wall reactor. Additionally, MEAs are prepared utilising the laser-generated Ir nanoparticles and in-situ characterised in a PEMWE test cell. Hence, in this work we focus on a novel Si nanostructure for the use as Ir support material. To induce an electrical conductivity of the support, Si was doped with boron before getting decorated with Ir nanoparticles. The analyses of Ir/Si:B catalysts are also given and compared with the results of unsupported Ir.



MATERIALS AND METHODS

A porous titanium transport layer (PTL) containing a diffusion bonded microporous Ti sintered powder plate was used as electrode substrate [4]. The design offers a large specific surface area and improved gas and water transport within the structure of the electrode.

For the catalyst preparation, surfactant-free iridium nanoparticles shown in Fig. 1(a) were synthesized by of colloidal nanoparticles in water. Parameters like the zeta potential, particle size, crystal structure and oxidation were determined [5]. On the other hand, doped silicon nanopowder has been synthesized by thermal decomposition of the gaseous precursors monosilane (SiH_4) and 6 at. %-diborane (B_2H_6) in argon, respectively. The incorporation of the p-type dopant boron, with an atom concentration of about 3 at.% is assumed to form a degenerated semiconductor. After the synthesis, Si:B material was loaded with 10 wt. % Ir nanoparticles, as displayed in Fig. 1(b), by a colloidal adsoption at pre-adjusted pH-value following an established colloidal procedure [5].
The obtained IrO_x and Ir-decorated Si:B 6 at. % nanoparticles were dispersed in a water based ink and sprayed on the substrate via an ultrasonic spray head in an Ar atmosphere, as schematically shown in Fig. 2(a) and Fig. 2(b). Physical characterisation was performed via scanning electron microscopy (SEM) and x-ray diffractometry (XRD). Linear sweep voltammetry methods in a three-electrode electrochemical cell were performed to determine the kinetics of the OER. Through-plane measurements were performed at 80°C and different pressures to investigate the electrical conductivity of the prepared electrode in an environment close to the one of a PEMWE. Finally, in-situ tests were performed in a self-developed single cell PEMWE based on hydraulic cell compression, facilitating an ideal contact between the materials.



RESULTS AND DISCUSSION

A succesful synthesis of colloidal 4 nm nanoparticles was obtained (Figure 1(a)). Exemplifying TEMs from Fig. 1(a) and Fig. 1(b) confirm the nanostructure of the iridium and thereof gained Si:B-Ir catalysts, respectively. The XRD measurements reveal the structure of silicon and. Boron is not observed since it is incorporated into the Si lattice. A possible shift of the Si diffraction peaks, due to B incorporation cannot be resoluted due to the widening of the peaks caused by nanostructured Si crystals. The XRD measuremets validate a succesful Si synthesis and the nanoparticle decoration, without the formation of an alloyed phase. Plasma atomic emission spectroscopy tests confirmed the chemical composition of the Si:B-Ir nanopowders, an average of 86 wt. % Si, 4.6 wt. % B and 8.5 wt. % Ir being analysed, which is close to the targeted nominal values through synthesis.

The SEM from Fig. 2(b) show the distribution of the Ir nanocatalyst on the Ti PTL (cross-section view in Fig. 2(d)) indicating a high-quality catalytic layer. The tendency of formation of Si:B agglomerates was as well observed. It is imperatively that the interconnection of Si based agglomerates allow for an electrically conductive path through the electrode. Electrochemical measurements of the nanoparticles sprayed on the Ti-PTL (Fig. 3(a)) showed a promising electrocatalytic activity towards OER. Moreover, through-plane electrical conductivity measurements (Fig. 3(b)) of the sprayed electrodes show similar values to the ones of the reference Ir black material, being a good sign for in-situ measurements.

(a) (b)

Fig. 3 (a) Linear sweep voltamograms of 1 cm^2 Ti PTL samples performed at room temperature in 0.5M H_2SO_4 (pH ≈ 0.3), E_{step} 5 mV s^{-1}, scanrate 5 mV s^{-1} and (b) through plane electrical conductivity measurements performed on 2 cm^{-2} samples at 80°C

The ongoing research covers a complete and innovative chain of electrode preparation to be used in PEM electrolysis technology from powder production, deposition using a novel method and comprehensive characterization.

CONCLUSIONS

The whole process chain is a very promising approach to qualify electrocatalysts for environmentally friendly and cost-effective energy conversion as the minimal use of the high-priced novel catalyst revealed encouraging performances. Further work is being carried out to complete the measurements with the above-described methods for both approaches and to validate the performance of the synthesised nanoparticles through in-situ tests in self-built PEMWE

ACKNOWLEDGEMENT

The project LIKELY is funded under the framework of “Leitmarkt NeueWerkstoffe.NRW” by the European Regional Development Fund (EFRE.NRW) (contract EFRE-0801480) and the state government of North Rhine-Westphalia. ABSTRACT

Various aqueous citrate electrolyte compositions for the Ni-Mo electrodeposition are explored in order to deposit Ni-Mo alloys with Mo-content ranging from 40 wt% to 65 wt% to find an alloy composition with superior catalytic activity towards the hydrogen evolution reaction (HER). The depositions were performed on copper substrates mounted onto a rotating disc electrode (RDE) and were investigated via scanning electron microscopy (SEM), X-ray fluorescence (XRF) and X-ray diffraction (XRD) methods as well as linear sweep voltammetry (LSV) and impedance spectroscopy. Kinetic parameters were calculated via Tafel analysis. Partial deposition current densities and current efficiencies were determined by correlating XRF measurements with gravimetric results. The variation of the electrolyte composition and deposition parameters enabled the deposition of alloys with Mo-content over the range of 40-65 wt%. An increase in Mo-content in deposited alloys was recorded with an increase in rotation speed of the RDE. Current efficiency of the deposition was in the magnitude of <1%, which is characteristic for the deposition of alloys with high Mo-content. The calculated kinetic parameters were used to determine the Mo-content with the highest catalytic activity for use in the HER.

Keywords: Anion Exchange Membrane Electrolysis, Nickel, Molybdenum, Electrodeposition, Hydrogen Evolution Reaction

INTRODUCTION

Hydrogen production via proton exchange membrane electrolysis (PEM) is a well established and commercially available technology, although still at a smaller scale than alkaline electrolysis. In an attempt to combine the benefits of both technologies, anion exchange membrane electrolysis (AEM) was created enabling high current densities like PEM-electrolyzers without the reliance on noble metal catalysts or highly concentrated and corrosive electrolytes, thus reducing the cost of the technology. [1]

Avoiding noble metal catalysts would also allow to replace platinum on the cathode side with cheaper materials, e.g. transition metal catalysts. Especially, Ni-Mo alloys showed superior activity for use in alkaline media for HER. For example, Xiao et al. reported one of the first AEM-cells with a pure water feed using Ni-Mo cathodes [2].

One technique to apply the catalyst material to the electrode that has already been used in PEM-electrolysis [3] is electrodeposition. This technique ensures that all catalyst particles are electrically connected to the substrate, thus, increasing catalyst utilization in the cell. Electrodeposition for Ni-Mo alloys is being researched for corrosion protection and HER catalysts. It follows the mechanism of induced co-deposition. Mo can only be deposited in the presence of transition metals like Ni and typically alkaline citrate baths are used [4].

An increase in the catalytic activity of electrodeposited NiMo alloys towards the HER has been reported with an increase in Mo-content from 10-40 wt% [5]. Decreasing activity has been reported with increasing Mo-content from 65-82 wt% [6]. For non-electrodeposited alloys an optimum was found at 50 wt% Mo-content [7]. Herein we showcase the creation and performance of electrodes with a Mo-content of 40-65 wt%, determined via physical and electrochemical characterization of the obtained electrodes.

EXPERIMENTAL

Manufacturing

An aqueous citrate bath with sodium hydroxide adapted from the work of Sun and Podlaha [6] was used as a base electrolyte. It contained 0.02 M nickel sulfate hexahydrate ($NiSO_4$ * 6 H_2O), 0.04 M sodium molydbate dihydrate (Na_2MoO_4 * $2H_2O$), 0.25 M tri-sodium citrate dihydrate ($C_6H_5Na_3O_7$ * 2 H_2O). The pH was adjusted via sodium hydroxide (NaOH) in the range of 8-10. Concentrations from the base electrolyte were varied in order to examine their effect on the alloy deposition and create different alloy compositions. Copper substrate discs with an exposed area of 1,3 cm² were used as the working electrodes for the deposition. A rotating disc electrode (RDE) serving as working electrode enabled defined hydrodynamics and better mass transport for the deposition, via variation of the rotation speed. A platinum wire served as the counter electrode. The deposits were created galvanostatically with an Ivium Vertex potentiostat with varied current densities. The substrates were polished and degreased before deposition.

Analysis

For the physical characterization of the samples, scanning electron microscopy (SEM), X-ray fluorescence spectroscopy (XRF) and X-ray diffractometry (XRD) measurements were conducted. Energy dispersive X-ray spectroscopy (EDS) mappings were conducted, to observe the distribution of the alloy components. XRF measurements were used to determine the composition of the deposited layers on a larger surface area. Based on these results and the loading of the samples, the current efficiency and partial deposition current densities of the metals and side reactions were calculated. Crystallographic information was obtained via XRD measurements.
For electrochemical characterization linear sweep voltammetry (LSV) measurements were conducted in an alkaline environment (1 M KOH) at AEM operating temperature (80°C). From these voltammograms Tafel plots were derived, to determine the kinetic parameters Tafel slope b, charge transfer coefficient α and exchange current density i_0. Moreover, impedance spectroscopy was performed in order to characterise the electrode-electrolyte interface.

RESULTS AND DISCUSSION

Effect of deposition parameters

The variation of different deposition parameters was analyzed in order to find effects of the parameters on the deposition and interactions between them. To achieve this, a response surface methodology design of experiments technique was used to create the experimental design for this study. The effect of the rotation speed on Mo- and Ni-content from preliminary experiments with lower Mo-content can be seen in Table 1. Increasing the mass transport of Molybdenum to the electrode surface via RDE increased the Mo-content in the alloys, analogous to reports on a rotating cylinder electrode [4].

Table 1. Effect of rotation speed on Mo- and Ni-Content in the alloy, determined by XRF

Rotation speed [1 min^{-1}]	Mo-Content [wt%]	Ni-Content [wt%]
0	10,3	89,7
2000	21,9	78,1
3000	24,0	76,0

Physical characterization

The physical characterization revealed the morphology of the samples and gave further information about the effects of the deposition parameters on the deposited alloy. Preliminary experiments with a slightly lower Mo-alloy content showed a homogeneous distribution of the components in the deposited alloy, presented in Fig. 1.

Electrochemical characterization

For the deposited alloys LSV was performed to evaluate their catalytic activity and find an optimum alloy composition with superior activity towards the HER. The cathodic sweeps were performed at AEM operating temperature to determine the overpotential of the HER on the prepared electrodes at defined current densities under operating conditions. To further examine the catalytic properties of the electrodes, Tafel plots were derived. The kinetic parameters charge transfer coefficient α and the Tafel slope b elucidate the reaction mechanism and allow for the determination of the rate determining step of the reaction. Additionally, the exchange current density i_0 in combination with the Tafel slope b describe the kinetic behaviour of the electrode, thus enabling comparisons between electrodes and reference samples to find optimal catalytic activity.

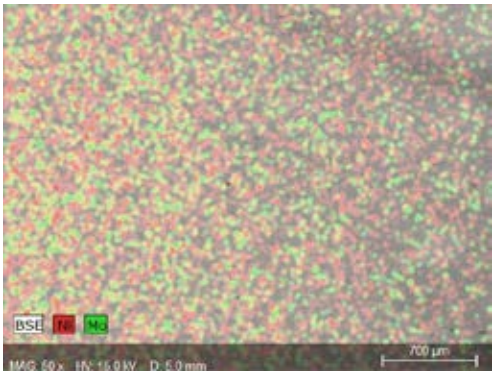

Fig. 1. EDS mapping revealing Ni- and Mo-distribution

CONCLUSIONS

The deposited NiMo alloys with Mo-contents in the range of 40-65 wt% showed promising physical and electrochemical properties for HER. The EDS-mapping revealed a quasi-homogeneous distribution of the alloy components. Additionally, the mass transport of the deposition was improved via RDE, resulting in increased transport of Mo-species to the electrode and thus increasing the Mo-content of the alloy.

ABSTRACT

Initial laboratory results using 3-D electrodes with forced electrolyte flow indicate a significant process intensification potential. This work aims to validate this process intensification on a larger scale, using a pilot-scale alkaline water electrolyser with a 6 kW cell stack working in the ranges 5-10 bar, 20-70°C and with 30% KOH. This pilot plant is also representative of industrial electrolysers in terms of gas collection, cell stacking and current distribution. In addition, it has been modified to allow for forced electrolyte flow using KOH compatible pumps.

The pilot system was first validated using standard 2-D electrodes and showed state-of-the-art results. Various cell stacks with 3-D electrodes were then tested under conditions of forced flow, showing interesting intensification potential. However, obstacles in terms of stack design still limit the flow effect. The latter are currently being tackled using CFD simulation tools.

Keywords: 3-D Electrodes, Alkaline Water Electrolysis, Pilot Demonstration, Process Intensification.

INTRODUCTION

Alkaline water electrolysis is a technology that is well proven, rather simple, mature and reliable. But the power density remains critically low. Previous work done in our group highlighted the synergetic effect of simultaneously using 3-D electrodes and forced electrolyte flow, leading to significant process intensification [1].

3-D electrodes, whose active surface is at least an order of magnitude larger than 2-D electrodes for the same projected surface, reduce the overpotential of the electrochemical reaction. But under natural convection, gas bubbles remain trapped inside these 3-D macroporous structures, which counterbalances their intrinsic advantage. Implementation of a forced electrolyte flow through the electrodes is therefore necessary in order to take full advantage of their increased surface area.

The present work describes the modifications done on a near industrial-scale electrolyser to allow the use of 3-D electrodes and forced electrolyte flow. State-of-the-art results were obtained using standard commercial 2-D electrodes, notably with no significant influence of the forced flow, as expected. Cell stacks with 3-D electrodes were then mounted and tested under varying conditions of forced flow. The flow effect is clearly present, but it is significantly weaker than what was previously obtained at the lab scale. The reason behind this performance gap clearly lies in the stack design, which is currently being improved through computational modeling. Furthermore, the effect of the 3-D stack configuration – i.e. pore size of both porous transport layers and catalyst layers – will also be reported.

MATERIALS AND METHODS

Fig. 1a shows a picture of the alkaline water electrolysis pilot system installed in our lab. It was initially a HyStat electrolyser from Hydrogenics. It has a flexible cell stack (up to 24 units) with a projected surface area of 314 cm². The standard 2-D electrodes are state-of-the-art catalyst-coated expanded nickel electrodes with a nickel mesh as pre-electrodes. The membranes are Zirfon Perl commercialized by Agfa. Without the use of pumps, the produced gas bubbles rise gravitationally to the liquid-gas separator, dragging some electrolyte with them. Fig. 1b shows the MagnoChem pumps with PumpDrive R variators, commercialized by KSB, that were added to allow forcing the electrolyte flow. The electrolyte flows back to the cell stack after the liquid-gas separator. The applied electrical field is perpendicular to the electrolyte flow (flow-by configuration).

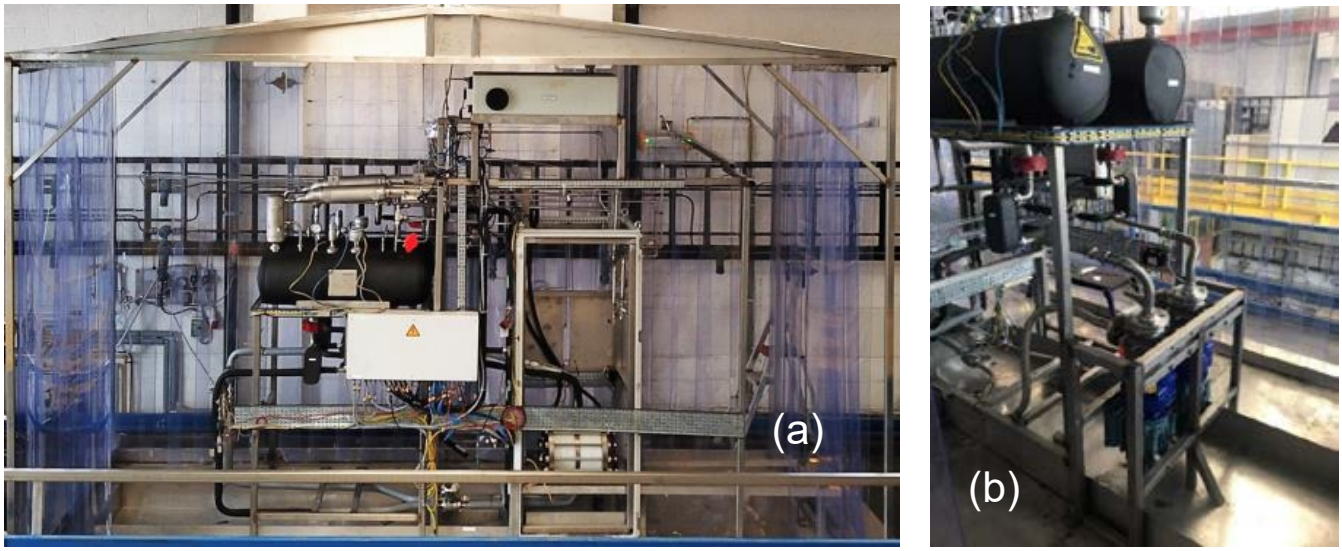

Fig. 1. (a) Picture of the pilot plant alkaline water electrolysis system and (b) added pumps used for forcing electrolyte flow.

The pilot allows applying a fixed current (DC), between 70 A and 140 A. The resulting cell stack voltage is obtained by measuring the voltage between the center of the stack and each end of the cell stack. For each applied current, one obtains the evolution of two voltages, one for each half stack, as shown in Fig. 2a. By dividing the applied current by the projected surface area, one obtains the applied projected current density. The average cell voltage for each half stack is in turn obtained by dividing the measured half-cell stack voltages by the number of cells in the half stack (12), as shown in Fig. 2b.

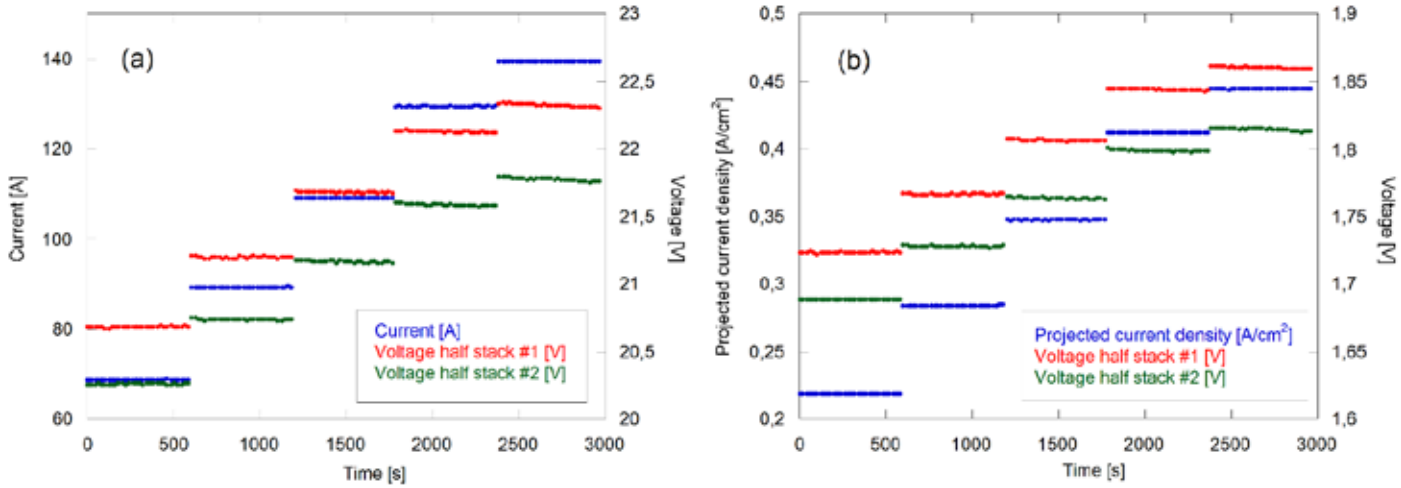

Fig. 2. (a) Applied current and resulting voltage on each half stack with standard 2-D electrodes at 6 bar and 40°C and (b) corresponding projected current density and cell voltage per stack. No forced flow.

RESULTS AND DISCUSSION

Fig. 3 shows the cell voltage of a custom 8-cell stack in benchmark conditions, where the standard 2-D electrodes have been replaced by 3-D nickel foams with 450 µm and 580 µm pore size. Each point in this figure is the average output voltage of a galvanostatic step, the latter being performed in the range 40-200 A. Unlike the projected current density in Fig. 2, Fig. 3 displays the cell voltage as a function of the so-called electrochemical current density j_{ECSA}, i.e. taking into account the entire electrochemical surface area (ECSA) of the 3-D catalyst layer.

The effect of pore size is clearly visible in Fig. 3, and confirms what we previously observed at the lab scale: big pore sizes allow for a more effective evacuation of gas bubbles, in turn exhibiting more surface area than small pore sizes. This observation can be extended to the porous transport layer (PTL), since, when the classic nickel mesh is replaced by a 580 µm pore size nickel foam, the cell voltage increases as bubble removal is less effective.

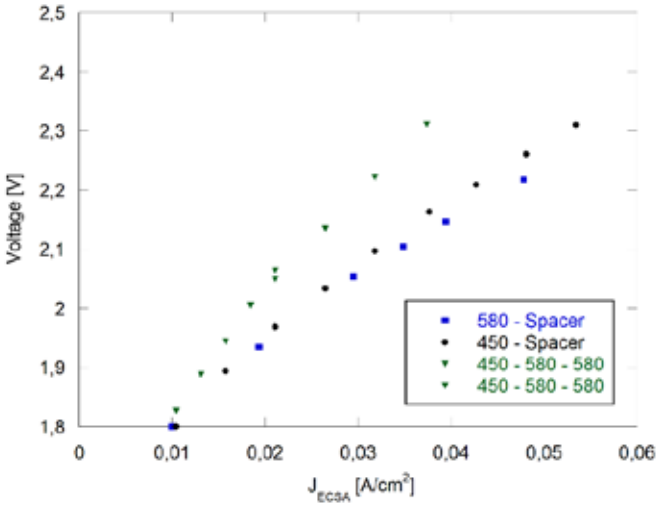

Fig. 3. Cell voltage as a function of j_{ECSA} at 6 bar and 70°C for three different nickel foam electrode configurations: 580 µm pore size as catalyst layer and nickel mesh (spacer) as PTL (blue), 450 µm pore size as catalyst layer and nickel mesh as PTL (black) and 450 µm pore size as catalyst layer and 580 µm pore size as PTL (green, two different data series). Forced flow: 560 L/h.

However, as explained above, the effect of forced flow on the cell voltage is much weaker than expected at the pilot plant. Limitations of the current cell design clearly appear when looking at the CFD simulations of the flow velocity in Fig. 4: the flow is turbulent when considering no friction on the walls, and inhomogeneous with friction. Bubble removal is clearly not optimal in such cases. Alternative stack designs are currently being considered.

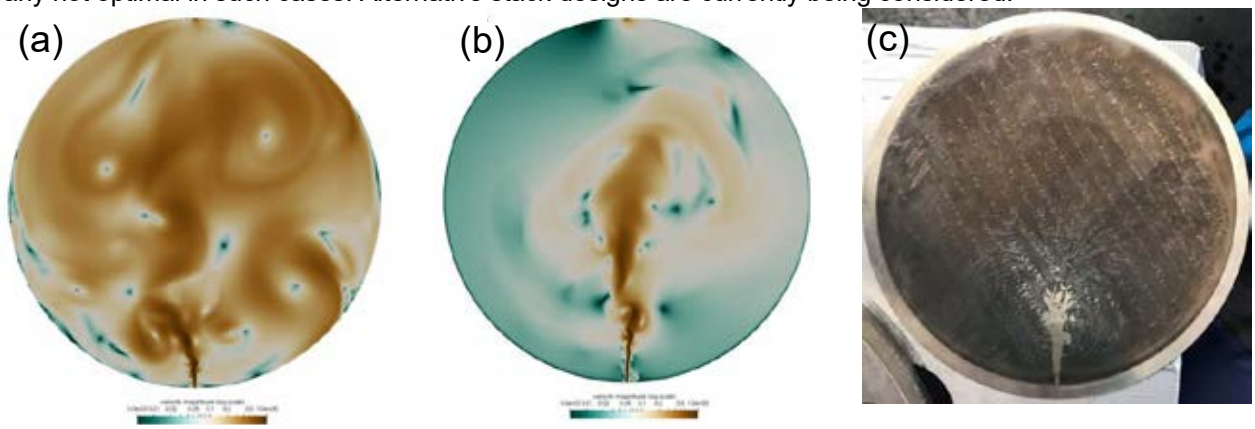

Fig. 4. Velocity Field [m/s] simulated by CFD for an empty cell (10 mm radius, 6 mm thickness) (a) without and (b) with friction on the cell walls. Picture (c) shows the pattern left by the electrolyte on a bipolar plate after experiments at the pilot plant.

CONCLUSIONS

An alkaline water electrolysis pilot plant was successfully adapted to forced electrolyte flow and 3-D electrode systems. The results not only confirm state-of-the-art data for industrial applications using 2-D electrodes, but also reliably reproduce results obtained at the laboratory scale on 3-D electrodes, notably highlighting the importance of PTL and catalyst layer design for effective bubble removal. Further design changes are necessary to unravel the full potential of forced flow.

ABSTRACT

Hydrogen is increasingly seen as a future fuel and a potential alternative to fossil fuels, as it is the cleanest and ideal energy carrier. Water electrolysis is one of the easiest methods to produce hydrogen, offering the advantage of simplicity. Rhodium is considered one of the best electrocatalysts for water electrolysis. This research was conducted to investigate the activity of electrodeposited Rh for its potential electrocatalytic application in acidic and basic water electrolysis. The electrode was fabricated from a 5g/L solution of $Rh_2(SO_4)_3$ electrodeposited at 3.00V for 3mins in a 92.5% Ag alloy substrate. Electrochemical characterizations were performed using cyclic voltammetry in a three-electrode set-up. The acidic electrolyte was a H_2SO_4 solution while the basic electrolyte was a NaOH solution. Results showed onset potentials of 1.4V and -0.2V for acidic OER and HER, respectively, while 0.6V and -0.9V for basic OER and HER, respectively. Consistent absolute value of limiting current, 8.00 x 10^{-3}A was observed for both reactions of the two electrolytes.

Keywords: Water Electrolysis, Cyclic Voltammetry, OER, HER

INTRODUCTION

Growing interest in renewable energy sources is an action to solve global energy crisis. As the development progresses, the need for energy storage system also increases. Hydrogen is a promising method to store energy. It can be produced through water electrolysis, a well-established conventional technology. The process requires a suitable electrocatalyst that provides the minimum possible overpotential to overcome various activation barriers. Inert metals like Rhodium are considered to be the best electrocatalysts. This study aimed to investigate the activity of Rhodium in an electrodeposit form when used as electrocatalyst in acidic and basic water electrolysis.

MATERIALS AND METHODS

The electrode is prepared by electrodepositing a thin coating of Rh in a 92.5% Ag alloy using a 5g/L solution of $Rh_2(SO_4)_3$. The electrodeposition was carried out in a two-electrode set-up, utilizing a Pt foil as non-consumable anode. The temperature during the process was maintained at 50°C. Optimal deposition parameter was identified to be 3V (0.587A) for 3mins deposition time.

The behavior of electrodeposited Rh has been investigated using cyclic voltammetry. A three-electrode electrochemical cell set-up with Ag/AgCl in KCl solution as reference electrode, Pt foil as counter electrode, and electrodeposited Rh as working electrode was employed. Voltammetric cycles were done at room temperature with scan rate of 25mV/s. Scans were started and ended at 0V potential. Measurement for acidic water electrolysis was done using 0.5M H_2SO_4 solution, with upper and lower vertex potentials of 2.0V and -1.0V, respectively. For basic water electrolysis, electrolyte was a 0.5M NaOH solution, upper vertex potential was 1.0V, and lower vertex potential was -1.5V. Short CV scans at the identified hydrogen and oxygen evolution regions were performed to assess stability of the electrode.

RESULTS AND DISCUSSION

Using Nernst equation, the operating voltage needed for a successful electrodeposition of Rh was identified to be greater than 1.861V to include the sum of overpotentials. Different combinations of deposition time and operating voltage were conducted. Results of experiment for Rh electrodeposition revealed the optimal parameter of 3V (0.587A) for 3mins deposition time, with an approximated deposit thickness of 1.88µm. Similar optimal deposition time and voltage has been defined by Rudolf, et.al. [1]. Excellent adhesion of Rh on Ag alloy was observed through adhesion test as per ASTM D3359-97 [2], and may be attributed to their properties satisfying the Hume-Rothery Rules for substitutional solid solution formation.
The activity of electrodeposited Rh in acidic and basic electrolytes has been investigated using cyclic voltammetry (CV). The set potential for CV was defined by calculating the corresponding reversible potentials for the anodic and

cathodic reactions using Nernst equation. The following conditions were used during CV scans: temperature, T = 25ºC; acid concentration, $[H^+]$ = 0.5M; basic concentration, $[OH^-]$ = 0.5M, oxygen gas pressure, P_{O2} = 0.21atm; hydrogen gas pressure, P_{H2} = 5 x 10^{-5}atm. Incorporating the given conditions to the Nernst equation, the following reversible potentials were calculated: $E_{anode(acidic)}$ = -1.202V; $E_{cathode(acidic)}$ = 0.109V; $E_{anode(basic)}$ = -0.408V; $E_{cathode(basic)}$ = -0.685V. Based on the calculated reversible potentials and adding the contribution of overpotentials, CV scans were done at 2.0V upper vertex potential and -1.0V lower vertex potential for acidic electrolyte, and 1.0V upper vertex potential and -1.5V lower vertex potential for basic electrolyte. Scans were started at 0V, varied linearly with time up to the upper vertex potential, scanned back with the same scan rate down to lower vertex potential, and finally scanned to reach back the 0V.

Figure 1A illustrates the full CV scan for acidic electrolyte and shows an abrupt increase in current at approximately 1.4V indicating an onset potential of OER, and an abrupt decline in current at approximately -0.2V indicating an onset of HER. Both reactions approached the same absolute value current of approximately 8.00 x 10^{-3}A, as shown in the plateau regions in Fig. 1Ac & i, providing the value of limiting current. In these regions, the change in current with increasing applied potential is minimal.

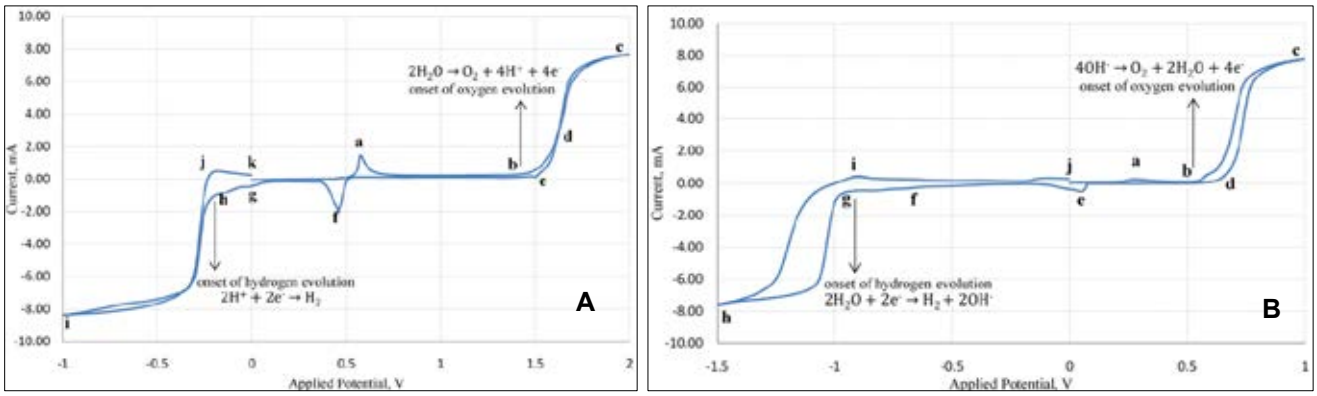

Fig. 1. Full CV scan of electrodeposited Rh in A) 0.5M H_2SO_4 and B) 0.5M NaOH taken at 25mV/s

$H_2O + Rh \rightarrow RhOH + H^+ + e^-$ (1)
$RhOH \rightarrow RhO + H^+ + e^-$ (2)
$RhO \rightarrow (1/2)O_2 + Rh$ (3)
$H^+ + e^- \rightarrow H_{ad}$ (4)
$2H_{ad} \rightarrow H_{2\,ad}$ (5)
$H_{2\,ad} \rightarrow H_2$ (6)
$OH^- + Rh \rightarrow RhOH + e^-$ (7)
$RhOH + OH^- \rightarrow RhO + H_2O + e^-$ (8)
$H_2O + e^- \rightarrow H_{ad} + OH^-$ (9)

The peaks observed at Fig. 1Aa (~0.6A) & f (~0.4A) correspond to oxygen adsorption and desorption, respectively on the electrode surface. Related studies proposed that the OER in acidic solution using a noble metal catalyst such as Rh follows the forward direction of reaction mechanisms given in Eqs. 1-3 [3, 4]. The first peak (Fig. 1Aa) corresponds to the dissociation of water to form the RhOH (Eq. 1) which immediately followed by oxidation to RhO (Eq. 2). Increasing the potential to 1.4V gives the onset for oxygen evolution (Fig. 1Ab, Eq. 3). From this point, the current rapidly increases with constant rate of potential until reaching a maximum value in Fig. 1Ac. On the reverse scan, a crossover potential (Fig. 1Ad) was observed at approximately 1.6V, indicating a nuclei formation. During the reverse scan, the system experienced an oxygen reduction reaction following the reverse directions of Eq. 1 to Eq. 3. The reduction peak in Fig. 1Ae corresponds to the reduction of O_2 into RhO immediately followed by the reduction to RhOH. The peak at Fig. 1Af corresponds to oxygen desorption. Upon reaching the starting point of CV which is at 0V, a downward peak started to form as an indication of HER. Based on a literature review by Hui Li, et.al, and a study by Jaksic, et.al, the HER in acidic medium using a noble metal catalyst may occur by the mechanisms described by Eqs. 4-6 [3, 4]. Figure 1Ag corresponds to hydrogen adsorption in which the H+ from the electrolyte upon meeting an e- diffuse and adsorbs on the electrode surface (Eq. 4). The onset for HER is displayed in Fig. 1Ah at ~-0.2V. The current rapidly decreased with constant rate of potential until it reached the value of limiting current in Fig. 1Ai. The scan from -1.0V to 0V shows a peak in Fig. 1Aj which corresponds to hydrogen desorption (reverse direction of Eq. 6 to Eq. 4). Fig. 1Ak may be attributed to void formation on the electrode surface due to hydrogen diffusion.

As with acidic electrolyte, CV scan in the basic medium revealed similar mechanisms for the HER and OER, but at different potential values. OER in basic solution using a noble metal catalyst follows the forward direction of reaction mechanisms given in Eqs. 7-8 then Eq. 3. [3, 4]. The first peak (Fig. 1Ba) corresponds to the adsorption of available hydroxide ion to form the RhOH (Eq. 7) which immediately followed by oxidation to RhO (Eq. 8). Increasing the potential to 0.6V gives the onset for OER (Fig. 1Bb, Eq. 3). Current then rapidly increases with constant rate of potential until limiting current value, Fig. 1Bc. The system experienced oxygen reduction during the reverse scan following the reverse directions of Eq. 3 and Eqs. 8 & 7. The reduction peak in Fig. 1Bd corresponds to the reduction of O_2 into RhO immediately followed by the reduction to RhOH. Fig. 1Be corresponds to oxygen desorption. HER for basic medium followed the mechanisms in Eq. 9 then Eq. 5-6 [3, 4]. Fig. 1Bf corresponds to hydrogen adsorption on the electrode surface (Eq. 9). The onset for HER is displayed in Fig. 1Bg at ~-0.9V. The current rapidly decreased until it reached the limiting current in Fig. 1Bh. A hysteretic portion observed on the HER region corresponds to hydrogen absorption [3]. Peak in Fig. 1Bi corresponds to hydrogen desorption (reverse direction of Eq. 9 then Eq. 6 & Eq. 5). Fig. 1Bj would be the effect of hydrogen diffusion forming voids on the surface of Rh electrode.

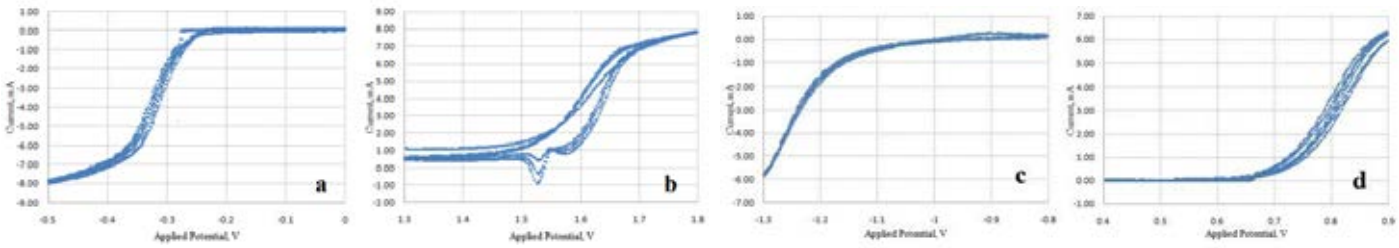

Fig. 2. Three-cycle CV scan of electrodeposited Rh taken at 25mV/s in a) 0.5M H_2SO_4 for HER; b) 0.5M H_2SO_4 for OER; c) 0.5M NaOH for HER; d) 0.5M NaOH for OER

The short CV scans of electrodeposited Rh in the HER and OER regions for both acidic and basic media are shown in Fig. 2. The figure indicates high stability of electrodeposited Rh; therefore, it can be used as both an anode and a cathode in acidic and basic water electrolysis. Further study was performed to confirm the stability of electrodeposited Rh during an extreme and long duration water electrolysis. The discussions were presented in the other paper of Bonifacio, et al [5].

CONCLUSIONS

Fabrication and characterization of electrodeposited Rh on Ag alloy for electrocatalytic applications in water electrolysis provided successful foundation of this study. From the identified optimal parameters, Ag alloy substrates were electrodeposited with thin coating of Rh. Cyclic voltammetry results showed the potential regions for HER and OER in both media and revealed the excellent activity of electrodeposited Rh in acidic and basic water electrolysis.

ABSTRACT

Applied research is focussing on reducing costs for membrane electrode assemblies (MEA) and improving the performance by reducing polarization losses. The present research is investigating MEAs for proton exchange membrane water electrolysis (PEMWE) based on glass fibre reinforced composite membranes assembled with gas diffusion electrodes or processed as catalyst coated membranes. Membranes were prepared by casting a polymer suspension onto both sides of a glass fibre fabric. Subsequently, the reinforced composite membranes were ex-situ investigated showing promising proton conductivity and comparable thermo-oxidative stability compared to commercial Nafion115 membrane. In-situ tests were performed by assembling the composite membrane into an MEA either with gas diffusion electrodes prepared via electrochemical catalyst deposition or ultrasonic spray coating, or catalyst coating of the membrane by ultrasonic spay coating. Ir was used as anode catalyst, Pt as cathode catalyst, respectively. The polarization curves were recorded using a single cell, hydraulic compressed test system. Preliminary results with a slightly thicker ssPS(CL)-PPSU membrane than the used reference material, showed that the synthesized, composite membrane with the self-prepared catalyst coating reached a cell voltage of 2.4 V at a current density of 2 A*cm^{-2}, making it competitive to the reference Nafion115 sample prepared and tested the same way.

Keywords: MEA, water electrolysis, composite PFSA/SSPS membranes, glass fibre reinforcement, in-situ.

INTRODUCTION

Recently, the 26th UN Climate Conference underlined the importance of limiting global warming to 1.5°C in this decade [1]. Hence, implementing an energy supply based on fluctuating, renewable sources and using hydrogen as reliable energy carrier is discussed [2,3]. Electrochemical water splitting technologies like PEMWE can represent a sustainable solution for hydrogen-based energy systems, due to their high energy efficiency, flexible dynamic operation, and the capability to produce compressed and pure hydrogen. Moreover, PEMWE based hydrogen production offers the opportunity to reduce greenhouse gas emissions up to 75 % compared to hydrogen production based on steam methane reforming [4].

One of the key components in PEMWEs is the MEA, consisting of proton exchange membrane (PEM) and the electrodes, being responsible for the electrochemical reactions. State-of-the-Art PEMWE use catalyst coated membranes (CCMs) based on perfluorosulfonic acid as hydrogen proton carrier due to their sufficient mechanical and thermal stability and chemical inertness. Scaling up the production and thus system size of PEMWE leads to a sharp increase in the partial costs of the MEA, due to the increased quantity of noble metal catalysts and fluorinated membranes [5,6]. Reducing membrane thickness and using a different polymer can help to reduce raw material costs and increase the PEMWE efficiency by lowering the polarisation losses caused by ohmic membrane resistance or increasing the operation temperature by improving mechanical and thermal stability of the PEM. Further, the MEA performance can be adjusted by applying different preparation methods depending on the electrodes used. Gas diffusion electrodes (GDEs) prepared by electrochemical catalyst deposition offer the possibility to increase catalyst utilization and therefore reduce MEA costs, where else CCM preparation is state-of-the-art for PEMWE.

In the present work, composite membranes are synthesized consisting of proton conductor, cross-linked ssPS particles embedded into a PFSA polymer matrix and reinforced by glass fibre fabric. The synthesized membranes are ex-situ investigated regarding thermogravimetry, ion exchange capacity, electrical resistance, and proton conductivity. Further, the membranes were used for MEA preparation by GDE or CCM approach using Ir as catalyst and Ti as porous current collector for the anode, Pt and a carbon-based gas diffusion layer as cathode current collector, respectively. MEA characterisation was done by in-situ investigations in a self developed, single cell PEMWE test system based in the principle of hydraulic compression.

EXPERIMENTAL

Membrane Synthesis and Characterisation

The membranes were prepared by dispersing PFSA polymer (Aquivion) and cross-linked ssPS particles in N,N-dimethylacetamide at 140°C. In a second step, the dispersion is coated onto a glass plate. Immediately, a glass fibre fabric (25 g*m^{-2}) is placed as a second layer on the top of the coating followed by coating the glass fibre fabric with the polymer dispersion (3rd layer) after 30 minutes. After evaporating the solvent at 80°C and 120°C the membranes are protonated with 1M hydrochloric acid and rinsed with deionized water.

For ion exchange capacity (IEC) measurements the synthesized membranes were soaked in saturated sodium chloride solution for 24h and subsequently titrated with 0.1 M sodium hydroxide solution. Electrical resistance measurement was performed in deionized water using a through plane cell made of stainless steel with an electrode diameter of 11 mm connected to a Methrom Autolab potentiostat. Thermal-oxidative stability was investigated using thermal gravimetric analysis (TGA, Netzsch) in oxygen atmosphere.

Membrane-electrode-assembly preparation

For the MEA preparation, Ir was used as anode and Pt as cathode catalyst material, respectively. CCMs were prepared via ultrasonic spray coating using an USI Ultrasonic System, Inc. apparatus, equipped with a heated vacuum table. Therefore, catalyst inks were prepared consisting of catalyst powder, 5 wt.% ionomer-dispersion, isopropanol, and deionized water.
GDEs were prepared via electrochemical catalyst deposition or catalyst coating of the electrode substrate. Titanium was used as anode, commercial carbon-based gas diffusion layer as cathode substrate, respectively. Electrochemical catalyst deposition was performed using a two-electrode configuration and precious metal electrolytes. Catalyst coated substrates (CCSs) were prepared using ultrasonic spray coating and catalyst inks reported for CCM preparation.

In-situ testing

Polarisation curves were recorded following the “EU harmonised polarisation curve test method for low-temperature water electrolysis” [7]. The used test system consisted of a single cell PEMWE with a maximum geometrical active area of 25 cm². The polarisation curves were recorded, applying 8 bar hydraulic pressure on the MEA in several cell temperature steps up to 90°C. An MaterialsM Instruments potentiostat was connected to the test system to apply current density and record cell voltage.

RESULTS AND DISCUSSION

Membrane characterisation

The thickness of the prepared PFSA/ssPS membranes is about 50 – 70 µm. Electrical resistance measurement results show lower electrical resistance of the synthesized PFSA/ssPS membrane compared to the Nafion115 reference membrane.
Figure 1 shows the thermo-oxidative stability of Nafion115 and PSFA/ssPS membrane.
The weight-loss up to 200°C is caused by water evaporation followed by desulfonation starting between 250°C and 300°C. The desulfonation temperature of the PFSA/ssPS membrane is as high as the desulfonation temperature of the Nafion115 membrane, indicating similar thermal-oxidative stability.

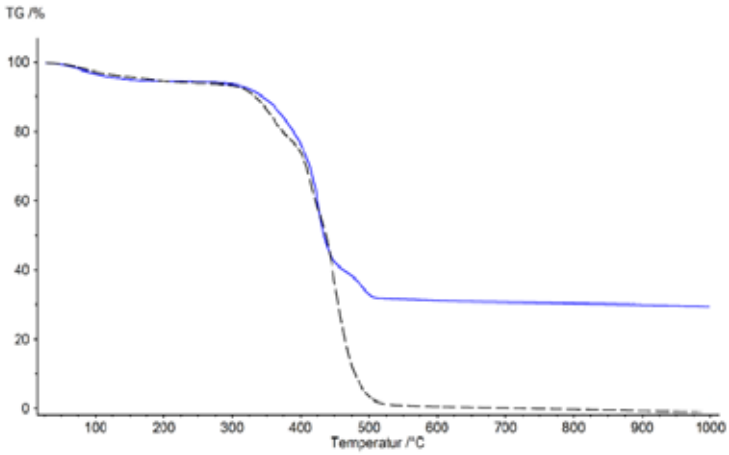

Figure 1: Thermo-oxidative stability of PFSA/ssPS, glass fibre reinforced composite membrane (blue) and Nafion115 (black).

Polarisation curves

Figure 2 shows the recorded in-situ polarisation curves at 80°C for the ssPS(CL)-PPSU membrane and the reference Nafion115 commercial membrane, both processed as CCMs via ultrasonic spray coating. The ssPS(CL)-PPSU membrane reached a cell voltage of 2.4 V @ 2 A*cm^{-2}, whereas the reference reached approximately 2 V @ 2 A*cm^{-2}, respectively.

In the region of low current densities, the polarisations curves superimpose, showing alike activation losses. In the linear region of the obtained polarisation curves the ssPS(CL)-PPSU membrane shows a higher slope and therefore

higher ohmic resistance compared to the reference membrane, leading to increased cell voltage at a current density of 2 A*cm^{-2}. These ohmic losses can be attributed to the increased membrane thickness of approximately 134 µm and therefore higher ohmic resistance, compared to the reference Nafion115 membrane (125 µm thickness). Additionally, the tested ssPS(CL)-PPSU membrane shows lower proton conductivity in the ex-situ characterizations, leading to a slightly poorer in-situ performance. Nevertheless, the composite ssPS-membrane shows promising performance for PEMWE that could be improved by further material improvements, e.g., changing the polymer matrix and adding a glass fibre reinforcement.

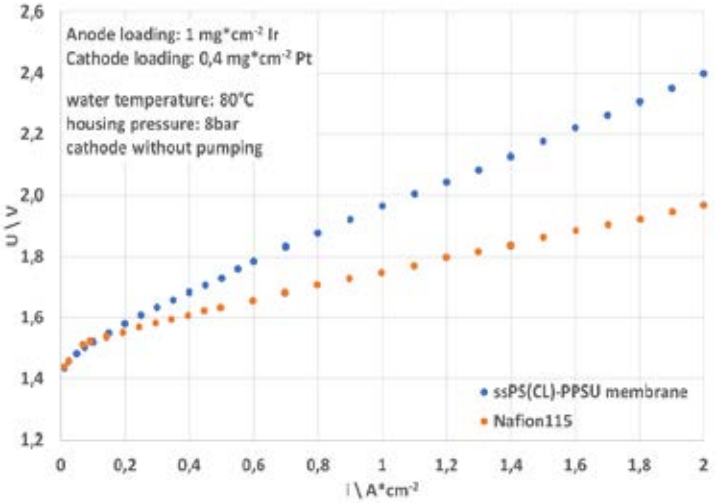

Figure 2: PEMWE polarisation curves recorded at 80°C working temperature, showing Nafion115 membrane (orange) and ssPS(CL)-PPSU membrane (blue).

CONCLUSIONS

The synthesized composite membrane indicates promising results for PEMWE. Additionally, a linear ionomer shall be developed and characterised. Therefore, in-situ tests with different MEA configurations are planned to be performed in the single cell, hydraulic compressed test system. Approaches containing GDEs with electrochemical deposited catalysts as well as CCS or CCMs prepared via ultrasonic spray coating will be used for MEA preparation. Moreover, the influence of the ionomer used for MEA preparation shall be investigated. Also, the operation temperature of the PEMWE will be varied to determine the thermal stability of the membrane.

ACKNOWLEDGEMENT

The present work has been carried out within the project “Entwicklung von kostengünstigen, langzeitstabilen und leistungsverbesserten Membran-Elektroden-Einheiten für PEM-Brennstoffzellen und PEM - Hochdruckwasserelektrolyseure vorzugsweise eingesetzt in Systemen mit hydraulischer Verpressung (HyPresMEA)“, part of the funding program “Forschung an Fachhochschulen”, being financially supported by the German Federal Ministry of Education and Research (contract number: 13FH257PA6). Furthermore, we thank GKN Sinter Metals Filters GmbH, Germany, for manufacturing the Ti-based current collectors and ProPuls GmbH, Germany, for supporting the in-situ investigations.

ELECTROCHEMICAL PERFORMANCE OF 3-D PRINTED ELECTRODE GEOMETRIES IN VIEW OF ENHANCED GAS EVACUATION DURING ALKALINE WATER ELECTROLYSIS

[1*] *Fernando Rocha,* [1] *Nathan Wauthy,* [1] *Renaud Delmelle,* [1] *Christos Georgiadis,* [1] *Joris Proost*

ABSTRACT

Water electrolysis plays a key role in the energy transition as it can be used to store energy by the conversion of electrical energy from renewable and intermittent sources to chemical energy in the form of hydrogen gas. Currently, the most mature technology is alkaline water electrolysis. The benchmark electrolyzer configuration is a zero-gap cell with porous electrodes. Gas evacuation is a challenge when using this kind of electrode, as bubbles can get trapped within the 3-D structure. This work aims to identify parameters that can help the construction of enhanced gas evacuation periodic electrodes. It was found that electrodes that direct the flow and present a lower pressure drop are better in terms of gas removal.

Keywords: Alkaline Water Electrolysis, Bubble Removal, Forced Electrolytic Flow, 3-D Printed Electrodes

INTRODUCTION

The state-of-the-art electrolysis cell configuration is a zero-gap assembly. In this configuration, the electrodes – often 2-D electrodes such as perforated plates, expanded metals, or meshes – are pressed against a separator with a thickness on the order of hundreds of micrometers [1]. Recently, 3-D electrode geometries such as foams and felts have been used with promising results [2]. Due to the stochastic nature of these geometries, the gas removal may not be optimal. As an example, Kou *et al.* (2020) observed an enhancement in gas evacuation when replacing foams by periodic 3-D structures [3]. An important method to build 3-D periodic metallic structures is additive manufacturing by means of laser beam melting. With the almost unlimited possible geometries that it allows to fabricate, it is important to find generic guidelines as to what kind of structure presents the best electrolytic performance. The study presented here analyzed two periodic geometries and found some trends in what kind of structures should the efforts be concentrated on to result in a more efficient gas removal. Computational fluid dynamics (CFD) simulations were used as well to quickly explore the potential of new geometries.

MATERIALS AND METHODS

The electrolytic solution used was 1 M potassium hydroxide (KOH), prepared by mixing KOH pellets (KOH > 85%, VWR chemicals) with deionized water (18.2 MΩ.cm, Sartorius Arium 611). The temperature was set at 70°C with the help of stirrer hotplates (C-MAG HS 7, from IKA). The cell contains the following parts: two end-plates with fittings for inlet and outlet of electrolyte; two nickel (> 99.5%, Alfa Aesar) current distributors to ensure removal/supply of electrical charge; two PTFE electrode housings to accommodate the electrodes and promote sealing; a Zirfon Perl UTP 500 diaphragm (500 ± 50 µm of thickness). Between each one of these parts, there is an ethylene propylene diene monomer (EPDM) layer to ensure sealing and to prevent mechanical wear. The electrode housing had a dimension of 2x2x0.8 cm. The electrolytic flow was controlled by gear pumps (GJ-N25.FF3S.A, Micropump) and measured by flow transmitters (Honsberg, model LABO-MID1-I/U/F/C). The electrolytic reservoirs were made of 316l stainless steel. To ensure sealing, the cell was pressed using 6 screws with a torque of 3 Nm each.

Current scans from 0-2 $A.cm^{-2}$ were performed with a scan rate of 0.025 $A.cm^{-2}.s^{-1}$. 5 minutes galvanostatic experiments were also realized with the help of a Solartron Modulab XM potentiostat equipped with a Booster 20 A. Computational fluid dynamic simulations were performed with the open-source MigFlow software [4]. The electrodes were built using laser beam melting and were composed, in view of ease of fabrication, of Inconel 625 alloy (Ni~60%, Cr~22%, Mo~9%, Fe~4%, Nb~3%) [5]. The shape of the electrodes was based on mathematical equations. The first one was a doubly-periodical minimum surface called Schwarz CLP, defined geometrically by:

$$t = \sin\left(\frac{2\cdot\pi\cdot z}{L}\right)\cdot\sin\left(\frac{2\cdot\pi\cdot x}{L}\right) - 0.4\cdot\sin\left(\frac{2.4\cdot\pi\cdot y}{L}\right)\cdot\cos\left(\frac{2\cdot\pi\cdot z}{L}\right)\cdot\cos\left(\frac{2\cdot\pi\cdot x}{L}\right) \quad (1)$$

and the second was a triply-periodical minimum surface called Gyroid, defined by:

$$t = \cos\left(\frac{2\cdot\pi\cdot x}{L}\right)\cdot\sin\left(\frac{2\cdot\pi\cdot y}{L}\right) + \cos\left(\frac{2\cdot\pi\cdot y}{L}\right)\cdot\sin\left(\frac{2\cdot\pi\cdot z}{L}\right) + \cos\left(\frac{2\cdot\pi\cdot z}{L}\right)\cdot\sin\left(\frac{2\cdot\pi\cdot x}{L}\right) \quad (2)$$

with *L* giving the periodicity and *t* being related to the void fraction. A value of *L* equal to 4 mm means that the structure repeats itself at each 4 mm. The lower the *L*, the higher the surface area. Notice that while Gyroids have the same symmetry in all directions, Schwarzs have a different symmetry for y-axis. In this study, all the Gyroidal structures had a *t* value equal to zero (50% void fraction), while the Schwarz CLP had a *t* value of 0.18 (61% void fraction). The electrochemical active surface area (ECSA) of each electrode was measured using the capacitance method: cyclic voltammetries (CVs) with different scan rates (50, 100, 150, 200, 250, 300, 350, 400 $mV.s^{-1}$) were applied in a range of 50 mV around open circuit potential (OCP) are used to estimate the capacitive current. This current is measured by taking half of the difference between the anodic current and the cathodic one. The slope of the plot of capacitive current against the CV scan rate gives out capacitance. To find the ECSA, the capacitance was divided by a specific capacitance of 20 $\mu F.cm^2$, as this value was reported recently in the literature [6]. This measurement was made at room temperature, 1 M KOH, Pt counter electrode, and Ag|AgCl *sat.* reference electrode. More details about the capacitance method can be found in ref. [7].

RESULTS AND DISCUSSION

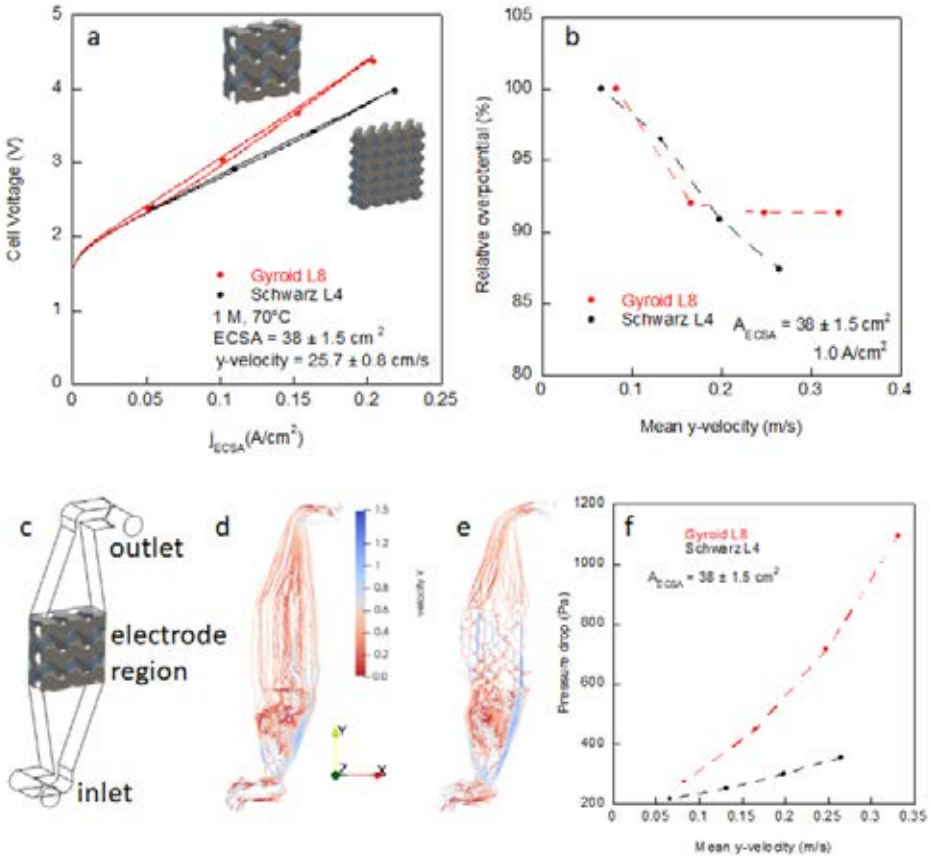

Fig. 1. a) Polarization curves for electrodes in the shape of a Gyroid with a lattice size of 8 mm and a Schwarz with a lattice size of 4 mm. ECSA for both electrodes was close to 38 cm^2 and the mean y-velocity close to 25.7 cm/s. Dots represent a current scan and circles the galvanostatic experiment b) Relative overpotential versus mean y-velocity for Gyroidal-shaped and Schwarz-shaped electrode at a current density of 1.0 A/cm^2 c) Geometry of a half-cell (could be the cathode or the anode). Streamlines colored by the y-velocity for a half-cell for d) Schwarz L8 e) Gyroid L4 f) Pressure drop caused by the electrode as a function of mean y-velocity for Gyroid L8 and Schwarz L4.

Comparing the two structures, it can be seen that for the same surface area and y-velocity, Schwarz CLP-shaped electrodes presented the best electrochemical performance, as shown in Fig. 1.a. The same trend was observed for all the y-velocities. Fig. 1.a compares a Gyroidal-structure with an *L*=8 mm with a Schwarz with an *L*=4 mm – both with approximately 38 cm^2. Decreasing further the *L* to 2 mm for all these structures, one reaches 81.6 ± 7.4 cm^2 of ECSA and, again, Schwarz presents the best performance. Since the electrodes are made of the same material, dismissing the presence of bubbles, one would expect the same polarization curves. The reason for the poorer performance for the Gyroidal-shaped electrode is the higher presence of trapped gas bubbles, covering part of the electrode area and thus reducing the electrochemical active surface area. To deepen the understanding of this process, one can look at the flow effect, shown in Fig. 1.b. It is shown that the increase in the flow causes a voltage reduction in all the structures. The higher percentual decrease in the overpotential indicates a more effective bubble removal caused by electrolytic flow in Schwarz-shaped electrodes. To explain the flow effect, computational fluid

dynamics simulations were performed. Fig. 1.c shows the geometry of a half-cell with electrode a Gyroidal electrode. Fig. 1.d show a half-cell with a Schwarz-shaped electrode (L=4) and Fig. 1.e shows a gyroidal-shaped electrode with an L=8. It is shown that while for Schwarz the flow is directed to y-direction (upwards) and almost no mixing was observed, Gyroidal structures deviate the flow, causing an increase in vorticity and dissipating more energy. From a quantitative point of view, we can look at the pressure drop caused by each electrode structure as a function of mean y-velocity. As shown in Fig. 1.f, for the same surface area, Gyroidal-shaped electrodes cause a higher pressure drop, meaning that more energy is needed to impose the same y-velocity. As a consequence, the removal of gases is less effective.

When comparing the couple of structures with an ECSA close to 38 cm^2 (Gyroid L = 8 mm and Schwarz L = 4 mm) with the couple with an ECSA of 81.6 cm^2 (Gyroid L = 2 mm and Schwarz L = 2 mm), it was observed that the Schwarz $L2$ presented a better performance than Schwarz $L4$. This can be attributed to the enhanced gas removal, allowing the increase in the active surface area, without a significant bubble entrapment. On the other hand, Gyroid L2 presented a poorer performance. Since the flow is not effective in this structure, the decrease in the periodicity (L) caused an important bubble entrapment, decreasing the active surface area to a value lower than the one obtained when L was equal to 8 mm.

CONCLUSIONS

After a careful comparison of two periodic 3-D electrode geometries, it was found that for the same ECSA and y-velocity, structures that present lower pressure drop allowed an efficient gas evacuation, increasing the electrochemical performance. It was observed that the deviation of the flow was the main responsible for the increase in the pressure drop. As a consequence, structures which direct the flow in only one direction should be privileged in the construction of new electrodes. Furthermore, an enhanced gas evacuation electrode allows the increase in the active surface area by the decrease in the “L” parameter, since the effect of gas coverage is highly reduced.

ABSTRACT

A proton exchange membrane (PEM) electrolysis system including electrolyzers and accessory systems has been developed to allow direct electrolysis to produce hydrogen under high pressure difference. Based on the system, the performance of the high-pressure hydrogen production electrolyzer under high pressure has been analyzed. The influence of operating parameters including current, circulating water velocity, circulating water temperature and compression force on the performance of the electrolyzer was analyzed by means of polarization curve and electrochemical impedance spectrum (EIS). The experimental results show that the temperature has the greatest effect on the electrolysis performance in the form of ohmic loss, activation loss and mass transfer loss simultaneously. The circulating water flow and the compression force have no obvious influence on the performance of the electrolyzer within the range selected in this study. The current density mainly acts on the ohmic impedance of the electrolyzer. It is worth noting that no significant change in voltage efficiency was found by gradually increasing the cathode pressure to 90 bar while the anode was kept at atmospheric pressure.

Keywords: PEM Water Electrolysis, High-Pressure Difference, Efficiency, EIS

INTRODUCTION

As a very promising method for green hydrogen production, hydrogen production from water electrolysis has good adaptability with renewable energy resources. Producing high pressure green hydrogen directly can eliminate the compression process after hydrogen production and save the cost of compression energy consumption and fixed investment at the same time. And proton exchange membrane electrolysis of water to generate hydrogen is the only way with this ability among several hydrogen production methods by electrolysis of water. Only Japan's Honda [1] company had developed a 70Mpa differential pressure PEM electrolyzer so far around the world, and they pointed out the advantages of this method in energy saving. However, it is not clear how this technology can be realized. Besides them, there are relatively few studies on electrolysis of operating pressure exceeding 70bar. Trinkle et al. [2] also studied the problem of hydrogen permeation in differential pressure electrolysis (below 3MPa). Generally speaking, there are few studies on the influence of higher pressure (above 7MPa) on the performance of electrolyzer. This paper discussed the influence of several operating parameters on the performance of electrolyzer designed for high pressure.

EXPERIMENT

The direct high-pressure hydrogen production system investigated has been developed by Tsinghua University. Platinum-plated sintered titanium fiber blanket was used as porous diffusion layer for both anode and anode. A unique frame structure was adopted in the cause of the good working state of the membrane, moreover, the sealing ring instead of sealing gasket was used to meet the sealing requirements between anode and cathode as well as between the electrolyzer and the outside environment. Finally, the electrolyzer was compressed by hydraulic equipment. The physical photo of the system is shown in Fig. 1. The other main operating parameters of the system and electrolyzer have been listed in Table. 1.

Table 1. Main operating parameters of the system and electrolyzer

Parameters (Unit)	**Value**	**Parameters (Unit)**	**Value**
Power consumption rate (W)	500	Cathode pressure (bar)	1-100
Number of cells	1	Anode pressure (bar)	1
Active area (cm^2)	170	Flow rate of circulating water (L/h)	50-500
Flow rate of hydrogen (L/h)	100	Operating temperature (K)	293-353

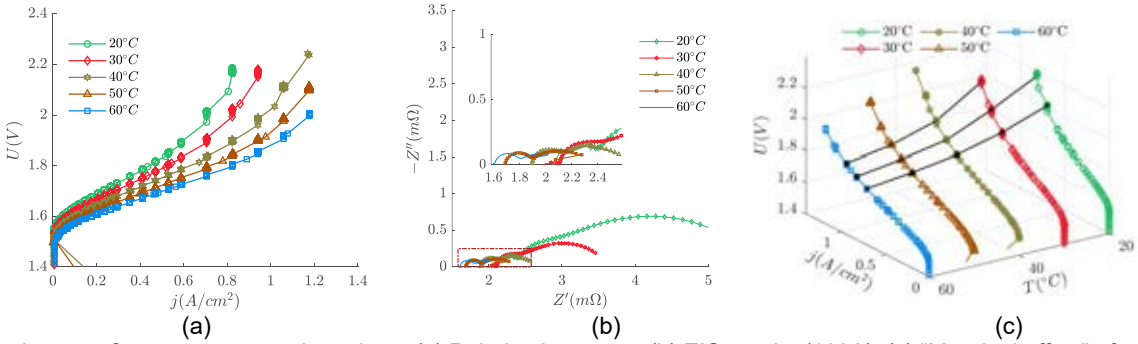

Fig. 1. The physical photo of the system

The circulating water temperature, circulating water flow, hydraulic equipment pressure and cathode hydrogen pressure were set as control variables respectively, and the standard measurement condition was stipulated as the temperature maintained at 333K, water flow at 150L/h, hydraulic pressure at 16MPa and hydrogen pressure at 1bar. When changing one of the parameters, keep the other parameters the same as the standard measurement condition. Among them, the test range of temperature was 293-333K, with 10K as the interval; the test range of water flow was 50-150L/h, with 25L/h as the interval; the test range of hydraulic pressure was 4-20MPa, with 4MPa as the interval; the test range of hydrogen pressure is 1-90bar, with 10bar as the interval. The polarization curve and EIS were tested at the same time after each change of working condition, and the current of EIS test was selected from 50-200A.

RESULTS AND DISCUSSION

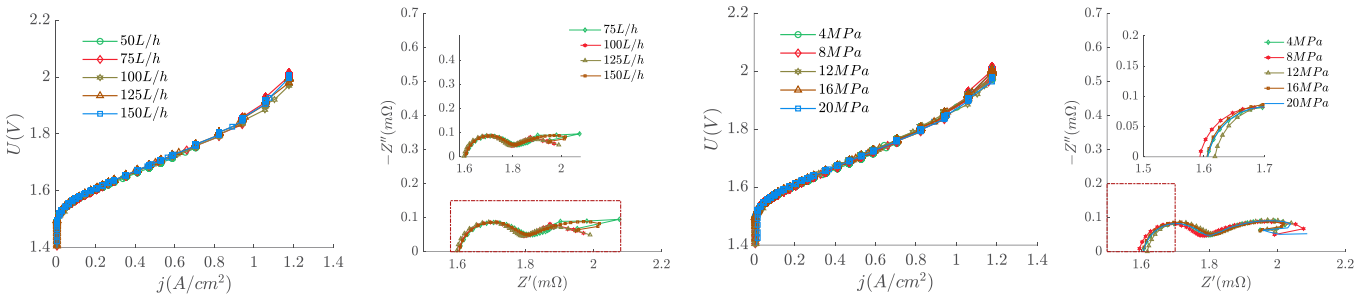

Fig. 2(a) shows the effect of temperature on the performance of electrolyzer. Obviously, the higher the cell temperature is, the more favorable it is to the performance of electrolysis cell (such as energy consumption et al.). On the other hand, this phenomenon can be explained from the results of impedance spectroscopy (Fig. 2(b)). When the temperature is lower, the ohmic impedance increases significantly, which can be explained by the conductivity of the membrane (Eq. (1)). Secondly, it is easy to find that the activation loss increases significantly at lower temperature, which can be explained by the composition of the activation overpotential (Eq. (2)). Finally, lower temperature will also lead to an increase in less obvious mass transfer loss. There is still no confirmed explanation for this part, which may be caused by the limiting current density. However, despite the positive impact of temperature increase on energy consumption, many literatures have reported the negative impact of high temperature (over 333K) on the durability of membrane. Meanwhile, there is a significant marginal effect of the benefits of temperature increase, which means that it is not a wise choice to simply increase temperature according to the black line in Fig. 2(c).

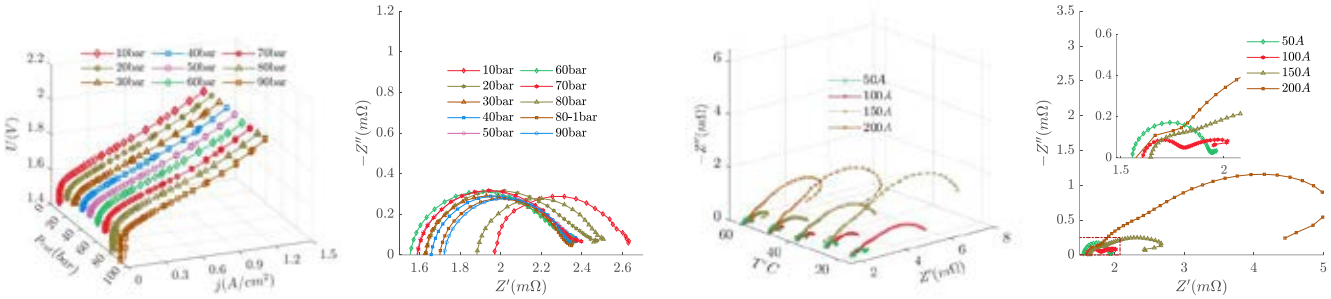
(a) (b) (c)

Fig. 2. The impact of temperature on electrolyzer (a) Polarization curve. (b) EIS results (100A). (c) “Marginal effect” of temperature



For circulating water flow and hydraulic pressure, the polarization curve results show that they have no significant effect on electrolysis performance, as shown in Fig. 3. An increase in water flow allows faster removal of the reactant oxygen, thus allowing the reaction rate to be unlimited. On the other hand, it has been reported that the increase of water flow will reduce the temperature on the membrane and thus reduce the efficiency. In this study, the heat produced by the cell is almost negligible, so the performance deteriorates with the increase of flow rate is not found. The reason why the compression force does not affect the sealing structure is related to the use of sealing ring and will not cause excessive compression of the reaction area in the middle.

(a) (b) (c) (d)

Fig. 3. The impact of flow rate and compression force (a)(c) Polarization curve. (b)(d) EIS results (100A).

The influence results of cathode pressure are shown in Fig. 4(a)(b). It is obvious that the increase of cathode pressure does not affect voltage efficiency (the polarization curve hardly changes), while the current efficiency will be seriously affected. The influence of current density can be shown by EIS results of different currents (Fig. 4(c)(d)). Obviously, the performance of electrolysis gradually deteriorates with the increase of current density, and all related polarization losses also increase, especially mass transfer losses.

CONCLUSIONS

In this paper, the effect of different operating parameters on the performance of the electrolyzer was explored based on the self-developed high-pressure hydrogen production system. The main conclusions are as follows:

- Although temperature has a great influence on the performance of electrolyzer, this "positive effect" will gradually decrease as the temperature increases. In order to balance durability and energy consumption, it is necessary to reasonably optimize the operating temperature.
- The effect of flow rate and compression force has different conclusions in different electrolyzers (power, sealing structure, etc.), in general, the flow rate can be considered to have little effect for commercial electrolyzers.
- The cathode pressure does not significantly affect the voltage efficiency but the current efficiency.
- Increased current density is beneficial for hydrogen production rate, but at the same time increases system energy consumption and in addition has a negative impact on mass transfer losses.

ABSTRACT

This study presents a non-noble metal nickel-copper catalyst, as a durable anode for alkaline ammonia electrolysis. We report that a nickel-copper catalyst can electrochemically oxidise ammonia to nitrogen at room temperature and atmospheric pressure. Cyclic voltammetry experiments in a three-electrode cell confirmed the nickel-copper anode had a lower overpotential for ammonia electrolysis when compared with other precious metal catalysts. Electrodes were prepared at a larger scale and evaluated in a membrane flow cell. Gas chromatography of the off gases confirmed that both, nitrogen at the anode and hydrogen at the cathode, were generated with relatively high faradaic efficiencies. Anode morphology and structure before and after electrolysis were investigated by X-ray diffraction (XRD), X-ray fluorescence (XRF), X-ray Photoelectron Spectroscopy (XPS) and scanning electron microscopy (SEM-EDS). Overall, the electrode showed good stability after continuous electrolysis in an alkaline ammonia electrolyte and the nickel-copper system is a potential electrocatalyst for efficient ammonia oxidation. Morever, hydrogen can be generated as a useful by-product at the cathode. The ammonia is effectively cracked into nitrogen and hydrogen without the consumption of water. The hydrogen produced can be used to power fuel cells, can be burnt in combustion engines or has the possibility to be injected into the gas grid and blended with methane.

Keywords: Ammonia, Hydrogen, Electrolysis, Electrolyser, Nickel-copper, Wastewater

INTRODUCTION

Ammonia is a common pollutant, present in municipal wastewater streams and is also a carbon-free energy carrier. Recently, technological solutions have been introduced to strip ammonia from wastewater [1]. The recovered ammonia can be electrochemically oxidised to benign nitrogen in an electrolyser, which can offer a cost-efficient technology to couple wastewater remediation at an anode with a production of a valuable hydrogen by-product at the cathode. Currently, the commercialisation of ammonia electrolyser technology is hindered by slow reactions at the anode and the cathode as well as the deactivation or degradation of the catalysts over time [2,3]. Consequently, the development of an inexpensive, efficient anode material is imperative to reduce costs associated with ammonia destruction and electrochemical hydrogen production.

Activity-wise, considering only thermochemical properties, Pt was shown as the most active monometallic catalyst followed by Ir and Cu for ammonia oxidation (AO) [4]. However, platinum group metals are rare and expensive and can be poisoned by adsorbed nitrogen intermediates produced during ammonia oxidation [5]. While inexpensive transition metals such as nickel are inactive towards AO due to rapid corrosion in alkaline media, electrooxidation is possible at $Ni(OH)_2$/NiOOH electrodes [6]. Still, the electrodes can be corroded and deactivated over time [7]. Bimetallic nickel-copper catalysts have been reported to have high activity for ammonia oxidation and have shown improved stability [8,9].

In this work, a bimetallic NiCu catalyst has been used as an anode for ammonia electrolysis in a divided electrolyser cell to couple the destruction of ammonia with the generation of hydrogen.

MATERIALS AND METHODS

Bimetallic nickel-copper electrodes were prepared by electro co-deposition as shown in Figure 1a. Electrochemical characterisation of ammonia oxidation was performed in a three-electrode cell, Figure 1b, where the NiCu electrode was the working electrode, Pt mesh was the counter electrode and Hg/HgO (1M NaOH) was the reference electrode.

For ammonia electrolysis, a commercial electrolyser was used (Dioxide Materials, USA). The schematic of the electrolyser assembly is pictured in Figure 1c. Two half-cells were separated by an anion exchange membrane. The anode used was the prepared NiCu electrode and the cathode was a commercial-grade cathode (Dioxide Materials, USA). The electrolyser system was connected to either a potentiostat/galvanostat for electrochemical analysis or a 10V/10A rectifier as a DC power supply for electrolysis experiments. The gases produced were analysed by a Gas Chromatography equipped with a Thermal Conductivity Detector (GC-TCD, Perkin-Elmer, United Kingdom).

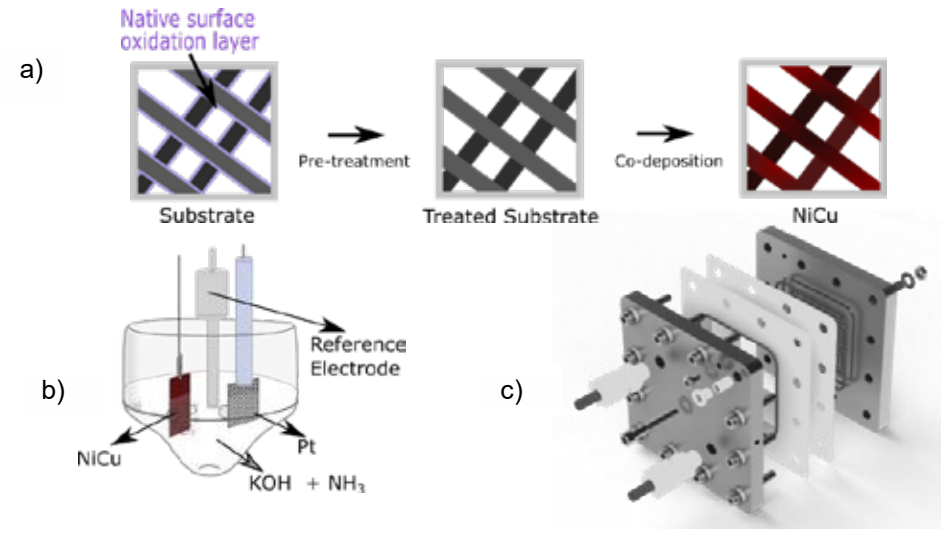

Fig. 1. a) NiCu electrode preparation b) Schematic of three-electrode cell c) Diagram of ammonia electrolyser (adapted from [10])

RESULTS AND DISCUSSION

To characterise the NiCu electrode, cyclic voltammetry experiments were performed, Figure 2a. Compared to 1M KOH, a sharp increase of anodic current density was observed when ammonia was introduced to the electrolyte, reaching 120 mA cm^{-2} at 0.7 V vs Hg/HgO. The overpotential at which the electrode reached 100 mA cm^{-2} was significantly lower (0.65V vs Hg/HgO), compared to an iridium oxide electrode (1.05 V vs Hg/HgO), pictured in Figure 2b.

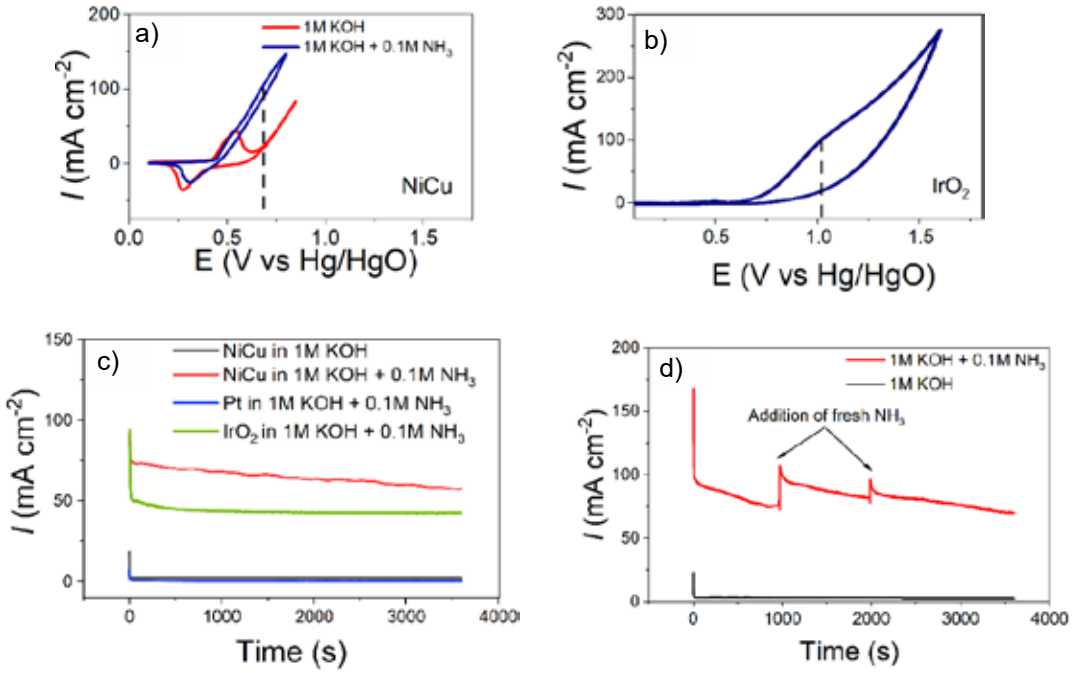

Fig. 2. a) NiCu electrode in 1M KOH and 1M KOH + 0.1M NH_3 (aq), recorded at 25 mV/s b) IrO_2 electrode in 1M KOH + 0.1M NH_3 (aq), recorded at 100 mV s^{-1} c), d) chronoamperograms of various electrode materials in 1M KOH and 1M KOH + 0.1M NH_3 recorded at potentials of ammonia electrochemical oxidation

To determine the stability of the NiCu electrode in ammonia, chronoamperometric experiments were performed, Figure 2c. NiCu electrode was able to maintain the highest current density of the electrodes tested (NiCu, IrO_2 and Pt). Furthermore, during chronoamperometry currents decreased with reducing NH_3 concentration but went up with an addition of fresh ammonia, showing high sensitivity and activity towards ammonia, Figure 2d.

In the electrolyser, the NiCu electrode exhibited lower cell potential when ammonia was added to the system, Figure 3. The GC-TCD data has confirmed nitrogen was generated at the anode while hydrogen was generated at a cathode.

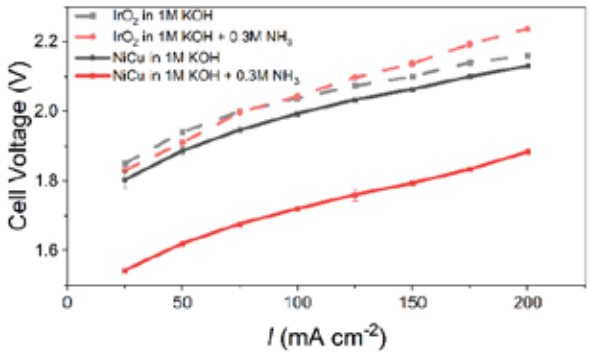

Fig. 3. Comparison of cell voltages recorded in an electrolyser using NiCu and IrO_2 anodes. Recorded at room temperature and ambient pressure, using an anion exchange membrane

CONCLUSIONS

The work has shown NiCu bimetallic catalyst as a suitable anode for electrochemical ammonia oxidation. Due to the electrode's high activity, stability and low cost, NiCu has the potential to be a good catalyst for ammonia oxidation which can be combined with hydrogen generation in large-scale commercial electrolysers.

ABSTRACT

In this contribution a powder metallurgical (PM) production process is outlined to produce highly active electrodes for the alkaline water electrolysis. Different catalytic coatings were produced on porous substrates, including foams. The electrochemical activity of the electrodes towards the hydrogen (HER) and oxygen evolution reaction (OER) were analyzed considering technical conditions. It can be shown that the performance of the catalysts can significantly be improved by adjusting the chemical composition and the catalytic loading. Furthermore, the catalytic coating obtained by the PM production route exhibits an excellent mechanical stability on different substrates.

Keywords: Alkaline Electrolysis, Cathode, Anode, Production Process

INTRODUCTION

For a future GW-industry of alkaline electrolysers, a large number of efficient and inexpensive electrodes has to be produced. According to the state of the art, mainly batch-based production processes are used, e.g. electrodeposition (e.g. De Nora [1], MTV GmbH [2]). For the development of a production process with a very high throughput of electrodes, two issues have to be considered: First, the produced electrodes have to be very active for the hydrogen (HER) as well as the oxygen evolution reaction (OER) and, second, the process has to be scalable. In this contribution, a powder metallurgical (PM) production process is outlined [3] to manufacture highly active electrodes. In particular, PM technologies are suitable to produce advanced materials for water electrolysis [3, 4]. The manufacturing technology can be applied to flat as well as porous metal structures. Especially, porous 3D electrode structures with a high surface area, a well-defined porosity for gas transport, a mechanically stable structure and a good electrical conductivity can fulfill the requirements for highly active, long-term stable and cheap electrodes. Accordingly, porous substrate based on metallic foam and fibre fleeces structures are chosen as electrode template. In this study, different examples of porous electrodes with a catalytic coating produced by PM production process are discussed with respect to the electrochemical activity for the HER and OER.

MATERIALS AND METHODS

A PM production process is employed to produce highly active electrodes for the HER and the OER. The approach comprises the deposition of powdery precursor onto a metallic substrate and subsequently a heat treatment to form a mechanically stable and electrocatalytically active catalyst on the surface (schematically shown in Fig. 1). By varying the powder to mesh mass ratio (PMR) different catalyst loadings can be achieved. The electrodes are evaluated in a 3-electrode setup at ambient pressure, at 353 K and in a 30 wt.-% KOH solution.

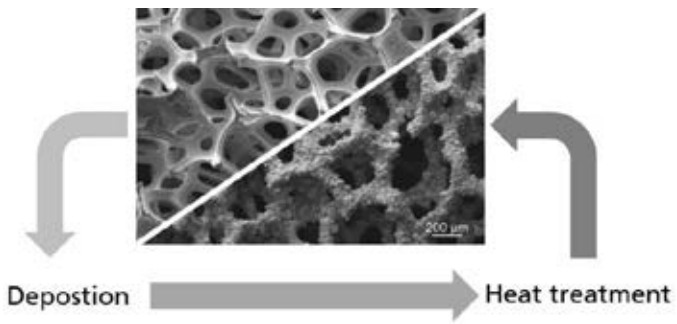

Fig. 1: Schematically description of the PM production process of electrodes.

RESULTS AND DISCUSSION

For the HER, Al was deposited onto different porous Ni materials (e.g. expanded metal, foam) in order to form a Raney-Ni layer on top of the substrate after heat treatment and a subsequent leaching step. The approach is

schematically given in Fig. 2. Due to the diffusion process during the thermal treatment, different Ni-Al phases are formed and a very homogeneous interface between the coating and the Ni core is formed. After the leaching step a lot of channels perpendicularly oriented to the bare Ni core can be seen, facilitating the easy detachment of gas bubbles. For the most active sample, the overpotential value for the HER was 50 mV at a current density of -0.3 A/cm². By using a higher PMR value, the stability of the Raney-Ni coating could be significantly enhanced, and the activity was strongly improved. For the best material, the HER caused no delamination of the catalyst layer, showing the high stability of the electrode. A plot of the HER overpotential versus the double layer capacitance C_{dl} (determined by cyclic voltammetry) suggests that the HER-activity is directly linked with the C_{dl}. Since the C_{dl} reflects the electrochemically active surface area, it is evident that the HER-activity also correlated with the surface area. These results demonstrate the high activity of Raney-Ni electrodes on the one hand and also the feasibility of a powder metallurgical approach to produce those electrodes. By applying a continuous heat treatment process, a high output of electrodes along with a strongly reduced CAPEX for the alkaline water electrolysis can be enabled.

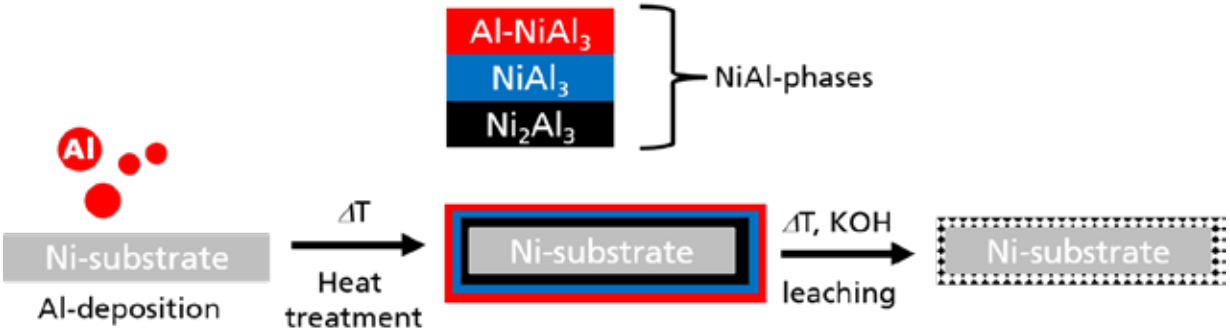

Fig. 2: Schematics of the powder metallurgical route to produce Raney-Ni electrodes.

For the OER a Ni-Mn coating was selected. Ni-Mn alloys have been described in the literature as supercapacitor materials [5], due to the high double layer capacitance. The approach was to coat the inner pores of a Ni foam with Ni-Mn to produce an active OER material. Therefore, Ni-Mn (70 at.-% Mn) powder was deposited onto the foam and after the heat treatment a mechanically stable electrode was formed. The cross section revealed the existence of two different Ni-Mn phases. As can be seen from Fig. 3 left, the post processing induces the leaching of the Ni-Mn phase with the highest content of Mn. This results in a hierarchical porosity: large pores of the substrate (> 200 µm) and small pores from the leached Ni-Mn coating (< 1 µm). The Ni-Mn modified substrate has a much lower OER overpotential in comparison to the bare substrate (see Fig. 3 right). The overpotential value was below 250 mV at 0.3 A/cm², reflecting the high OER activity. The excellent activity of the prepared anode is also underlined in the contribution with a benchmarking of literature known values. In contrast to the cathode, the surface area of the anode material has no major impact on the OER activity. However, the intrinsic activity appears to be the main parameter influencing the activity.

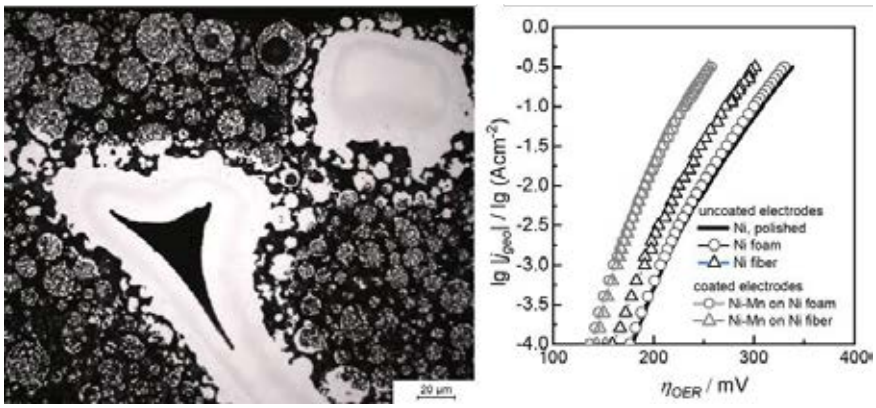

Fig. 3: left) SEM image of the catalyst attached to the substrate after a heat treatment and right) representative OER Tafel plots.

CONCLUSION

In summary, a powder metallurgical production process is outlined to produce highly active electrodes for the HER and OER in alkaline media. By using a continuous furnace for the heat treatment in future a high output can be realized.

With respect to the different alkaline electrolyzer technologies (gap or zero-gap design), the process is also applicable to flat (e.g. perforated metal sheets) as well as to porous (e.g. foams, fibre fleeces, meshes) substrate materials.

ABSTRACT

Green hydrogen production by water electrolysis constitutes a fundamental process for the transition to the hydrogen economy. While alkaline water electrolysis is considered a mature technology to this end, recent work has shown that we can achieve further process intensification with forced electrolyte flow through macro-porous 3D electrodes. The objective of this work is to simulate and analyze electrolyte flow through an industrial-scale pilot and through lab-scale 3D printed electrodes using Computational Fluid Dynamics (CFD). Initial results show that our current pilot cell design is inadequate for forced flow and offer insights in order to design a cell structure that is more suited for gas removal.

Keywords: Computational Fluid Dynamics, Alkaline water electrolysis, Forced Flow

INTRODUCTION

Recent experimental results show that forced electrolyte flow through foams or 3D printed electrodes can offer a significant increase in performance [1,2]. Increased surface area offered by these structures leads to a higher hydrogen production rate while forced flow permits efficient bubble removal. The aim of this work is to complement experimental work with CFD simulations in order to obtain a better understanding of the full field flow characteristics inside the electrode. Reviewing the relevant literature, we observe this kind of analysis has rarely been addressed [3].

Our lab-scale experiments on 3D printed structures show the benefits in terms of performance. Unfortunately, we do not observe the same behaviour in an industrial-scale pilot that is modified for electrolyte flow. We perform here simulations of single-phase flow of electrolyte to assess the hydrodynamic behaviour of the cell for both cases: the industrial-scale pilot and the lab-scale 3D printed electrodes. Our objective is to associate electrochemical performance with flow characteristics in order to design an appropriate geometry for industrial-scale electrolyzers.

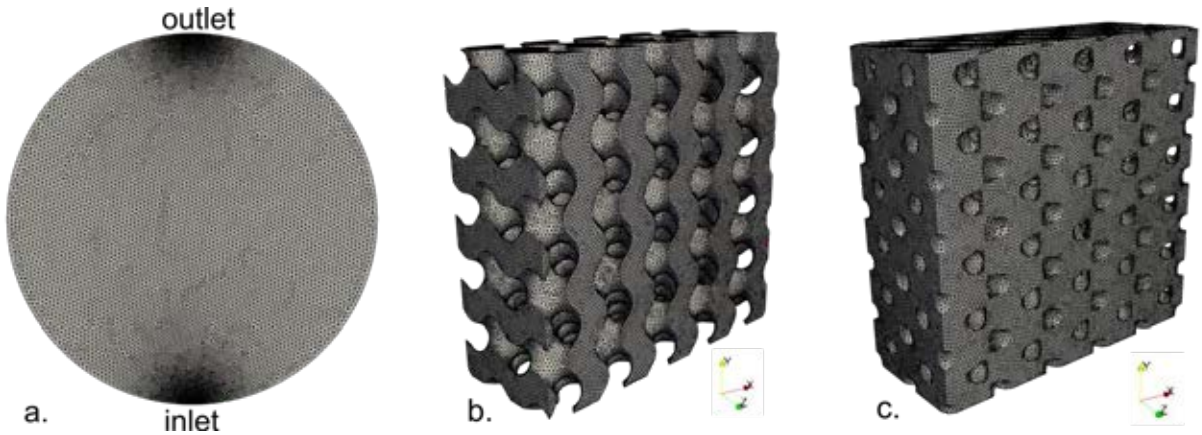

Fig. 1. Computational meshes. a) 2D pilot. b) Gyroid structure. c) Schwarz structure.

MODELING

The geometry of the pilot-scale electrolyzer is circular with a radius of 195 mm and a width between the front and the back plate of 6mm. The inlet at the bottom has a diameter of 2mm and the extractor outlet has a diameter of 4mm. The model geometry of the cell was created and meshed using Gmsh [4] with an interior mesh size of 0.025 m and reduced mesh size of 0.0125 m near the inlet and the outlet (Fig. 1.a.). For the 3D printed electrodes, we use the equations of [5] and create models for a Gyroid and a Schwarz structure. We generate the geometry on a 20x20x8 mm rectangular region and we mesh with an element size of 0.005 m (Gyroid on Fig. 1.b. and Schwarz on Fig. 1.c.). Mesh element sizes were chosen to resolve the flow scales of interest, for which the explicitly described geometries of the 3D printed electrodes require a smaller mesh size.

The incompressible Navier-Stokes equations for a single-phase flow were solved using the Finite Element Method (FEM) implemented in MigFlow software [6]. The electrolyte is water with density ρ = 1000 kg/m^3 and kinematic viscosity v = 0.003 Pa s. For the case of the pilot cell we make the assumption of a 2D flow since the width is small compared to the diameter. To account for the drag of the front and the back walls of the cell we make the hypothesis of a Poiseuille flow in the direction of the flow. For the electrode structures we run 3D simulations since we want to observe the associated flow phenomena such as the vorticity intensity. The boundary conditions for the simulation are the inlet velocity of the electrolyte and zero pressure at the outlet.

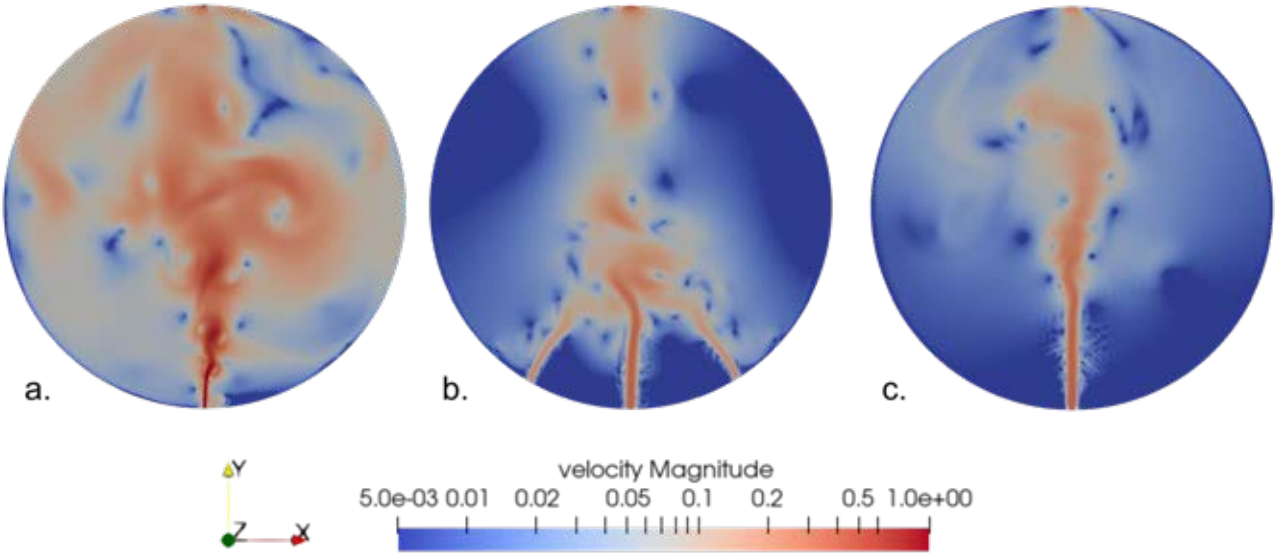

Fig. 2. Velocity profiles for three pilot inlet configurations. a) Current experimental setup. b) Three inlets. c) Inlet of bigger size.

RESULTS AND DISCUSSION

The flow rate chosen for the pilot simulations is 62.5 L/h. This value is a bit higher than the experimentally measured flow rate for the operation of the pilot cell with natural convection. It is therefore the lower limit for which we should consider forced flow. The inlet velocity of the fluid is then calculated at 1.45 m/s for an inlet area of 0.002 m x 0.006 m = 0.000012 m^2. High inlet velocity through the small opening produces a jet stream flow, which quickly evolves to a shear layer and leads to flow instabilities. Vortical structures are generated and convected throughout the domain, as visualized in Figure 2.a. This kind of flow would lead to concentration of gases that circulate or even remain stagnant in certain regions of the cell.

We investigated the possibility of modifying the inlet conditions in order to obtain smoother velocity profiles throughout the cell. At first, we use two supplementary inlets on symmetrical positions. The situation in this case gets more perplexed, as we would also have a mixing of the three jets in the middle of the cell (Fig. 2.b.). As another option, and since we identify as the cause of instability the high electrolyte velocity on the input, we also examined the possibility of a larger input area and thus lower velocity for the same flow rate. This choice only delays the onset of instabilities forming even though it leads to a less turbulent flow (Fig. 2.c.). In the general case though, we are aiming for flow rates up to 600 L/h where an enlarged inlet would not mitigate turbulent effects.

In the case of 3D printed structures the impact of forced flow is significant, and in particular we observe better performance on Schwarz structures compared to Gyroid ones. By performing 3D flow simulations on a Gyroid and a Schwarz structure of similar surface area, we can identify some qualitative characteristics that promote electrochemical efficiency. For average velocities of 1 m/s flow through the electrode, we can see that for Schwarz the flow is more laminar and thus could offer better gas removal (Fig. 3.b.). The structure of the Gyroid on the other hand leads to higher vorticity and mixing in the x-z directions, therefore there exist regions where gas evacuation may be hindered (Fig. 3.a.).

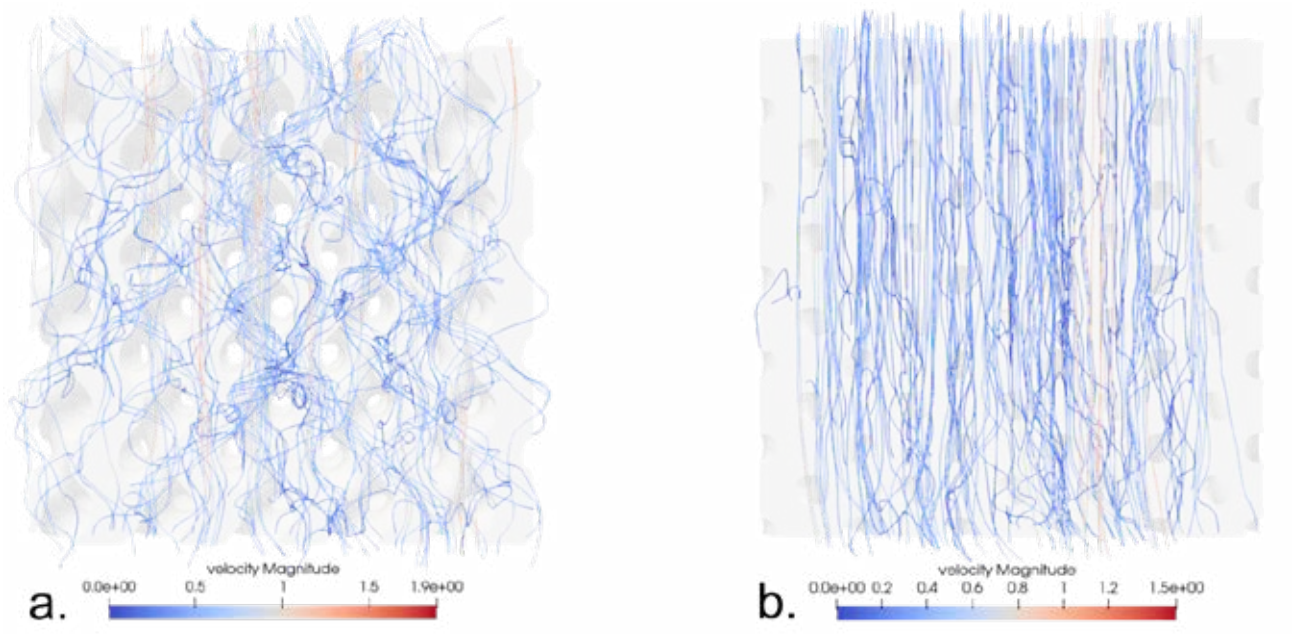

Fig. 3. Velocity streamlines on a) Gyroid and b) Schwarz 3D printed structures.

CONCLUSIONS

We performed computational fluid dynamics simulations to obtain insights about the performance of electrolysis with forced flow. Flow characteristics on the pilot show that the current setup is inadequate to enhance performance with forced flow. For 3D printed structures, we conclude that it is important to have geometries which on the one hand offer high surface area and on the other hand can accommodate a smooth flow evolution. The next step of our developments is to incorporate such a 'flow-guiding' structure in the pilot cell. This work is the initial step towards the modeling of the whole process that will simulate the two-phase flow of the electrolyte and the hydrogen gases.

ABSTRACT

Thermal energy storage has been accompanying energy systems the moment their full potential was realized, from these, the phase change material is a key element in increasing the efficiency of the photovoltaic thermal system, through research it was shown that phase change materials increase the efficiency by lowering the temperature of the panel which leads to a higher efficiency. In the paper, the effects of several phase change materials will be observed in Cyprus and analyzed to assess the best PCM to optimize hydrogen production. A MATLAB model that was validated will be used to assess the performance of several PCMs in the production of hydrogen in north Cyprus. The study shows that the pcm causes an increase in efficiency and the power output of the total system, in addition to that the one that shows the most significance phase change material that will cause the optimal hydrogen production as well as the range of which t chose the PCM for better hydrogen production.

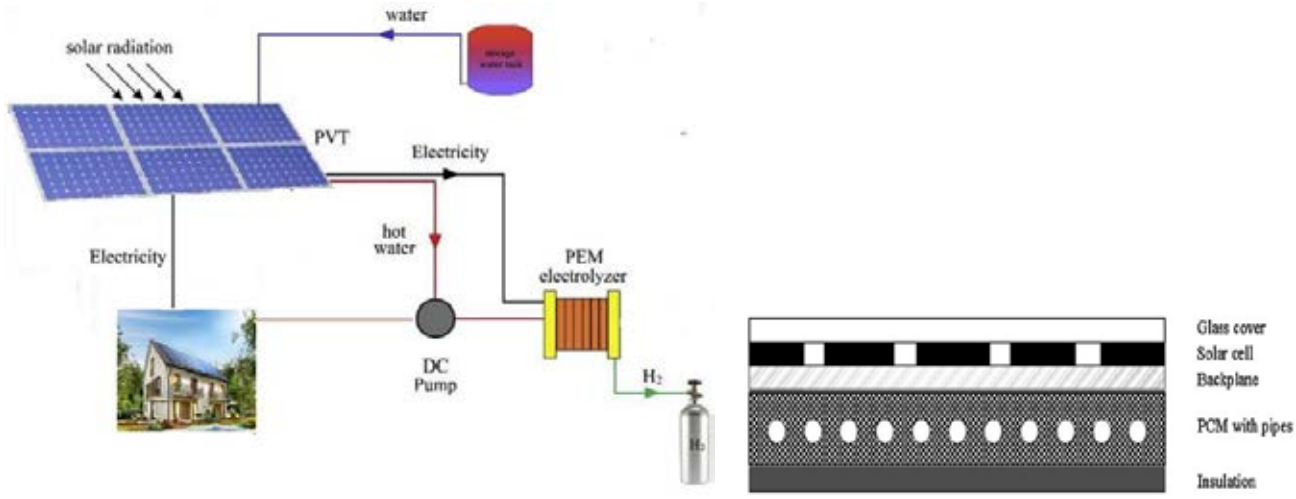
INTRODUCTION

The stepping stone that turned the events and raised awareness amongst nations was the aftermath of the industrial revolution that was the cause of several disasters inflicted on our environment. Olabi et al. [3] indicated in his review that the repercussions of this event created a mass increase in the C02 emissions and led to global warming. In the midst of this crisis, the early industrialized countries came together to prevent further damages. After the 1973 oil crisis adding to the problem, the countries came together in order to try to solve the problem at hand. They discussed the issue but it wasn't until the Kyoto protocol of 1997 which was an international treaty following the 1992 United Nations Framework Convention on Climate Change that a solution started to take place. After 21 years of negotiations the countries seemed to reached a global agreement to lower their emissions. Kannah [4] added that in Paris 2015 during the Conference of Parties meeting with the presence of almost 200 countries produced a legally binding agreement to ensure that the global warming is kept below 2°C which is a compulsive end that modulates and tells the economies around the globe to decarbonize spacious parts of the world's power system. From this history we can notice the importance of hydrogen and therefore further research towards improving and optimizing the use and production of this gas is the key to a greener future. Therefore, a system that produces hydrogen is needed and to be able to have a higher efficiency of that system we can use phase change materials to increase the efficiency pf the PVT system. Christopher et al. [2] explained in his research, the PCMs and their used in solar thermal application, in addition to that the researchers assessed the energy storage systems with cascaded configurations using phase change materials.

METHODOLOGY

In this study, the system observed in Fig. 1 part a is considered using the proposed photovoltaic thermal panel which is integrated with phase change material for the purpose of electricity, heat and hydrogen generation for a off grid setting. The design parameters were gathered and then the temperatures calculating based on the energy balance equations of the system which were then solved using a developed code using MATLAB. The energy and exergy analysis of the system has been calculated and shall be presented.

Equations



Some of the Energy balance equation as gotten from Brown et.al. [5] and Babayan et. Al [6] that have been used in the research are as follows:

$$\partial Qpcm = W \times L \times [Ubp \times (T_pm - T_pv))) - (hw \times (T_pm - T_fm)) - (U_bar_L \times (T_pm - T_in))]\partial t \quad (1)$$

$$if\ Qpcm < Qsol$$
$$Tp = Tmp - ((Qsol - Qpcm)/Cpcms), \lambda p = \lambda pcms$$

$$if\ Qsol\ < Qpcm < Qliq$$
$$Tp = Tmp, \lambda p = \lambda pcms \times ((Qliq - Qpcm)/(Qliq - Qsol)) + \lambda pcml \times ((Qpcm - Qsol)/(Qliq - Qsol))$$
$$if\ Qliq\ < Qpcm$$
$$Tp = Tmp - ((Qpcm - Qliq)/Cpcml),\ \lambda p = \lambda pcml$$

$$H_2O \Rightarrow H_2 + \frac{1}{2} O_2 \quad (2)$$

(a) (b)

Fig. 1. a) Proposed System Schematics b) PVT-PCM Proposed Panel

RESULTS AND DISCUSSION

As can be seen in Fig. 2, the simulation based on the MATLAB code personally designed is almost identical to the simulation done by Brown et. al [5] using the parameters indicated in the research, then the system was introduced as proposed in figure 1. The results of the temperature variation can be seen in Fig. 3 with shows an identical slope and behavior as seen in Babayan et. al [6] meaning the results gotten for the MATLAB code are reliable hence the research will try to assess the energy and exergy analysis of the system as well as the hydrogen production rate.

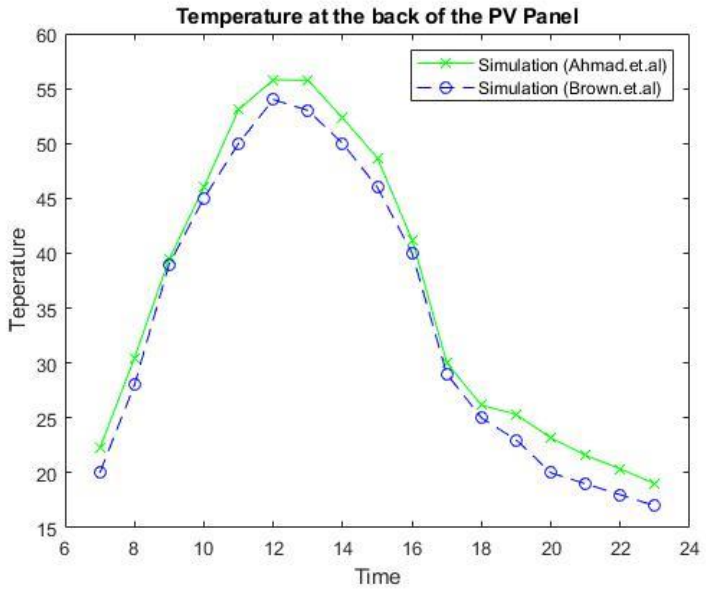


Fig. 2. Comparison between Simulated results

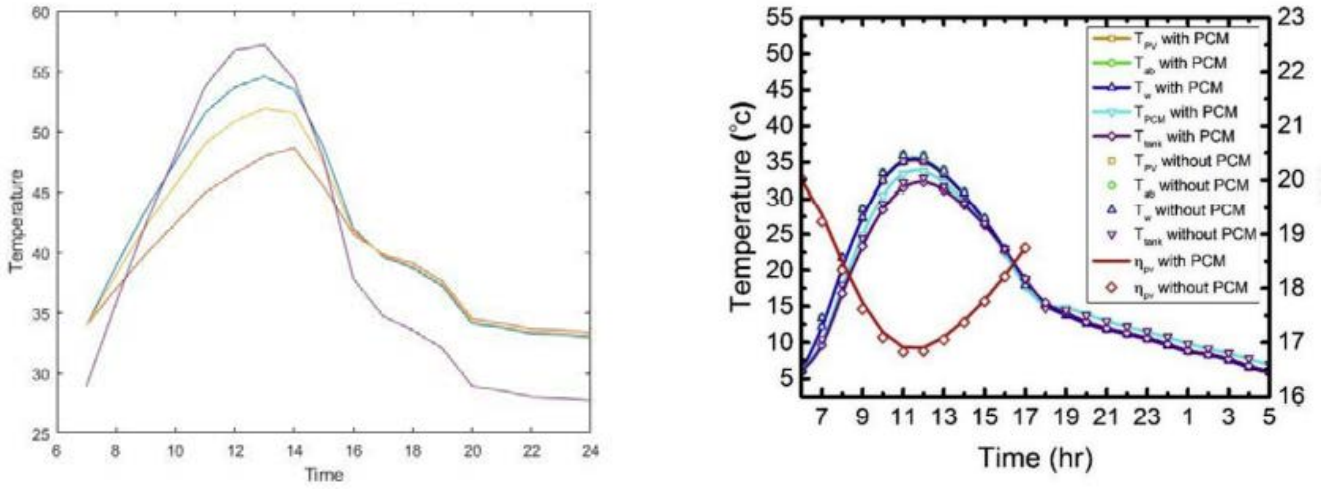

Fig. 3. Comparison of the variation of PV, water, absorber, PCM temperatures with respect to time

CONCLUSIONS

This study hopes to achieve

- The PVT temperature should decrease due to the phase change material which leads to a higher system efficiency
- The residue electricity for the panel is enough to initialize the proton exchange membrane which will start the production of hydrogen
- Hydrogen is stored in a tank which can be later connected to a fuel cell for further use in the energy production at night

ABSTRACT

The challenge of meeting the growing worldwide energy demand requires progress in using renewable energy sources and hydrogen technology. Regenerative fuel cells (URFCs) are expected to be part of this energy system shift. URFC is an electrochemical device that can operate alternately as a fuel cell (to produce electricity) or water electrolyser (to produce hydrogen). Merging of WE and FC in a unique device would decrease costs due to the reduced use of precious catalysts. However, the way to develop an efficient device is still opened. Oxygen electrode in URFC is a limiting component because of the sluggish kinetics of the oxygen reduction and oxygen evolution reaction (ORR and OER). Moreover, there is not a common material that catalyses both reactions: the most suitable materials for ORR and OER are platinum and iridium, respectively. Consequently, it is necessary to reach a compromise in the composition of a bifunctional oxygen catalyst (BOC) based on Pt and Ir to improve, or at least sustain, the activity and stability with the lowest noble metal loading possible. The present work reports the polyol synthesis of Ir-decorated Pt nanoparticles with different compositions (Ir10/Pt90, Ir20/Pt80, and Ir40/Pt60). For a good understanding of the electrochemical properties, morphological and chemical surface composition of the nanoparticles have been studied by means of XRD, EDS, TEM, XPS, and RDE techniques. The results showed that the nanoparticles with an Ir:Pt ratio 20:80 display the best results.

Keywords: PEM Unitized Regenerative Fuel Cell, Catalyst, Polyol Method, Iridium, Platinum.

INTRODUCTION

Nowadays, the world faces a great energy challenge that involves two main aspects: meeting the rise of the global energy demand and reducing of carbon emissions to the atmosphere. The efforts to reach these targets go through the electrification of end-use sectors and the energy transition from fossil fuels to renewable energy. Fuel cells (FCs) and water electrolysers (WEs) are green technologies for electricity and hydrogen production, respectively [1]. Merging of these devices in a Unitized Regenerative Fuel Cells (URFC) would represent substantial decrease of costs due to the reduced use of precious catalysts. However, the way of developing an efficient and durable unit is still opened.

Proton exchange membrane water electrolysers (PEM-WEs) and proton exchange membrane fuel cells (PEM-FCs) have similar configuration and both technologies work with a solid polysulfonated membrane. Nevertheless, the oxygen electrode has different requirements depending on the operation mode. There is not a common material that catalyses the Oxygen Reduction Reaction (ORR, for FC mode) and the Oxygen Evolution Reaction (OER, for WE mode). The most suitable material that catalyses the ORR is the platinum, whereas OER can be catalysed by iridium, but not Pt [2]. As a consequence, it is necessary to focus the attention on the development of a metal combination that works as bifunctional oxygen catalyst (BOC). In this regard, BOCs based on Pt and Ir have been investigated in the past years and most of those catalysts were obtained by mechanical mixing of powders [3]. Consequently, the bad dispersion of the components led to a low bifunctional performance. Herein, we present an efficient route for the preparation of Ir-decorated Pt nanoparticles in a two-steps one-flask synthesis by the polyol method containing polyvinyl pyrrolidone (PVP) as a capping agent. The use of PVP permits the Pt nanoparticles to stabilize during the synthesis and prevents from agglomeration enlarging their surface area [4]. Thus, Ir nanoparticles are highly dispersed on the Pt surface which is a great strategy for maximizing the utilization of precious metals. This work systematically studies the effect of catalyst composition ($Ir_{100-x\%}/Pt_{x\%}$) through a three-electrode system with the purpose of finding the best Pt-Ir mass ratio that optimizes the ORR and OER performance without compromising their stability.

EXPERIMENTAL

Materials

The metal precursors chloroplatinic acid hexahydrate ($H_2PtCl_6 \cdot 6H_2O$, 99.99%) and dihydrogen hexachloroiridate (IV) hydrate (($H_2IrCl_6 \cdot xH_2O$ 99.99%), polyvinylpyrrolidone (PVP) 10,000 MW, and ethylene glycol (99%) were acquired from Alfa Aesar. Sulfuric acid (H_2SO_4, 95.0-97.0%) was acquired from Honeywell Fluka. Hydrogen peroxide (H_2O_2, 30%) was acquired from Emsure. Isopropanol (p.a) was acquired from Penta, and commercial Pt black and Ir black were acquired from Fuel Cell Store. The water used in all tests was ultrapure (Millipore, 18.2 MΩ cm).

Synthesis of Ir-decorated Pt nanoparticles

The Ir-decorated Pt nanoparticles (NPs) were prepared by deposition of Ir NPs on the surface of Pt NPs through the polyol method. This method uses a polyol, ethylene glycol in this work, acting simultaneously as solvent and reducing agent. Prior of the synthesis, the metal precursor solutions were prepared by combining the metal precursor powder and ethylene glycol in a concentration of 0.04 M. Furthermore, PVP was added to each precursor solution and dispersed under sonication for 30 minutes. In a typical Pt NPs synthesis, the Pt precursor solution with PVP was contained in a round bottom flask submerged in an oil bath and heated under reflux and vigorous stirring at a temperature of 160º for one hour. Subsequently, the Ir precursor solution with PVP was introduced in the synthesis flask with the aim of reducing the Ir precursor directly on the surface of the already existing Pt NPs. The Ir synthesis parameters were kept the same as the Pt synthesis, 160ºC of temperature and 1 hour of reaction time. To remove the PVP from the nanoparticles surface, the methodology reported by Monzó et al. was followed. Briefly, the suspension of nanoparticles was mixed with a H_2O_2/H_2SO_4 solution, centrifugated and rinsed with ultrapure water.

Physicochemical and electrochemical analysis

The microscopy and spectroscopy techniques used are listed below. X-ray diffraction (XRD) patterns were recorded using a Rigaku SmartLab diffractometer with a Cu Kα-source (λ = 1.54059 Å) operating at 9 kW and completed in the angle range from 20º to 140º. The elemental chemical composition was evaluated by energy dispersive X-ray (EDX). The analysis was carried out at accelerating voltages of 20 kV in a Tescan MIRA 3 apparatus equipped with a Bruker Quantax detector XFlash 6|10 spectrometer. The surface chemical composition of the nanoparticles was measured through X-ray photoelectron spectroscopy (XPS). The analysis was performed in ultra-high vacuum chamber equipped with a SPECS Phoibos 150 hemispherical analyser and Mg (Kα) X-ray source. The morphology and structure of the catalysts were characterized by means of high-resolution transmission electron microscopy (HR-TEM), including scanning mode (STEM), supported by electron diffraction (ED) in a JEOL NEOARM 200 microscope at accelerating voltage of 200 kV. The electrochemical characterization of the nanoparticles was investigated by rotating disk electrode (RDE) technique in a three-electrode setup from Pine Research Instrumentation. The electrodes used were a Pt counter electrode (AFCTR5), a standard $Hg/HgSO_4$ reference electrode, and a glassy carbon disk as working electrode. All the experiments were conducted on an aqueous H_2SO_4 solution (0.5 M) electrolyte at room temperature and using a Bio-Logic SP-50 potentiostat.

RESULTS AND DISCUSSION

The physicochemical characterization confirms the raspberry-like morphology of the nanoparticles where Ir nanoparticles with a smaller size of about 2 nm decorate Pt nanoparticles of about 8 nm. Fig. 1 left shows the HR-TEM images of the catalyst. In addition, XPS spectra (Fig. 1 right) shows how Ir composition on the surface is enlarged in comparison with the EDS composition (bulk composition). This circumstance influenced the electrochemical behaviour of the catalysts compared to the pure commercial Ir and Pt nanoparticles (see Fig. 2). Activity towards ORR was slightly reduced due to the Ir coverage that reduced the number of Pt active sites accessible, while OER activity was improved in comparison with the commercial reference Ir black. The reason of the increased activity of the as-synthesized nanoparticles is linked to the non-reversible oxidation process occurred at the high potentials at which OER happens. In addition, it was discovered not only a complete oxidation of the Ir nanoparticles but their change into the highly active species (Ir hydroxides) directly related to the improvement of the OER rate [5]. The formation of these oxides was observed in the presence of the Ir3+ state at the XPS spectra obtained from the samples after an electrochemical activation by RDE technique. The origin and cause of the production of these species is still under development.

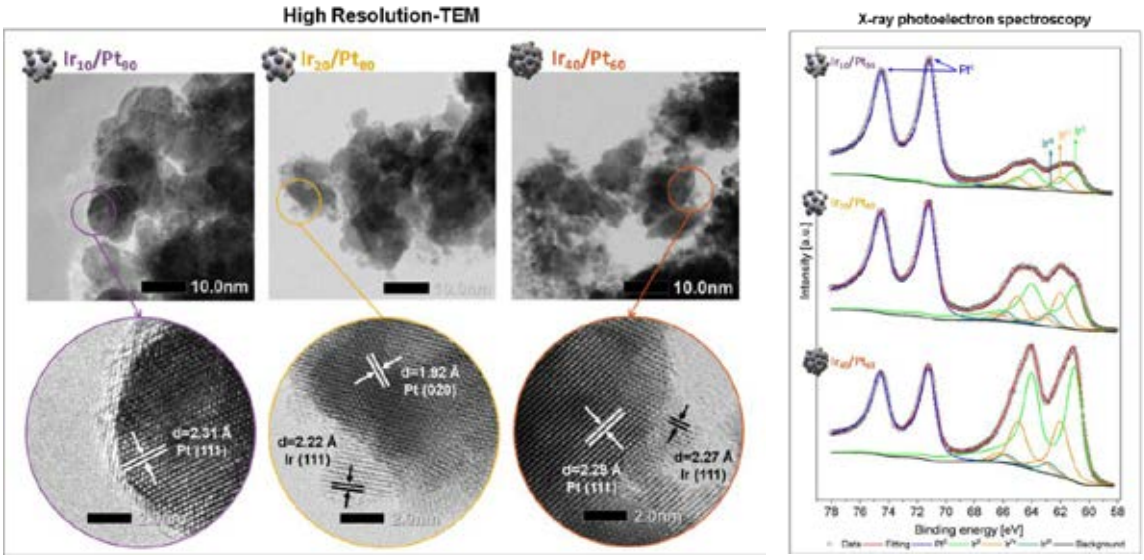

Fig. 1. HR-TEM images of the catalysts (left) and XPS spectra of the catalysts (right).

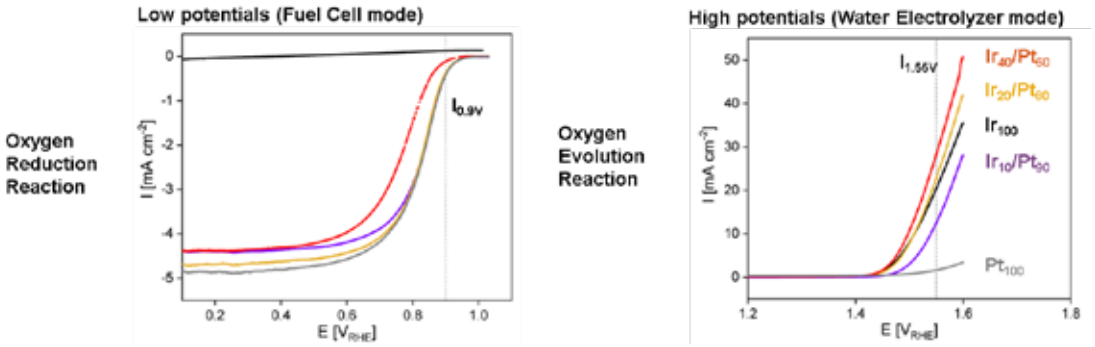

Fig. 2. Linear sweep voltammetry of the catalysts at low and high potentials.

CONCLUSIONS

Ir-decorated Pt nanoparticles with a raspberry-like structure was synthesized through polyol method. All the bimetallic samples displayed higher Ir mass activity than that of commercial Ir due to an improved utilization of the Ir nanoparticles and their complete oxidation to a highly active Ir3+ state. Finally, IrPt-based catalysts showed smaller Pt mass activity than that of commercial Pt due to the Ir coverage that reduces the availability of Pt active sites. Nevertheless, Ir10/Pt90, Ir20/Pt80 had a comparable activity. Also, $Ir_{20}Pt_{80}$ exhibited remarkable stability in both durability test modes. Thus, it is a promising candidate for the oxygen catalyst in PEM unitized regenerative fuel cells.

ABSTRACT

An integrated system is studied to supply green hydrogen feedstock for ammonia production in the Netherlands. The system compares wind and solar resources when coupled to alkaline and PEM electrolysis with a compressed hydrogen storage system. The nominal installed capacity of the electrolysis plant is around 2.3 GW, the most suitable energy source is offshore wind, and the preferred storing technology is pressurized tubes. The levelized costs of hydrogen (LCOH) are 5.30 €/kgH_2 and 6.03 €/kgH_2, and the levelized costs of ammonia (LCOA) are 1.22 €/kgNH_3 and 1.34 €/kgNH_3 for alkaline and PEM technologies, respectively.

Keywords: Green Hydrogen, Green Ammonia, Levelized Cost, Renewable Energies

INTRODUCTION

Ammonia is the material with the highest emission intensity per ton of product in the industry sector, accounting for more than 1% of global emissions as 95% of the hydrogen feedstock is derived from fossil fuels [1]. One possible way to decarbonize ammonia and hydrogen production is combining industrial electrolysis and electricity generated by renewable sources, known as green hydrogen (GH). When GH is used as feedstock, the ammonia produced is called Green Ammonia (GA). Different initiatives and studies have been announced for GH and GA in the industry and in the academy. On one hand, the industry presents the information without revealing the methodology of the studies such as in [2]. On the other hand, the studies found in the academic literature develop methodologies for GH and GA production without linking the demand to the industry's requirements as in [4]. For this reason, this work is intended to bridge the gap between the development of a methodology with the needs of the industry sector for GH and GA production systems at a large scale.

MODEL DEVELOPMENT

The main components of the Green Hydrogen Integrated System (GHIS) are the variable energy resources (VRES), the Electrolysis Plant, and the Hydrogen Storage System, as shown in Fig. 1. The VRES are wind and solar. The technologies selected for the electrolysis plant are alkaline (AEL) and PEM (PEMEL). The storage system uses Compressed Hydrogen Technologies, and the Ammonia plant is considered to find the demand for hydrogen. The analysis is limited to the main components inside the red dashed line.

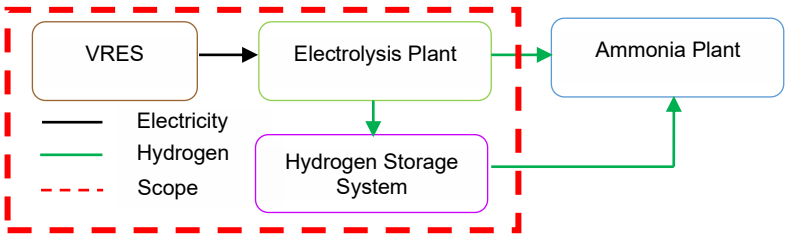

Fig. 1. General representation of the GHIS.

Hydrogen Demand

The nominal hydrogen demand is based on the production requirements of the largest fertilizer plant in the Netherlands, and it is assumed to be the addition of the stoichiometric plus the storage requirements of the ammonia synthesis process. The former is defined using Eq.(1), and the latter is defined as 25% of the stoichiometric demand that corresponds to the flexibility of the ammonia production process [6].

$$NH_3\ \ Synthesis: N_2 + 3H_2 \rightarrow 2NH_3 \quad (1)$$

Electrolysis Plant

The nominal installed capacity of the electrolysis plant is found using Eq.(2). The values for the E_s for AEL and PEMEL technologies are based on typical values for commercial electrolyzes here considered as 52 kWh/kg at 64% efficiency and 50 kWh/kg at 67% efficiency with flexible operation between 20-100% and 10-100% [7], respectively.

$$P_{plant} = E_s / \dot{V}_{H_{2-nom}} \quad (2)$$

Variable Renewable Energy Sources Characterization

The VRES are fully dedicated to power the electrolysis plant. The wind resource is assessed using a typical wind profile with hourly resolution of the Dutch part of the North Sea to find the Average Power Density in W/m^2 of the wind resource [8]. For the solar energy resource, the data for the global horizontal irradiation is retrieved from the Photovoltaic Geographical Information System (PVGIS) of the European Commission [9]. Both resources are compared using the C_F defined in Eq.(3).

$$C_F = AEP_{act}/AEP_{theo} \tag{3}$$

Green Hydrogen Production and Storage

First, the hourly power output of the VRES is compared with the flexible operation range of the electrolyzers. Then, each value of the VRES energy output above the minimum partial load threshold is divided by the specific energy consumption using Eq.(4) to find the actual hydrogen yield. When the energy output is below the minimum partial load, the electrolyzers cannot operate due to safety reasons. Above this threshold, the electrolyzer produces hydrogen. For example, at nominal capacity, the difference between the nominal demand and the stoichiometric demand fulfills the storage requirements.

$$\dot{V}_{H_2-act} = P_{VRES}/E_s \tag{4}$$

Economic Assessment

The production costs for hydrogen and ammonia are assessed with the LCOH and LCOA respectively.

RESULTS AND DISCUSSION

Applying Eq.(4), the actual production of hydrogen is 45% and 46% of the nominal demand and applying Eq.(1), it is possible to cover 56% or 58% of the total annual demand of ammonia using AEL and PEMEL, respectively. The effects of the ranges for flexible operation make PEM technologies operate more hours throughout the year, and the energy curtailed could power auxiliary systems and compressors. Oxygen and heat are valuable subproducts of the electrolysis process and can be further utilized in different industrial applications such as steel plants and low-temperature district heating respectively. The water requirements given the actual hydrogen production are equivalent to 650 Olympic swimming pools per year.

The nominal installed capacity of the electrolysis plant applying Eq.(2) corresponds to 2.38 GW and 2.29 GW for AEL and PEMEL technologies, respectively. The VRES have the same nominal installed capacity, assuming they are fully dedicated to powering the electrolysis plant. Applying Eq.(3), the C_F of the wind and the solar resources are 47% and 13% respectively. Due to the higher C_F of wind compared to solar, the analysis is narrowed down to the electrolysis plant coupled to offshore wind. The storage system capacity is 3.94 ktonH_2 and equals the entire storage product of the month with the highest yield, which is January. The storage technologies considered are geological storage pressurized tubes cylindrical and spherical vessels. The comparison is made considering the geographical location, storing pressure, and capacity of each technology. Based on this, the most suitable technology is pressurized tubes as geological caverns are in the north of the country, making this solution non-realistic due to the location of the ammonia plant in the south. The LCOHs are 5.30€/kgH_2 and 6.03€/kgH_2 and the LCOAs are 1.22 €/kgNH_3 and 1.34 €/kgNH_3 for AEL and PEMEL, respectively. The results are summarized in Fig. 2. and compared with the costs of producing hydrogen and ammonia with the steam methane reforming process (SMR) and using electricity from the grid to cover 100% of the hydrogen demand. The price of electricity makes up a considerable part of the total costs

Fig. 2. Comparison of the results for the LCOH and LCOA for the GHIS.

The current annual emissions of the ammonia plant are 3.2 $MtCO_2$ [10], or 12% of the total emissions of the industry sector in the country, which are 26$MtCO_2$ [11]. Using the GHIS would be possible to avoid approximately 1700ktCO2, the equivalent to reduce more than 50% the current total emissions of the plant or 6% of the emissions of the sector.

CONCLUSIONS

The GHIS consists of an electrolysis plant power by fully dedicated VRES. Due to geographical conditions, offshore wind energy is the most suitable source with the highest C_F compared to solar energy. To cope with seasonal fluctuation, pressurized tubes are the preferred storing technology. The LCOHs and LCOAs of the GHIS are higher than the production costs using SMR. Finally, with the GHIS, it would be possible to reduce the current total emissions of the industry sector in the Netherlands up to 50% compared to the current values.

HIGH-PRESSURE PEM WATER ELECTROLYSIS BASED ON HYDRAULIC SINGLE CELL COMPRESSION

[1*] *Florian J. Wirkert,* [1] *Ulrich W. Rost,* [1] *Jeffrey Y. Roth,* [1] *Michael Brodmann*

ABSTRACT

Hydrogen needs to be compressed, such as up to above 100 bars for seasonal storage or even 700 bars to meet pressure levels for mobile applications. Up to now, high pressure hydrogen production in combination with high operation dynamics can only be handled by proton exchange membrane water electrolysis (PEMWE). However, not only but also due to still limited outlet pressures of about 40 bars, which requires additional compressors to meet storage pressure levels, PEMWE is still subject of intensive research. In this work a novel high-pressure electrolyzer system is described that was engineered with respect to hydraulic single cell compression to meet this task. Homogeneous pressure distribution throughout the entire active area is achieved via a hydraulic medium entirely surrounding the active cell components, also providing waste heat management independent of the electrochemical operation conditions. Construction details of a near industrial scale PEMWE system for an operation at a balanced 100 bar outlet pressure level are given. Further, findings related to cell performance indicated by polarization curves that were obtained up to 6 A cm^{-2} during 100 bar operation are described. Finally, a 600-hour long-term run at 2 A cm^{-2} is presented, revealing performance degradation to be in µV h^{-1} range and hydrogen crossover to be below 50 % of the lower explosion limit on the anode side.

Keywords: PEM Water Electrolysis, High-pressure, Hydraulic cell compression, Modular Stack Design

INTRODUCTION

Producing hydrogen at high pressures via polymer electrolyte membrane electrolysis (PEMEL) utilizes the mechanism of electrochemical gas compression along with the electrolysis process itself. This kind of compression provides a higher efficiency compared to mechanical gas compression. In addition to that, an additional device comprising moving parts can be omitted, saving further space and investment as well as maintenance costs. To make use of these potential advantages, it is necessary to create high-pressure PEMEL stacks with at least the efficiency and lifetime as stacks using conventional PEMEL technology. The concept based on the principle of hydraulic single cell compression described in this work is meant to address this issue. The applicability of this approach for high-pressure hydrogen production was already demonstrated on lab-scale [1], while in a later experiment, also, the performance preserving scalability to an industrial level was validated [2]. For a possible large-scale manufacturing and operation major design changes were implemented and a novel modular approach was created providing scalability both in stack size and size of the active cell area [3]. Now, to investigate the capability of the new development for high-pressure production and long-term stable operation, an experimental test run was conducted using a PEMEL stack consisting of three single cells with an active cell area of 210 cm^2 each.

SCIENTIFIC APPROACH

The principle of hydraulic cell compression is based on the approach of inserting a single PEMEL cell in flexible pockets as shown in figure 1. The force to compress the active cell components is provided via a hydraulic medium completely surrounding the flexible pocket. Once this hydraulic medium is pressurized, the pressure is homogeneously distributed over the active cell area. As this pressure is responsible for electrically connecting the single components of a cell (pole plates, porous current distributors (PCD), gas diffusion layers (GDL), and catalyst coated membrane (CCM)), the current distribution follows the pressure distribution and is, hence, also homogeneously distributed. This is profitable for an increased lifetime, as the formation of local hot spots is prevented. In addition, the compression level may easily be adapted to an optimum depending on the components used, especially the GDL and

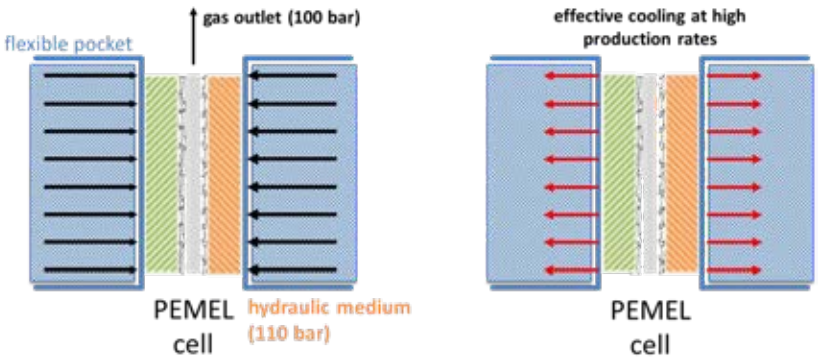

Figure 1: Schematic drawing of a PEMEL cell integrated in a flexible pocket.

the PCD. For the setup used here, previous findings show a minimum applicable pressure level of 6 bar, while during standard operation the hydraulic pressure is set to 10 bar. The pressure of the hydraulic medium may not just be adapted to the optimum compression level, but also kept constant as the overall pressure level is increased. With increasing gas pressure (oxygen and hydrogen) inside the cell, the pressure of the surrounding hydraulic medium is increased accordingly. In the example shown in figure 1, the optimum level of 10 bar cell compression is maintained at a gas outlet pressure of 100 bar by increasing the pressure of the hydraulic medium to 110 bar. Additionally, creating a circulation of the hydraulic medium, it may be used to control the temperature of the inserted PEMEL cell. Thus, temperature management is possible independent of the process media circulations providing an effective cell cooling without affecting the actual electrochemical process. Temperature management and hydrogen production may, therefore, be optimized independent from each other, providing possible advantages especially at elevated current densities and highly dynamic operation scenarios. Mentioned operational environments are equal for each single cell of a stack, as each cell is individually surrounded by the same hydraulic medium. For a future large-scale production and operation with an increased active cell area, a new approach was developed with the flexible pocket being part of the cell itself. In this approach, two half-cells comprising a plastic cell frame and a monopolar plate each form an empty space between those pole plates, in which the active cell components may be integrated, as shown on the left-hand side of figure 2. The channels for media conduction are integrated in the call frames, providing a parallel media supply of all cells once the cells are stacked together (right-hand side of figure 2). As the hydraulic medium is able to penetrate the space between the pole plates via respective channels, the active area of each single cell is still surrounded by the hydraulic medium guaranteeing the same operational environment as described above.

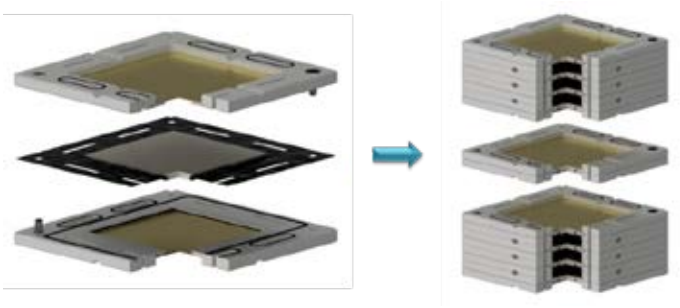

Figure 2: Schematic drawing of the presented modular stack design comprising single cells forming flexible pockets for active cell components.

MATERIALS AND METHODS

In order to investigate the capability for large-scale operation, a stack consisting of seven single cells has been manufactured with an active cell area of 210 cm^2, as shown in figure 3. For the experiments carried out for this work, the stack was operated with three single cells. The test run was performed with the stack being integrated in a containerized test system being capable of a 100 bar operation. For this purpose, it comprises an integrated pressure vessel, in which different stacks may be integrated for investigation. Pictures of the utilized test environment are also shown in figure 3. After stack installation followed by an initial break-in procedure (slowly increasing the current density to 1 A/cm^2 and maintaining this current density for 1 h), the experimental test run was started by increasing the hydrogen production pressure to 95 bar at a constant current density of 2 A/cm^2. Once high-pressure operation was established, a polarization curve was recorded up to a current density of 6 A/cm^2 at an operational temperature of 52°C, in order to investigate the capability of this design approach for high power density operation. Subsequently, the current density was set to 2 A/cm^2 and maintained for 600 h, to investigate the long-term behavior of the stack. The temperature of the stack was established at about 65 °C during this long-term test. Cell voltage of the cell placed in the middle of the stack was recorded the entire time representing the behavior of cells in the environment of a larger stack. [4]

Figure 3: Photograph of the PEMEL stack used for high-pressure operation (for this work it was operated with three single cells) and of the utilized test environment taken both from the inside and the outside.

RESULTS AND DISCUSSION

The polarization curve recorded initially at the beginning of the test run is depicted in figure 5. As our focus lay on the cell and stack design, the important result was, that there was no limitation due to insufficient media transport at high current densities.
However, this result may be addressed not just to the stack and cell design, but in particular also to the advanced inner cell components provided by the partners being described in detail in the collective publication [4]. The not entirely linear behavior of the cell voltage with increasing current may originate from an increasing temperature at elevated current densities.
Results obtained from the subsequently conducted long-term test are shown in figure 6. Fluctuations in the recorded curves are visible, as the system was sensitive to environmental temperature changes. The drop visible after around 500 h of operation was caused by an externally induced safety shutdown of the whole system. The average degradation recorded during 600 h of operation was 4.43 µV/h. [4]

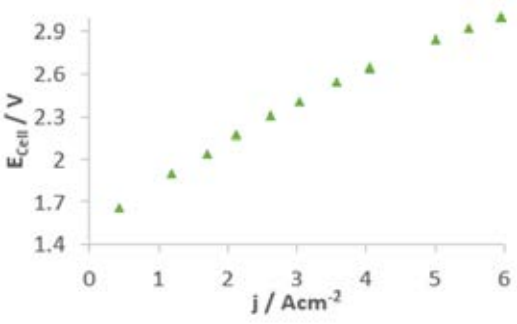

Figure 4: Polarization curve recorded at 52°C and ambient hydrogen output pressure.

CONCLUSIONS

It can be concluded that the investigated cell and with that the entire stack showed a polarization behavior and degradation rate similar to state-of-the-art PEMEL systems validating the capability for large-scale high-pressure hydrogen production. Nevertheless, further investigations are necessary to fully understand the influence of high-pressure operation, especially when high-pressure operation is maintained over a longer time.

EXTERNAL EFFECTS ON THE HIGH FREQUENCY EIS RESPONSE OF A PEM ELECTROLYSIS CELL

ABSTRACT

Electrochemical impedance spectroscopy (EIS) is a very useful tool to characterize and distinguish the electrochemical processes in an electrolysis cell. However, to exclude external influences on the results, a method to pre-evaluate them is suggested and its usefulness is demonstrated by a faster and better fitting of the equivalent circuit model (ECM). In fact, if not considered in the ECM, the inductance artificially increases the ohmic resistance obtained at high frequencies (HFR). This effect increases at higher current densities.

Keywords: Inductance, EIS, ECM, PEM electrolysis, HFR

INTRODUCTION

Electrochemical impedance spectroscopy (EIS) is an important method to monitor the state of health of an electrolysis cell. With this characterization method is possible to distinguish electrochemical processes in the cell, based on their frequency responses. However, in reality, the response of a cell does not only depend on the cell components and materials, but it is often also influenced by external noises, coming from cables and connectors. Especially for higher current densities, these effects can become so significant that they need to be taken into account in the equivalent circuit model (ECM) in order not to interpret the obtained EIS results incorrectly [1]. For instance, the PEM electrolyser response with positive imaginary part of the impedance is usually ignored [2], however this might lead to significant overestimation of the high frequency resistance of the cell [3]. While this has already occasionally been done in other studies on PEM electrolysers [4, 5], a stringent methodology to assess these external influences and to quantify their effects on the real response of a PEM water electrolysis cell is lacking.

EXPERIMENTAL

Electrochemical Impedance Spectroscopy (EIS)

EIS measurements are performed for reference and in-situ measurements at the following current densities 0.3, 1, 2, and 3 A/cm^2 and at 80°C, a water flow rate of 0.2 l/min and at ambient pressure for in-situ measurements. The spectra are recorded in a frequency range between 0.1 Hz and 10 kHz and with a stabilization time of 3 minutes.

Reference Measurements

The measurement type used for assessing the external influence is going to be referred from now on as reference measurement. The setup used in this test is sketched in Figure 1 and it is composed by current and sense cables that connect the potentiostat to the current collectors of a cell. The latter is a typical electrolysis cell, but with a gold coated titanium plate, instead of the catalyst coated membrane (CCM).

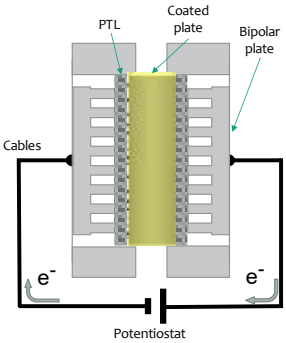

Figure 1. Schematic setup of reference measurement.

The response of this setup under different current densities is characterized via EIS, as explained in the subsection EIS. With this setup, the contribution of the hardware used for in-situ measurements except from those originating from the CCM can be obtained.

In-situ Measurements

The in-situ measurements are performed with the same cell (bipolar plates and porous transport layers), potentiostat, cables and their position as in the reference measurement, but a CCM is assembled instead of the gold coated plate. The cell is activated via two galvanostatic steps at 0.2 and 1 A/cm^2 for half an hour each, followed by a potentiostatic step at 2.2V held for 6 hours. After this, a characterization of the cell performance is carried out through polarization curve and EIS. In this report we will focus just on the results of EIS.

Fitting Model

Before applying any fitting to the collected data, the linearity, causality and time dependence of the data have to be evaluated and the non-conforming data would be filtered [4]. After this point, the evaluation of the Bode and Nyquist plot gives an indication of the elements composing the equivalent circuit model (ECM), which is going to be used to fit the behavior of the setup or cell under the different conditions. For the reference measurement, an ECM composed by an ohmic resistance (R_{ohm}) and a modified inductance (L_{alpha}) in series is used [6], while for the in-situ measurements, a modified inductance (L_{alpha}), an ohmic resistance (R_{ohm}), and two resistance-capacitance (R-C) elements are used. The analysis of the model is run using a specific package in python [7]. The recursive iteration to reach the best fit needs as input parameters the ECM, initial values for each element, and the domain of the fitting values.

RESULTS AND DISCUSSION

ECM of Reference Measurements

In the common approach, the setup used for the reference measurements with electrically conductive components and the interface between them, would be characterised as a resistor. However, already at frequencies higher than 70Hz, a change of behaviour towards a higher positive imaginary part is evident in the Niquist plot, as well as an increasing phase angle in the Bode plot, as per Figure 2. This evidence denotes an additional inductive effect to the supposed resistive behaviour of the setup. These results are therefore fitted by an ECM model that includes a modified inductance and a resistance. As the values of L_{alpha} acquired with the mentioned fitting model prove to be significant, a modified inductance is included in the ECM of the in-situ measurements (see below) and the values obtained in the reference measurements are used as initial parameters of the fitting.

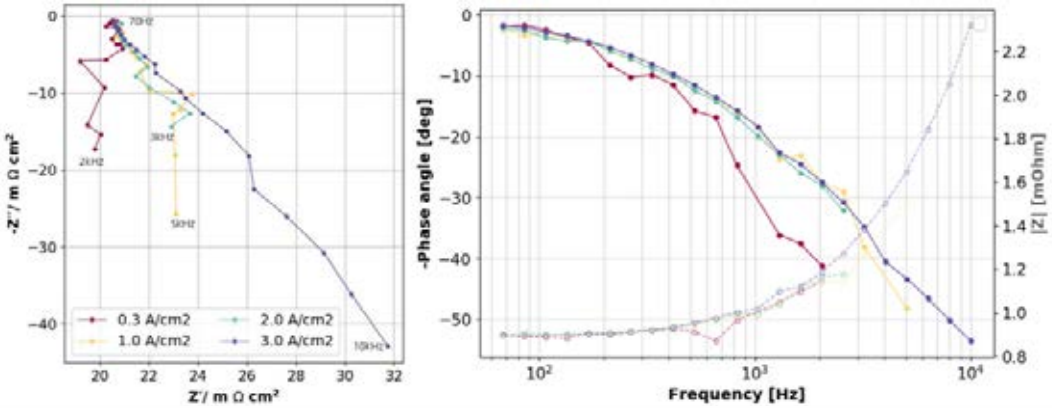

Figure 2. Niquist and Bode plot of reference measurement at different current densities.

ECM of In-situ Measurements

The EIS measured during in-situ measurements show at frequencies above 60 Hz an inductive behaviour under all current densities. After their initial evaluation, the ECM calculation is performed, and the values of each element of the ECM are obtained faster and result in a better fitting, when the initial values are defined by the L_{alpha} from the reference measurement.

The results of the fitting also present a discrepancy between the HFR, as intercept to the x-axis in Nyquist plot, and R_{ohm} calculated by the ECM model shows that the real R_{ohm} has a lower value than that obtained from the uncorrected HFR for all current densities. This shift to higher values of HFR can be assigned to the external influences as quantified via reference measurement. The interplay of HFR and inductance has also been quantified and modelled by Shin and Cruz-Manzo [1, 3]. As visible from Figure 3, this effect increases with increasing current density.

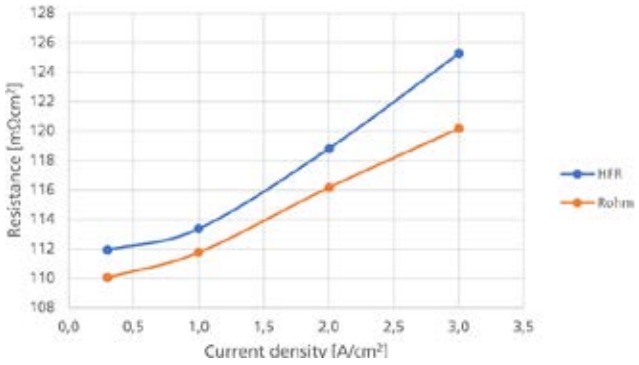

Figure 3. HFR from EIS and Rohm from ECM at different current densities for in-situ measurements.

CONCLUSIONS

A reference measurement procedure was used to quantify the influence of external components as demonstrated by fitting against an ECM including a modified inductance. The latter was therefore included in the ECM for in-situ measurements and the influence onto the HFR was quantified. The obtained results can then reduce the computing time of ECM, give a more correct evaluation of the ohmic resistance of the cell and also on other processes that are masked by the inductive effects deriving from external influences. While the external influences will depend on the used hardware, they in any case need to be checked in order to obtain accurate and reliable results.

ABSTRACT

The research carried out presents an integrated analysis of the green hydrogen production process from water hydrolysis; and of the transformation stages from water treatment, electrolytic production, separation, drying, compression, cooling and conditioning operations to reach hydroduct injection specifications, through simulation and plant balance (BoF); considering effluent recovery; using a calculation model to determine the different energy consumptions and used; the renewable energy efficiency factor to quantify the energy demand required by the process for the target control flow, this allowed the determination of the production indices, which correspond to scaling and mass production parameters such as the overall process efficiency , hydrogen flow index and the generated power index, to achieve the operational specifications of hydrogen product delivery, these and aim to have a quick guide for the determination of capacities in scale systems.

Keywords: *Green Hydrogen; Energy efficiency; Balance of Plant (BoF).*

INTRODUCTION

The world production of H2 is around 40 million tons per year, according to data from the International Energy Agency (EIA). Currently, practically 96% of the world's hydrogen is produced from fossil fuels, mainly by reforming natural gas with water vapor, and is consumed as a component of conventional processes (chemical and petrochemical industry) (González, 2018).
On the other hand, hydrogen transport technologies are mature, but not widespread, this leads to the search for opportunities in the transmission of low-pressure pipelines (HBP) from 20 to 80 bar_g and high-pressure pipelines (HAP) from 350 at 700 bar_g (Zabrzeski, 2019).
The physical nature of hydrogen will provide capacitance restricting the cycles, reducing management costs and distribution of green energies, Figure 1 represents the management diagram; There are many demonstration projects of production systems that have been studied in isolation, but in the scaling-up processes they reveal the need to improve the efficiency, durability and reliability of the systems in order to work with renewable energies.

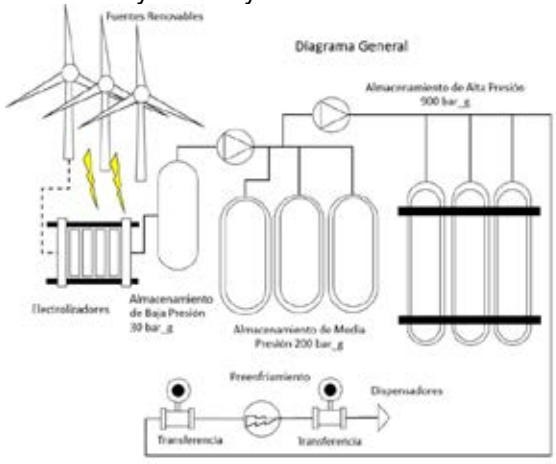

Fig. 1. H_2 handling overview diagram.

Based on the points mentioned; The present work seeks to establish a set of referential parameters and indicators, which facilitate the estimation in the rapid scaling analysis of hydrogen production units; that allow inferring the global energy demand of the system and the expected yields. These are indices of interest in the estimation processes and in

the quantification of the intensity of associated investment in renewable energies, likewise these indices and configurations encourage the development of future analyzes aimed at obtaining other parameters of interest that allow to serve as a reference to the development of hydrogen as an energy development agent.

MATERIALS AND METHODS

System configuration

It was developed based on the sequence of operations and unit processes for the determination of production and performance indices, starting from the general approach and from there to the discrete or elements following a process of increasing functional complexity.

The configuration process followed the following steps:

A. Synthesis: Allows the configuration of the topology of the production system (Figure 2), allowing the conceptual process to be developed and integrates the energy sources in their different forms such as electricity, heat and refrigeration. B.
B. Sequencing: Preparation of inputs and conditioning of materials: Integrates the activities to perform the removal of encrusting ions and impurities in the raw water up to the entrance to the electrolyzer.
C. Configuration: In this stage, a more detailed breakdown of operations is carried out prior to the configuration of the process flow diagram where particular elements will be represented in detail, each of these operations can be evaluated as a subsystem and its performance can be analyzed and analyzed. characterized.
D. Plant Balance: From the flowchart, the material and energy balance of the plant is developed for the target production volume; through the modeling of the system and serves as the basis for the approach of the process flow diagram in the CAPE OPEN type simulation software.

The Figure 2 presents the flowchart of matter and energy with the various operations and processes involved in the production of green hydrogen.

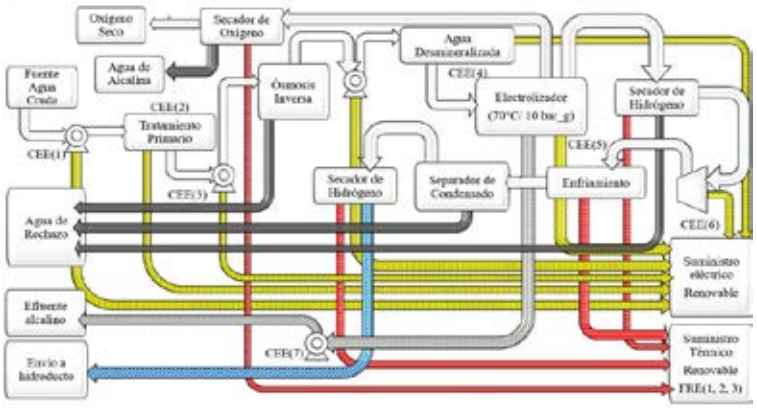

Fig. 2. Process flowchart.

System modeling

The modeling and simulation allowed to recreate in a virtual way the selected processes to be able to study their behavior, in order to analyze the consequences and effects of the different conditions and makes it possible to compare the design alternatives that may arise, without having to bring them to reality. Expensive scale models to carry out evaluations of the final performance of the systems from the unit balances.

This approach makes it the ideal tool for determining scaling parameters; and I imply the selection of the different components related to the process, as well as the thermodynamic packages, equations and methods to solve the general system once the various recirculation's and cycles have been defined; the material balance for each unit is defined as:

$$\sum_{1}^{j}(EM_j) = \sum_{1}^{i}(SM_i) \quad + ACM \tag{1}$$

For the energy balance we have:

$$\sum_{1}^{n}(EE_n) = \sum_{1}^{m}(SE_m) \ + ACE \tag{2}$$

With the simulation model in numerical convergence for the currents of matter and energy. The Balance of Plant BOF is carried out from operation “a” to “m”; the net energy balance expression is as follows:

$$BNE = \sum_{1}^{k}(FRE_i) - \sum_{1}^{g}\frac{(CEI_j)}{\varepsilon_j} \tag{3}$$

The global efficiency of the system is determined from the relationship established in equation 4.

$$\sum_{1}^{g}\frac{(CEI_g)}{\varepsilon_g} \rightarrow \frac{\dot{m}_{H_2}}{PM_{H_2}} \Delta H_{f H_2O}) \tag{4}$$

RESULTS AND DISCUSSION

Below are the results of the evaluation of the behavior of the production model for a control volumetric flow of 3,216 Nm3/day of H2, for this condition the energy consumption and the heat removal requirements for handling conditions for low pressure pipelines (HBP) and high-pressure pipelines (HAP). The main difference between HBP and HAP lies in the requirement of hypercompression and subsequent cooling.

This is an important factor due to the discharge pressure required by the second case, greater than 700 bar_g. The table 1 present the results generated by the model and are used as input data for the determination of the 3 plant scaling parameters IFH, IPG and IRQ.

Table 1. Summary of WHEC-2022 formatting details

12) Cooling	- ---	- 39.50
- ***Consume Global***	- ***920.7***	- ***1007.6***

CONCLUSIONS

The production indices determined with this work are a valuable tool for sizing and scaling hydrogen production units and allow a rapid evaluation of elements such as energy consumption, production, heat removal requirements and generated energy capacity, it should be noted Given the structure and configuration of the model, these parameters are linear with respect to their dimensional analysis for the discharge operating scenarios evaluated for low and high pressure. Among the most relevant data of the present, the efficiency of the process in the case of HBP is 49% and HAP is 44%, this means that it discharges at 700 bar_g and implies a 5% reduction in efficiency due to the additional requirements of compression, meanwhile the hydrogen flow rate is reduced by 8.6% due to the increase in pressure between these scenarios.

ABSTRACT

The so-called hydrogen economy has become particularly important in global and national energy policies. In this paper, a methanol generation system is proposed that uses a high temperature electrolysis process and biomass gasification unit to follow this trend. Biomass is subjected to gasification in the oxygen and steam atmosphere. Hydrogen is produced in solid-oxide electrolysis, to which heat is supplied from the reactor's cooling. As a result of gasification, synthesis gas is obtained, consisting mainly of CO_2, CO, H_2. The gas is cooled and cleaned, and the separated tars can be used for biofuels production. The heat from gas cooling is used in the electrolysis process, too. The purified gas is used for the production of methanol. The analysis aims to calculate the efficiencies of the proposed system and indicate the potential for optimization of the processes by pointing out strengths and bottlenecks. As a result, the proposed cycle consumes 14.2 kg/h biomass in the gasifier and 52.12 kW power in SOEC, contributing to 61.4 kg/h methanol generation. Accordingly, the total energy efficiency is found to be 42.16%. In addition, sensitivity analysis showed that higher target purity of methanol and lower syngas temperature could lead to more methanol production.

Keywords: Gasification, SOEC, Methanol production, Hydrogen production, Thermodynamic modelling.

INTRODUCTION

The Energy Union (EU) strategy adopted by the European Commission aims to reach net-zero greenhouse gas emissions by 2050 [1]. To do so, renewable energy sources (RES) are increasingly used, among which wind and solar are the most common. The specificity of their operation is that they deliver energy in a fluctuating manner, with a strong dependency on weather and daylight period. One of the options for wider use of RES and stable production of energy is energy storage in the form of fuels, such as hydrogen produced in the electrolysis process and potentially further converted to synthetic natural gas (SNG), methanol and others [2]. In this paper a system for production of methanol is proposed that is using high-temperature electrolysis and biomass gasification processes.

Several research has been done in this area, the most significant of which is Alzahrani and Dincer [3] in 2018. They optimized a 1 MW solid oxide electrolysis (SOE) unit from energy and exergy viewpoints to produce hydrogen. Compared to low-temperature electrolyzers, high-temperature ones have higher conversion efficiency. On the other hand, there are some disadvantages to using this kind of electrolyzer, the most significant of which is providing high-temperature steam. This novel configuration exploits an electric heater for steam generation so that several renewable energy sources can provide input electricity. Finally, they found that the highest second law efficiency would be 87.12% if stack temperature, pressure, and current density could be 1168 K, 8 MPa, and 5000 A/m^2 respectively. Daneshpour and Mehrpooya [4] integrated photovoltaic thermal (PVT) solar collector and planar cathode-supported solid oxide electrolysis cell (SOEC) for cogeneration of power and hydrogen. They validated their system by an exothermic mode which does not need an additional heater, and its efficiency reached 54% with 7458 kg/h hydrogen generation. Habibollahzade et al. [5] optimized and compared a biomass-based solid oxide fuel cell (SOFC), SOEC, and gas turbine (GT) using four gasification agents to produce power and hydrogen simultaneously. In their proposed system, the waste heat of SOFC is recovered in a GT which provides electricity for SOEC. They found that O_2 is by far the best gasification agent from both efficiency and cost perspectives. Having said that lowest emission and highest hydrogen production can be reached by using CO_2 as a gasification agent. Their optimization result showed that exergy efficiency and unit cost would be 45.25% and 16.21 $/GJ, respectively. Additionally, their proposed system's levelized emission and hydrogen generation were found to be 7.745 t/MWh and 8.561 kg/h, in turn.

According to the previous works, the integrated system proposed here has not been modelled yet. Some of its innovations can be written as follows: SOEC improvement by integration with energy & fuels production, Oxygen utilization improves SOEC, eliminating the necessity of an air separation unit (ASU), and Thermodynamic analysis of a negative carbon emission system.

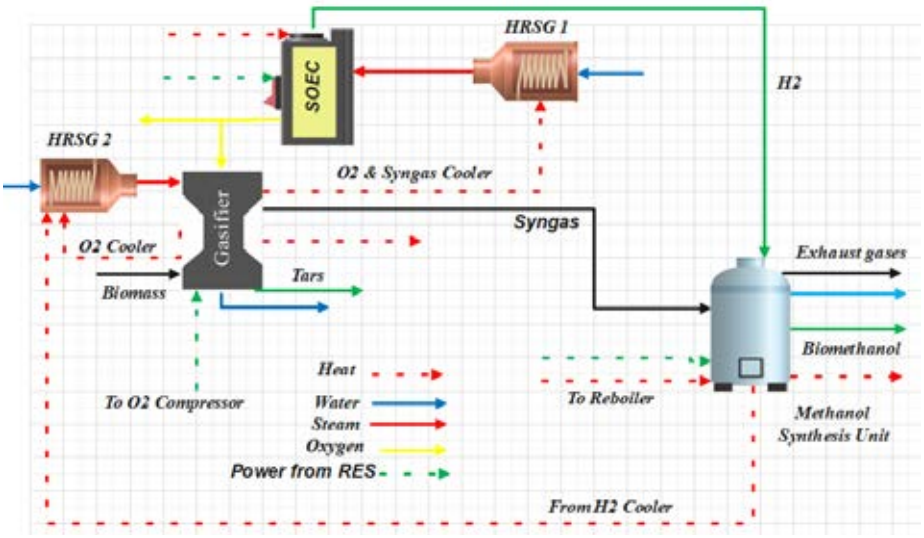

Fig. 1. Schematic diagram of the proposed system for biomethanol production.

MATERIALS AND METHODS

In the proposed system, biomass and input electricity are the prime movers aiming to generate biofuel. Specifically, oxygen from electrolyser and steam are the gasification agents allowing to produce syngas. Then, hydrogen generated in solid oxide electrolyser and syngas enter the methanol synthesis (MSU) unit to produce methanol. As shown in Fig. 1, the heat recovered from gasifier cooling is provided to SOEC. It is noteworthy that the high-temperature electrolyser is endothermic in this study, so additional heat is needed. In addition, the hydrogen and oxygen cooler provide thermal energy for heat recovery steam generator 2 (HRSG 2). All of the pinch point temperature differences are considered in these heat integrations. As the first stage of the modelling, the energy conservation or the first law of thermodynamics is considered. This rule 1st law and the mass balance of the equipment are commonly defined as follows [6]:

$$\dot{Q} - \dot{W} + \sum_{\mathrm{i}} \dot{m}_{\mathrm{i}} \left(h_{\mathrm{i}} + \frac{V_{\mathrm{i}}^2}{2} + g z_{\mathrm{i}} \right) - \sum_{\mathrm{e}} \dot{m}_{\mathrm{e}} \left(h_{\mathrm{e}} + \frac{V_{\mathrm{e}}^2}{2} + g z_{\mathrm{e}} \right) = \frac{\mathrm{dE}}{\mathrm{dt}} \quad (1)$$

$$\sum_{\mathrm{i}} \dot{m}_{\mathrm{i}} = \sum_{\mathrm{i}} \dot{m}_{\mathrm{e}} \quad (2)$$

Consequently, all the components are separately evaluated by the energy and the mass balance equations, which has been done using Aspen Plus and MATLAB software.

In order to calculate the total energy efficiency, the useful products should be divided by input energies, as shown below:

$$\eta_{\mathrm{En,tot}} = (\dot{m} \cdot LHV)_{\mathrm{Biomethanol}} \Big/ \left[(\dot{m} \cdot LHV)_{\mathrm{wood}} + \dot{W}_{\mathrm{SOEC}} + \dot{W}_{\mathrm{MSU}} + \dot{W}_{\mathrm{O2,Comp}} + \dot{Q}_{\mathrm{SOEC}} + \dot{Q}_{\mathrm{REB}} \right] \quad (3)$$

in which $\dot{m}$ and LHV refer to mass flow rate and lower heating value, in turn. Additionally, $\dot{W}_{\mathrm{O2,Comp}}$ refers to electricity consumption of oxygen compressors in the gasification unit, and $\dot{Q}_{\mathrm{REB}}$ indicates reboiler duty in the distillation column.

RESULTS AND DISCUSSION

Table 1 presents the essential properties of the designed system for methanol generation. As shown, the gasifier consumes 14.2 kg/h biomass. On the other hand, a high-temperature electrolyser uses 52.12 kW electricity and 64.99 kW thermal energy. Finally, the methanol synthesis unit consumes 3.81 kW of power, which is able to generate 61.4 kg/h methanol. In addition, there are two oxygen compressors in the gasification unit, which use 1.55 kW of electricity, and reboiler of the distillation column needs 28.08 kW of heat. As a result, the overall thermal efficiency of the cycle found to be 42.16%.

Table 1. Main specifications of the proposed cycle for methanol production.

Parameter	Unit	Result	Parameter	Unit	Result
Methanol production rate	kg/h	61.40	**Power consumption of MSU**	kW	3.81
LHV of biomethanol	kJ/kg	21011.1	**Power consumption of oxygen compressors**	kW	1.55
Biomass consumption of gasifier	kg/h	14.2	**Heat demand of SOEC**	kW	64.99
LHV of wood waste	kJ/kg	15830	**Reboiler duty**	kW	28.08
Power consumption of SOEC	kW	52.12	**Total energy efficiency**	%	42.16

Fig. 2 shows the impact of gasifier temperature on produced methanol in various target purities. This figure shows that the methanol production rate enhances by increasing the target purity of methanol. As can be seen in Fig. 2, the higher the gasifier temperature, the less methanol is generated. The reason behind that is that heat demand of the gasifier increases by enhancing its outlet temperature, so more vapour is produced in the outlet stream, which means less syngas and methanol can be generated.

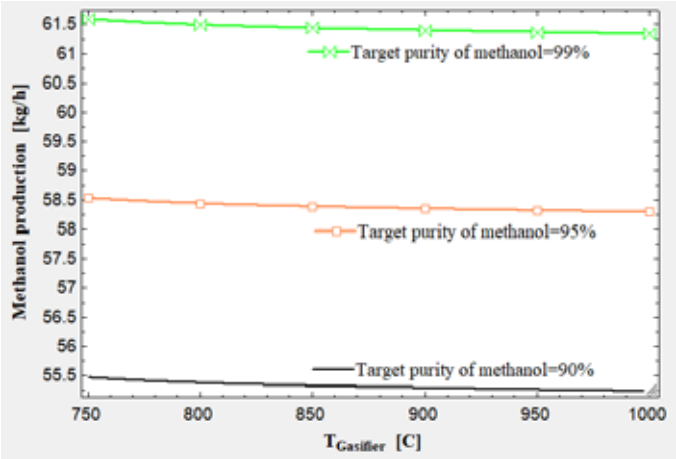

Fig. 2. The effect of gasifier temperature on methanol production rate in different target purities.

CONCLUSIONS

In the present study, a methanol synthesis unit that benefits from high temperature electrolyzer and biomass gasifier is modelled. Accordingly, it is found that the proposed cycle uses 14.2 kg/h biomass and 330 kW electricity in SOEC, leading to 61.4 kg/h methanol production. Additionally, a parametric study showed that a higher target concentration of methanol and lower gasifier temperature could cause more methanol production.

ABSTRACT

We describe a new concept in water electrolysis – a '*capillary-fed electrolysis*' (CFE) cell. In such a cell, water is supplied to the hydrogen- and oxygen-evolving electrodes by capillary-induced transport along a porous inter-electrode separator, leading to inherently *bubble-free* operation at the electrodes. An alkaline CFE cell of this type is shown to outperform commercial alkaline and PEM electrolysis cells under normal operating conditions. The CFE cell required a cell voltage of only 1.51 V, equating to 98% energy efficiency (vs the Higher Heating Value, HHV, of hydrogen), at 0.5 A cm^{-2} and 85 °C, with an energy consumption of 40.4 kWh/kg hydrogen (vs. ~47.5 kWh/kg in commercial electrolysis cells). This surpasses the target set by the *International Renewable Energy Agency* (IRENA) for 2050 to decrease the energy consumption of water electrolysis cells to <42 kWh/kg. The high energy efficiency significantly decreases the *levelized cost of the hydrogen (LCOH)* produced.

Keywords: Hydrogen, Green Hydrogen, Electrolysis

INTRODUCTION

Many nations are seeking to move towards a greener economy in which hydrogen energy storage plays a pivotal role. However, uptake is limited by the uneconomical cost of producing renewable (*'green')* hydrogen. Low-cost green hydrogen, made from water using renewable energy, will be vital to achieve *'net zero'* emissions in the global energy system. Green hydrogen is needed to decarbonise sectors that cannot use renewable electricity directly, like heavy transport, chemicals, and steel.[1] It is estimated that 15-25% of energy in a net zero global economy, worth >$1 trillion p.a., will be provided by green hydrogen by 2050.

Inspired by the historic evolution of water electrolysis cells, which recently culminated in *polymer electrolyte membrane* (PEM) cells that directly produce one of the gases in a gas collection chamber rather than bubbling through the liquid electrolyte, a *capillary-fed electrolysis* (CFE) cell concept was developed in which both gases are produced directly (Fig. 1).[1] In such a cell, the aqueous electrolyte is constantly supplied to the electrodes by a spontaneous capillary action via the porous, hydrophilic, inter-electrode separator from a reservoir at the bottom of the cell.

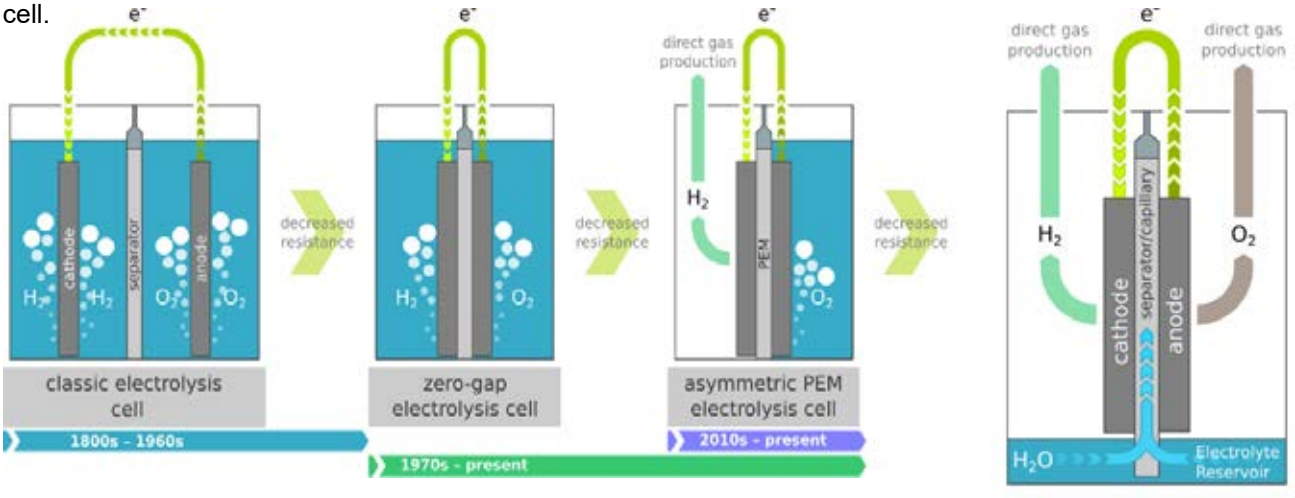

Fig. 1. Historic evolution of water electrolysis cells leading to the capillary-fed electrolysis (CFE) cell on the far right.

Porous gas diffusion electrodes are compressed against opposite sides of the separator. The electrodes draw in liquid laterally from the separator and are covered with only a thin layer of the liquid electrolyte. When a suitable voltage is applied to the electrodes, the generated H_2 and O_2 gases migrate through the thin layer of liquid on their respective electrodes, producing *bubble-free* electrolysis in which water is converted directly to the bulk gases without forming gas bubbles.

In avoiding gas bubbles 'masking' the electrodes, the liquid electrolyte maintains full access to the catalytic sites on the electrode, including the most active crevice, cleft and defect sites that are the first to be blocked by bubble formation, sometimes permanently so. The flow of water reactant to an electrode also does not counteract the flow of the gas products away from the electrode, thereby avoiding the counter multiphase flows and their associated mass transport limitations, found in conventional water electrolysers.

RESULTS AND DISCUSSION

A capillary-fed electrolysis cell with a rapidly wicking SUPOR microfiltration membrane as the separator, and employing existing, well-known NiFeOOH oxygen evolution and Pt/C (0.5 mg Pt/cm^2) hydrogen evolution electrocatalysts on fine Ni meshes, with 27% KOH electrolyte, yielded water electrolysis performance that exceeded conventional, bubbled control cells, and commercial alkaline and PEM cells (Fig. 2).[1] Faradaic efficiencies were shown to approach 100%, with low gas crossover (<0.14 vol% H_2 in the O_2 stream; 0 vol% O_2 in the H_2 stream).[1] The cell also required a less complex and less energy hungry balance-of-plant than conventional, bubbled alkaline and PEM electrolysis cells.[1]

Table 1 shows the performance of the capillary-fed cell at 85 °C.[1] At a current density of 0.5 A cm^{-2} that is commonly used by commercial alkaline electrolysis cells in operation, a cell voltage of only 1.506 V was needed to produce hydrogen (vs. ~1.77-1.79 V by commercial alkaline and PEM cells in normal operation, respectively). This represents 98% cell energy efficiency (HHV), with consumption of 40.4 kWh per kg of hydrogen produced, which is within the IRENA target for the year 2050.[1] The capillary-fed cell demonstrated sustained high and stable performance over extended periods from 1 day to 30 days continuously at 85°C and 20°C respectively, when held at a fixed voltage.[1]

Table 1. Performance at 85°C of the capillary-fed electrolysis cell with PTFE at the anode

Current density (A cm^{-2})	Cell voltage (V)	Energy efficiency (HHV) (%)	Energy consumption (kWh kg^{-1} H_2)	(kWh Nm^{-3} H_2)
0.294	1.470	100	39.4	3.55
0.500	1.506	98	40.4	3.64
0.800	1.551	95	41.6	3.75
1.000	1.575	93	42.2	3.80

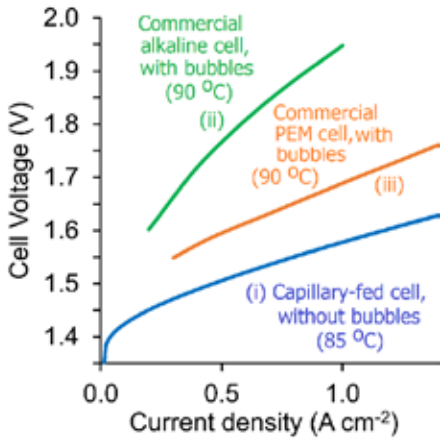

Fig. 2. V-I plots for water electrolysis by: (i) the capillary-fed cell, and a representative state-of-the-art commercial: (ii) alkaline cell, and (iii) PEM cell.[1]

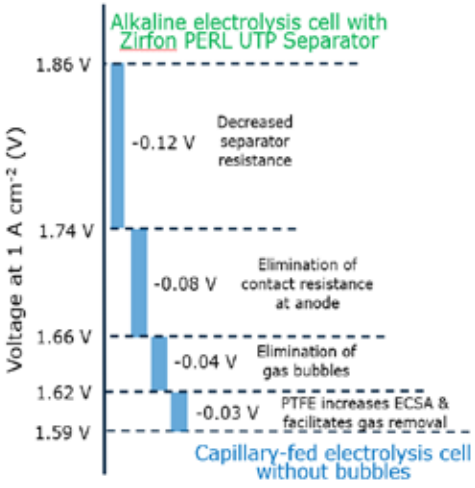

Fig. 3. Sources of the voltage decline at 1 A/cm^2 and 80 °C by the capillary-fed cell vs. a control, conventional, bubbled alkaline electrolysis cell with a Zirfon PERL UTP 500 separator and having identical electrodes and electrocatalysts. ECSA = electrochemically active surface area of the anode.[1]

Analysis of the capillary-fed cell relative to a control, conventional cell at 80 °C demonstrated that the improvement in energy efficiency did not have a single origin. Rather, there were several smaller contributions that, cumulatively, led to the observed 270 mΩ cm^2 reduction in cell resistance at 1 A cm^{-2} (with an accompanying 0.270 V decline in the voltage).

Fig. 3 schematically depicts the main contributions at 1 A cm^{-2} compared to a control, conventional alkaline cell with a standard commercial Zirfon PERL UTP 500 separator and having the same electrodes, with the same NiFeOOH and Pt/C electrocatalysts. As can be seen, the separator used in the capillary-fed cell had a 120 mΩ cm^2 lower resistance than the commercial Zirfon PERL separator, yielding a 0.120 V decline. It was also less resistive than the Nafion separators used in commercial PEM electrolysis cells, being 174 mΩ cm^2 less resistive than Nafion™ 117 and 96 mΩ cm^2 less than Nafion™ 115. Welding of the anode of the capillary-fed cell to its bipolar plate eliminated a contact resistance of 80 mΩ cm^2 (0.08 V) deriving from a poorly conductive Ni oxide layer on the Ni surfaces. Avoiding gas bubbles reduced the resistance by another 40 mΩ cm^2 (0.04 V), while incorporation of poly(tetrafluoroethyelene) (PTFE) in the anode increased its *electrochemically active surface area (ECSA)* by ~12-fold, to, potentially, ~241 cm^2 per 1 cm^2 geometric area, producing a further 40 mΩ cm^2 (0.04 V) decline.

CONCLUSIONS

This work introduced the concept of a capillary-fed electrolysis (CFE) cell and demonstrated that, using known catalysts, it significantly improved the energy efficiency of producing hydrogen from water. At an operating current density employed in commercial alkaline electrolysis cells of 0.5 A cm^{-2}, a cell voltage of only 1.506 V was needed to produce hydrogen at 85 °C. This represented a cell energy efficiency of 98% (HHV), with consumption of 40.4 kWh kg^{-1} H_2, or 3.64 kWh Nm^{-3} H_2. This result surpasses commercial electrolysis cells, which consume ~47.5 kWh kg^{-1} H_2, and exceeds the 2050 IRENA target of <42 kWh kg^{-1}.

ABSTRACT

In this study, we report on enhancing the surface area of bare copper electrodes via femtosecond laser processing for its application in alkaline water electrolysis. It is shown that the laser nanostructuring process creates unique and hierarchal nanostructures superimposed over spiky microstructures. Analysing the effect of various laser parameters indicate that scanning speed greatly effects the microstructures by decreasing its dimensions and increasing porosity. The results also shows that laser processing has significantly enhanced the surface area with spiky and superhydrophilic structures. Furthermore, this process is expected to improve the hydrogen evolution reaction (HER) kinetics by allowing more electrode to electrolyte interface, which can favor the enrichment and formation of protons on structured Cu cathode.

Keywords: Femtosecond Laser; Hydrogen Evolution Reaction; Electrode; Nanostructuring

INTRODUCTION

The electrochemical water splitting for efficient renewable hydrogen production has been considered a critical step in hydrogen economy [1]. In commercialization of low temperature electrolyzers (PEM and AEM), the primary need is to develop a highly porous electrode materials as catalyst which is economical, durable and highly active [2]. To accelerate the sluggish oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) in water electrolysis, different types of noble Platinum (Pt) alloys have been used as electrocatalyst materials which are costly and has adversely affected the electrochemical performance of electrolyzers due to its high loading effects and poor durability [3]. Under these circumstances extensive studies has been carried out to explore and develop non noble Pt less materials as an alternative option [4].

H_2 production from alkaline electrolysis is one the most efficient (I.e., conversion efficiency ≈ 80%) processes which can replace the conventional fossil fuel-based H_2 production techniques [5]. However, it comes with the highest production cost (~$4 - $6/kg H_2) which mainly comes from the use of noble metal as an electrode catalyst [6]. Nonnoble transition metal based electrodes (e.g., Ni, Ti, Cu, Co Mn, etc.) possess higher overpotentials for H_2 generation which make it inefficient (high electricity input required) [7]. Scientists have made a tremendous effort to reduce the overpotential of nonnoble metals by the formation of metal oxides (MOx), nitrides, and carbides using wet chemistry methods such as CVD, hydrothermal, and other electrochemical tuning techniques but the problem with these techniques is that they are limited to laboratory scale and comes with a lot of challenges [8].

Recently Ultrafast laser processing technology has been proved a viable technique in improving functions of solid surfaces through the creation of various microstructures through melting and ablation techniques [9]. It has been proved a useful tool in altering the optical, mechanical, and electrical properties of metals for a wide range of fields such as photonics, plasmonic [10], and energy fields [11]. Compared to etching, plasma ablation, and other surface treatments process, femtosecond laser (FS) surface processing is prompt and has higher accuracy, efficiency, controllability, and repeatability which can introduce favorable microstructures with higher physical stability and surface area. (surface area > tens fold compared to pristine) [12]. The higher surface area means more electrode to electrolyte interface and thus higher H_2 conversion output.

MATERIALS AND METHODS

Pristine Cu plates with dimensions 20×20mm area and 2mm thickness were used as cathode material for laser processing and electrochemical HER reaction in for alkaline electrolysis in1M KOH solution. All plates were washed with acetone and DI water multiple times and were dried in convection over at 80℃ overnight. An amplified high power-based laser system (model AFS-UFFL-300-2000-1030-300 from Active Fiber Systems GmbH, Jena, Germany) for surface nanostructuring (Fig. 1). The laser source delivers femtosecond laser pulses centered at 1030 nm, with 40 femtosecond duration and 50 kHz repetition rate. The laser power was controlled using a combination of a half-wave

plate (HWP) and a thin-film polarizer (TFP) to deliver single pulse energy of 200 µJ. Finally, the attenuated laser beam was focused on the Cu substrate through an F-Theta lens and a raster scanner using the scan head (FARO tech. Xtreme-20, Faro Technologies, Inc., Lake Mary, FL, USA). The focal spot diameter on the substrate was ~ 70 µm with a laser fluence of 4 J/cm^2. We selected a series of decreasing scanning speeds starting with 50, 20, 10 and 5 mm/s with a spacing width of 80 µm between two adjacent microgrooves (step size). The surface morphologies were investigated with scanning electron microscopy (SEM-EDX) (TESCAN VEGA3) SEM equipped with an EDX spectrometer (Tescan, Brno, Czechia). Water contact angle (WCA) measurement was conducted using Drop Shape Analyzer (DSA-100, KRUSS, Matthews, NC, USA). We will be performing electrochemical measurements with CHI 660 potentiostat (CH Instruments USA) in three electrodes cell setup in which Cu plates will be used as working electrode, Pt wires as counter electrode while Ag/AgCl as reference electrode.

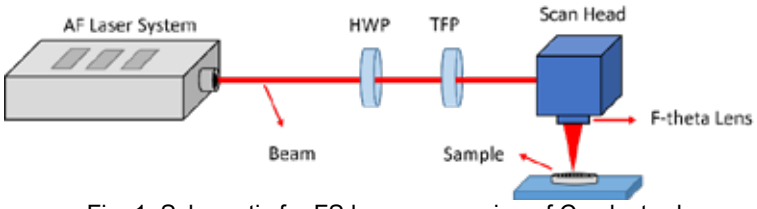

Fig. 1. Schematic for FS laser processing of Cu electrodes

RESULTS

Fig. 2 (A-D) shows the SEM micrographs of laser structured Cu electrodes with at scanning speed of 50, 20, 10 and 5 mm/s respectively. The analysis depicts that with decreasing scanning speed the morphology is significantly changing, and the microstructures are transforming from dorm shape structures towards Fig 2. (A & B) to spiky needle structures which much high surface area and porosity. There is an appearance of nanostructures superimposing over larger microstructures at low scanning speeds (Fig. 2D) along with nanoparticles which are due to the melting of Cu and rapid cooling in air. SEM analysis shows very hierarchical and reproducible structures which can be very promising in HER.

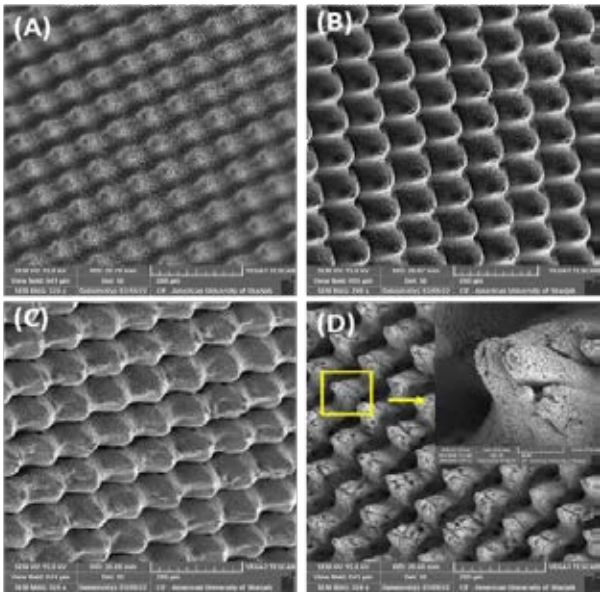

Fig. 2. SEM analysis of laser processed Cu plates with hierarchical microstructures

In order to determine the wettability of laser processed Cu electrodes (LS-Cu) we performed WCA analysis. As shown in Fig.3. the laser structured Cu electrodes surface possess superhydrophilic nature on which water drops expands immediately within fraction of second. The superhydrophilic nature along with high surface area allows more electrode to electrolyte interface thus increasing water splitting efficiency.

We are further characterizing and testing the electrochemical activity of LS-Cu electrodes for overall water splitting process in electrolysis cell which we cannot explain here due to max 3 pages limits. In case of short paper acceptance further data will be presented in conference in detail.

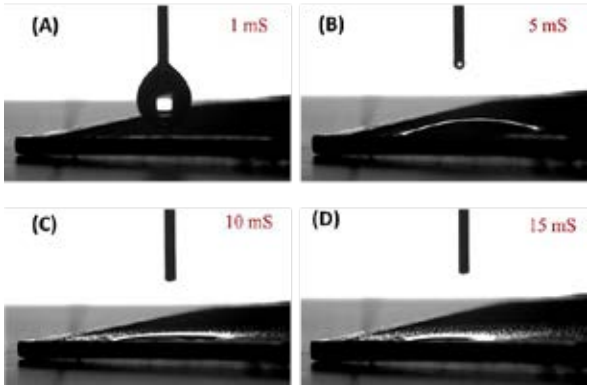

Fig. 3. WCA analysis of LS -Cu 0.5 mm/s electrode surface showing splitting of water in milliseconds (mS)

CONCLUSION

Femtosecond (FS) laser processing of nonnoble electrodes with unique surface micro/nano structures exhibits high surface area and superhydrophilicity compared to pristine plates. The nanoparticles on the top of needle shape microstructures can produces strong electric fields under negative polarization which in addition with former two surface properties favor the formation of protons and recombination of adsorbed hydrogen atoms in water splitting leading to an accelerated HER kinetics in alkaline water electrolysis.

ABSTRACT

Three-dimensional (3D) printing technology presents a higher flexible technique to produce different complex geometric shapes compared to conventional manufacturing. This technology is known as additive manufacturing (AM) may be also suitable for industrial production. AM method is widely used in different areas, including construction, medicine, energy, and electrochemistry, recently. Polymeric materials such as polylactic acid (PLA) and acrylonitrile butadiene styrene (ABS) filaments are used in the 3D printing process. In this study, the conductive polymeric anode electrodes are prepared using 3D printing method. Then, these electrodes are coated with Pt in different thicknesses (0.5, 1, 1.5, and 2µm) by the electron beam evaporation (EBM) method. A thin Cr adhesion layer (20nm) is used to improve the adhesion of the Pt coating on the sample surface. After the completion of the coating process, the polymeric electrodes are named as Pt-0.5, Pt-1, Pt-1.5, and Pt-2. Pt coated 3D printed polymeric electrodes have been physically characterized by using Field Emission Scanning Electron Microscopy (FE-SEM), FE-SEM/Energy Dispersive X-Ray Spectroscopy (FE-SEM/EDX), FE-SEM mapping, and X-Ray Powder Diffraction (XRD) techniques. Cycling Voltammetry (CV), Linear Sweep Voltammetry (LSV), Electrochemical Impedance Spectroscopy (EIS), and Chronoamperometry (CA) analysis of the Pt coated electrodes have been conducted to evaluate their electrochemical performance.

Keywords: Additive Manufacturing, 3D Printed Polymeric Electrode, Thin Film

INTRODUCTION

Today, global energy consumption and energy needs have increased due to the increasing population and lifestyle. As a secondary energy source, hydrogen is considered as one of the most promising potential solutions and energy carriers to meet the growing energy demand [1]. Electrolysis of water is one of the easy methods to produce hydrogen, and it does not emit any by-product or carbon emissions other than oxygen and hydrogen. Proton Exchange Membrane Water Electrolysis (PEMWEs), which is another promising method among water electrolysis methods, has many advantages such as high efficiency, high current density, and operation at lower temperatures [2]. PEMWEs represent a concept in a solid electrolyte. PEMWE is known as an alternative to alkaline water electrolyser, and it can be operated under high current densities. PEMWE present a sustainable solution for the generation of hydrogen and oxygen, and they can be integrated with renewable or alternative energy sources like solar and wind. The membrane electrode assembly (MEA), bipolar layers (BPs) with flow channels, gas diffusion layer (GDL), or gas diffusion electrode (GDE) are essential components of PEMWEs. Among these components, GDEs have an important place for the distribution of flow. However, adherence to desired geometries and coating thicknesses of GDEs provide a significant cost disadvantage for researchers. To eliminate or minimize the effects of this disadvantage, the development of rapid production methods in PEMWEs has an important place. AM method, also known as 3D printing among rapid production methods, has recently paved the way for rapid prototyping (faster times to market) for industrial applications. With the use of the 3D printing method, complex designs can be turned into products or material quickly and cost-effectively [3, 4]. AM technology enables to be produced lighter, cost-effective, and faster for components of PEMWEs. Interest in AM technology has greatly increased since 2014, and it has become more common for using PLA and ABS filaments in the 3D printing process [5]. To increase the electrical conductivity and corrosion resistance of 3D printed materials (such as electrodes or supercapacitors), the process of coating is one of the most promising ways [6].

In this study, 3D printed graphene-based conductive electrodes are produced from conductive PLA filament (Volume Resistivity: 0.6 ohm-cm), and samples are coated with Pt by using a EBM thin film coating method. Electrochemical properties of polymeric electrode samples for OER in acidic media have been investigated by CV, LSV, EIS, Tafel curves, and CA techniques. The surface morphology, crystallinity, and elemental composition of polymeric electrodes have been examined with FE-SEM, FE-SEM/EDX, and XRD analysis.

MATERIALS AND METHODS

Preparation of Polymeric Electrodes by 3D Printing Method

Polymeric based electrodes were designed using SolidWorks drawing software with 22.40mmx22.40mmx1.5mm (length/width/thickness) dimensions, and electrodes were prepared by the 3D printing method. An 3D printer (Ultimaker 2^{++}) (with a 0.4mm diameter extrusion nozzle) and Black Magic conductive PLA filament (available from 3D compare) were used for 3D printing the anode electrode samples. The Standard Triangle Language (*STL) file format of the electrode designs was converted into Cura 2.0 3D printing slicer program software and saved as a GCode file to start printing the designed samples. For the printing process of polymeric electrodes, the printing speed was set at the rate of 30 mm/s, and the nozzle and bed temperature were adjusted to 60 and 200°C, respectively [7]. All polymeric electrodes were printed at 100% infill and 0.1mm layer thickness. The dimensions of the designed polymeric electrodes for electrochemical measurements can be seen in Fig.1.

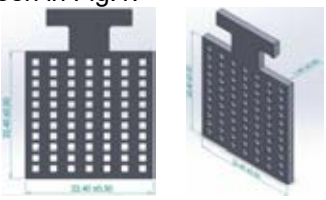

Fig. 1. Dimensions of the designed electrodes for electrochemical measurements a) front view and b) side view

Thin Film Coating of Polymeric Electrodes

Before starting the thin film coating of the electrodes, series of cleaning procedures were conducted to the electrodes. To ensure the surface of the electrode was clean, the samples were firstly immersed in ethanol for 5 minutes in an ultrasonic bath. Then, electrodes were carefully cleaned with deionized (DI) water and dried in a nitrogen (N_2) atmosphere. After the completion of the cleaning process of the polymeric electrodes, the samples were coated with different thicknesses (0.5, 1, 1.5, and 2µm) of Pt using the electron beam evaporation method [8, 9]. A thin Cr adhesion layer (20nm) is used for better adhesion of Pt film coating. Thin films prepared via the electron beam evaporation technique at different film thicknesses were denoted as Pt-0.5, Pt-1, Pt-1.5, and Pt-2. The schematic view of the thin film coating of the electrodes is given in Fig. 2.

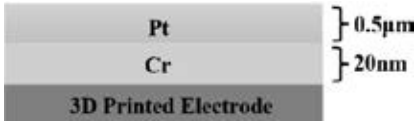

Fig. 2. Thin film coating process of polymeric electrodes

Determination of Electrochemical and Surface Properties of Polymeric Electrodes

The surface morphologies and elemental analysis of the polymeric electrodes were analyzed by using FE-SEM and FE-SEM/EDX techniques, respectively. The crystalline and phase structure of samples was investigated by using XRD analysis. Electrochemical properties of polymeric electrodes were investigated using CV, LSV, EIS, and CA analysis. All the electrochemical measurements were carried out in 0.5M H_2SO_4 solution using Pt wire as the counter electrode, Ag/AgCl (3M KCl saturated) was used as a reference electrode and polymeric electrode was used as the working electrode [10]. Fig. 3. shows three-electrode electrochemical cell configurations for electrochemical analysis.

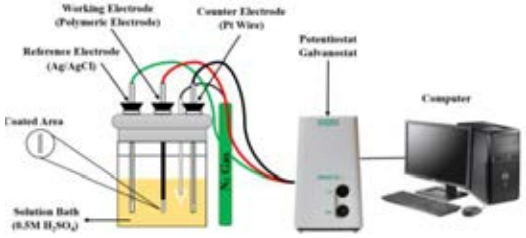

Fig. 3. The three-electrode electrochemical cell configuration

CONCLUSIONS

In this study, polymeric electrodes are prepared by the 3D printing method, and then the electrodes are coated with a thin film method. According to the electrochemical analysis measurements, an increase in the corrosion resistance of the polymeric electrodes is expected with the increase of the coating thickness in thin film coatings. Thanks to Cr

interlayer, adhesion performance of the Pt is enhanced. In addition, due to high conductivity of the Pt metal, contact resistance of the electrodes are improved.

ABSTRACT
Using the first principle calculations, we studied the hydrogen evolution reaction (HER) activity of pristine Biphenylene (BPh) and B, N, P decorated BPh sheet. HER activity of BPh sheet is not encouraging, it is similar to pristine graphene. However, doping of P on top of one carbon atom of the BPh sheet improves its activity better than Pt-catalysts. We analyzed the adsorption mechanism of dopants (B, N, P) and hydrogen adsorption with Bader charge analysis and density of states (DOS) analysis. We have compared all our best HER activity results in the reaction coordinate and volcano plots of pristine, B, N, P-doped BPh sheets, and they indicate that P doped BPh is a powerful catalyst for HER activities.
Keywords: Hydrogen production, HER, Biphenylene, first principle calculation

INTRODUCTION
To fulfill the energy demands while keeping a pollution-free environment requires alternative resources, independent of fossils fuels. A high energy density of 143MJ/kg [1], abundant in composite form, and pollution-free utilization make hydrogen energy a promising fuel. However, ~ 96% of total produced H_2 is produced using fossil fuels through the steam reforming process [2]. Expensive Pt groups metal (Pt, Pd, Ru, Ir, and Rh) are employed in electrolysis to produce the remaining ~ 4% hydrogen. Hence, searching for cost-effective and pollution-free catalysts is of utmost importance. A new allotrope of carbon, 2D Biphenylene (BPh), is synthesized [3] recently and found to be mechanically robust and stable up to 4500K [4]. In this work, we have studied the HER activity of pristine BPh, and B, N, P-decoration on it in many different configurations. We found that Gibbs free energy ΔG^{H^*} of P-decorated Biphenyle 0.02 eV surpassed Pt-catalyst (ΔG^{H^*}=0.09) and analyzed the DOS and Bader's charge transfer for binding mechanism. All our results are compared with each other in the reaction coordinate and volcano plots.

COMPUTATIONAL METHODS
All the simulations are performed using plane wave density functional theory code VASP [5,6] with Perdew-Burke-Ernzerhof pseudopotential. Electronic configuration of $2s^22p^2$, 1s, $2s^22p^1$, $2s^22p^3$, $3s^23p^3$ were considered for C, H, B, N, P respectively. The kinetic energy cutoff and kpoints are selected in well converged ranges, which are 500eV and 7x7x1, respectively. Monkhrost special points were employed to integrate on Brillouin zone. The 2x2x1 supercell of Biphenylene sheet has been utilized with lattice constants a=9.03Å, b=7.51Å, and vacuum 10.5Å in the perpendicular direction to the sheet. For self-consistent DFT iterations and structural relaxation, energy convergence and Feymann-Hellman forces' convergence criteria are 10^{-5}eV and 10^{-2} eV/A, respectively.

BPh+N+H	**ΔG**	-2.23	-0.30	-1.40	-1.48	-0.55	-1.56	0.89	-1.40	-1.38
BPh+P+H	**ΔG**	-0.82	0.02	-1.09	-0.78	-0.42	-0.60	1.23	-1.21	-0.79

Table 3. Bader charge analysis on adsorption of H on BPh+P

	@A1	@A2	@B1	@B2	@B3	@B4	@C1	@C2	@C3
Charge gained by P	-0.37	-0.06	-0.24	-0.37	-0.31	-0.30	0.18	0.41	-0.38
Charge gained by H	0.36	0.36	0.35	0.41	0.41	0.37	0.44	0.40	0.36

RESULT AND DISCUSSION

We start with optimizing the structure of BPh and comparing their structural parameters like lattice parameter, bond-length, bond-angle, etc., with the previous literature [5,6]. We doped hydrogen atoms at several possible positions at 2Å away from the BPh sheet in different configurations, as shown in Fig. 1(a). After optimization, pristine BPh shows HER properties similar to graphene, except A1 and B4 positions. The adsorption energy, Gibbs free, the distance between H to the nearest C atom, are presented in table 1. The following equation is used to compute Gibbs free energy [7],

$$\Delta G^{H^*} = E_{ad} + 0.24 \quad (1)$$

where E_{ad} = E(H+system)–E(system)–0.5*E(H_2). Using eq^n (1), exchange current density can be calculated [7] by

$$I_0 = -ek_0(1+\exp(|\Delta G^{H^*}|/k_B T))^{-1} \quad (2)$$

Where k_0=1 (theoretical values) and T=300K.

From Table 1, we can see that BPh+H@A1 and BPH+H@B4 have small Gibbs free energy 0.31 eV. To improve HER activity, we consider doping external adatom D (where D=B, N, P) on BPh. The binding strength of dopant D and their distance to the nearest carbon atom are presented in table 2. B, N, P are bonded with the BPh sheet

more strongly through charge transfer. From Bader charge analysis, for BPh+P(@A2), P donate 0.5e to the BPh sheet. The same can be concluded from the partial density of states in Fig. 2(a), which shows that after decoration of P atom on BPh sheet, the states near Fermi level reduce significantly. BPh is non-magnetic (not shown here). However, on doping P atom, the density of stated becomes unsymmetric as in Fig. 2(c) because of 0.5e charge gain from P atom. After finding that adatom D binds strongly with the BPh sheet, we proceed with the adsorption of the H atom. After optimization, the results are presented in Table 3. The optimized structure of BPh+P+H(@A2) is plotted in Fig. 1(b). From the Gibbs energy analysis, we find that B doping is worsening the result. N doping barely improves the results, and P doping drastically improves HER activity which surpasses ΔG^{H^*} = 0.02 eV Pt catalyst (0.09 eV). From Bader charge analysis, we found that in optimized BPh+P+H(@A2), P and H gain -0.06e and 0.36e amount of charges. Table 4 shows that except BPh+P+H@A2, in all other configurations, the amount of lost/gained charge is more, resulting in strong bonding between P-H and hence higher ΔG^{H^*}. The same is verified using the partial density of states (Not plotted here). Also, from the total density of states profile, we observed that adsorption of H atom makes the whole system BPh+P+H non-magnetic. The small amount of charge transfer from P in the adsorption process of H might be leading to good values of binding energy, i.e., neither strong nor weak. All our best results are plotted in the reaction coordinate Fig 1. (c) and found exchange currents computing using eq^n (2) and the relation between ΔG^{H^*} and i_0 are shown in volcano plots Fig 1(d).

CONCLUSION

Using DFT calculation, we predicted that HER activities of biphenylene are mostly inactive, but its decoration with the P atom improves the result (ΔG^{H^*}=0.02eV) significantly, surpassing Pt-catalyst (ΔG^{H^*}=0.09 eV). From the reaction coordinate plots and volcano plots, we conclude that P-doped BPh is a promising catalyst for HER activity.

ACKNOWLEDGMENT

Mukesh Singh would like to express his special thanks to CSIR for funding his Ph.D. research projects and Spacetime High-Performance computing at IITB for resources.

IRIDIUM-RUTHENIUM CATALYST ON SPUTTER-ETCHED MEMBRANE FOR PROTON EXCHANGE MEMBRANE WATER ELECTROLYZERS

[1] Tomáš Hrbek, [1]Peter Kúš, [1]Vladimír Matolín, [1]Iva Matolínová*

ABSTRACT

We present an iridium-ruthenium-based catalyst (25 % Ir, 75 % Ru) for Proton Exchange Water Electrolyzers (PEM-WE) with low iridium loading (158 μg cm^{-2}), prepared by magnetron sputtering. We use no additional support for the PEM-WE's anode. The sputter-etching of the PEM replaces them – its simultaneous plasma and deposition of a cerium oxide layer during reactive magnetron sputtering leads to a pronounced fiber-like structure on its surface. The prepared catalyst is tested for 1272 hours in a single-cell PEM-WE, demonstrating excellent activity and stability. We focus on stability, which is the crux of a low-iridium-loading catalyst. We search for its origin through several electrochemical and surface analysis methods – Potential Electrochemical Impedance Spectroscopy, Energy X-Ray spectroscopy, X-ray Photoelectron Spectroscopy, and Scanning Electron Microscopy.

Keywords: magnetron sputtering, PEM-WE, lateral conductivity, iridium-ruthenium

INTRODUCTION

The ever-increasing energy demands of modern society and the nearly unanimous commitment to limiting global warming by lowering greenhouse gas emissions through renewable energy sources lead to a significant transformation of the worldwide energy and transportation sector [1]. Hydrogen Economy is built around the electrochemical "power-to-gas" conversion of electricity into H_2 through the process of electrolysis in times of energy overproduction and subsequent use of generated hydrogen in various ways. The key technology of the Hydrogen Economy is Proton Exchange Membrane Water Electrolyzer (PEM-WE) – a device that uses electrical power to drive electrochemical water splitting into hydrogen and oxygen utilizing a proton conductive membrane [2]. Nonetheless, the principal drawback of PEM-WEs that is becoming increasingly problematic as more significant numbers of units and installations appear worldwide is their dependence on noble metals essential for catalyzing the individual redox reactions in the cells. Specifically, it is platinum (1000 USD/oz) on the cathode of PEM-WE and iridium (5100 USD/oz) on the anode of PEM-WE [3], where iridium presents the problematic part due to the sluggish anodic Oxygen Evolution Reaction. Massive research is being conducted on the problematics of low- or zero- iridium catalysts for the anode [4–7], using several different approaches. This work presents a magnetron-sputtered, iridium-ruthenium-based catalyst for PEM-WE, which utilizes our two previous works: An iridium-ruthenium-based catalyst (25 % of iridium and 75 % of ruthenium), and a sputter-etching modification of PEM [6], which allows increasing the active surface area significantly. We present a study of this catalyst's activity and stability and explain why this PEM-WE is so stable compared to a similar PEM-WE with the same amount of Ir and without Ru.

EXPERIMENTAL

Sputter-etched structures were created on a Nafion PEM membrane (50.8 μm thick, Chemours) via a sputter-etching procedure as described in [6]. The modified membrane was covered by the investigated catalytical layers – pure iridium (70 nm) and mixed iridium-ruthenium (280 nm, 25 % of Ir). The layers were used for the assembly of PEM-WEs, the former called MEA Ir 100, the latter MEA Ir-Ru 25:75. As a liquid gas diffusion layer (LGDL) for the anode, a micro-grained sintered porous Ti (Mott) with a 50 nm protection layer of platinum was used. The commercial platinum catalyst supported by carbon (Pt 0.5 mg cm^{-2}, FuelCellStore) was used as a cathode gas diffusion electrode (GDE). Prepared MEAs were then pressed between an anodic current collector (made of Ti) and a cathodic current collector (made of carbon). Titanium was chosen as a material for the anode side due to its corrosion resistance. The PEM-WE performance was tested by the BioLogic SP-150 Potentiostat. The single cell operating temperature was 80 °C. For all measured samples, surface morphology was routinely checked by a Tescan MIRA III Scanning Electron Microscope (SEM) before and after the electrochemical procedure to follow possible morphological changes. A Quantax EDX detector (Bruker), installed within the MIRA III SEM, was used to estimate the bulk composition of the measured samples. XPS setup (K_α Mg X-ray source, 1253.6 eV) was used to unravel the surface chemical composition. A SPECS Phoibos 150 hemispherical analyzer made spectra acquisition in FAT (Fixed Analyzer Transmission) mode. The number of scans was individually set for each measured element to attenuate the noise. The charging effect was determined by the detailed measurements of the Fermi edge and compensated accordingly. Fitting of the obtained spectra was done by KolXPD software.

RESULTS AND DISCUSSION

The samples (MEA Ir-Ru 25:75 and MEA Ir 100) were investigated in long-term stability in a PEM-WE. The results can be seen in Figure 1. Immediately, it stands out that MEA Ir-Ru 25:75 shows a better performance than MEA Ir 100. The better activity can be easily explained by the improved activity of the iridium-ruthenium catalyst, which is known [8–10]. However, also much better stability is observed. That contradicts the standard belief that an iridium-ruthenium-based catalyst is always less stable than the iridium one. By various surface and electrochemical analytical techniques, we concluded that the origin of the instability of MEA Ir 100 is its insufficient layer thickness which leads to a decreased lateral conductivity with time.

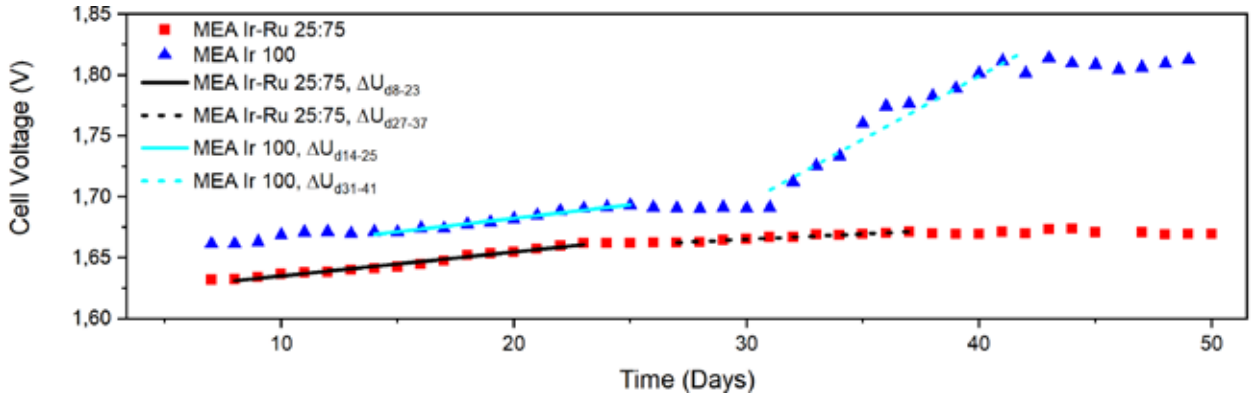

Figure 1. The long stability of MEA Ir 100 and MEA Ir-Ru 25:75. Linear regression fits the linear parts of the degradation curve.

CONCLUSIONS

Magnetron sputtering can be utilized for the preparation of a low-iridium-loading PEM-WE with good activity and stability without any additional supports. We concluded that the biggest issue of the catalysts with extremely low iridium loading is the lateral conductivity which decreases as the operation of the PEM-WE proceeds. A possible solution is to utilize magnetron sputtering of an iridium-ruthenium mixed catalyst. This approach has advantages: magnetron sputtering allows us to create a homogeneous and interconnected thin film. Secondly, the cheaper ruthenium enhances the catalysts activity and the thickness of the layer, which leads to better electrochemical performance.

ABSTRACT

In this study, energy, exergy and sustainability analyses are performed for a solar energy-based hydrogen production system, which is modeled with TRNSYS and Engineering Equation Solver (EES) software packages. This system consists of solar photovoltaic panels (PVs), a controller, an electrolyzer, a metal hydride hydrogen tank used for hydrogen production and storage, and Proton Exchange Membrane Fuel Cell (PEMFC) for electricity storage. Dead state temperature is taken as 0 ºC. The results revealed that the PEMFC had the highest energy efficiency of 53.28%. Exergy efficiencies of the solar PV panel, the electrolyzer and the PEMFC were determined to be 9.66%, 60% and 29.39%, respectively. The exergetic sustainability index of the electrolyzer had the maximum value of 2.501.

Keywords: Exergy, Hydrogen Production, Electrolyzer, Efficiency, Solar Energy

INTRODUCTION

Hydrogen is considered to be the clean energy fuel of the future. Many attempts have been made for producing hydrogen in recent years using various technologies. Among the hydrogen production methods adopted in the world, 95% of hydrogen production belongs to stream reforming. Hydrogen production from fossil fuels causes increasing greenhouse gas emissions. For this reason, it is very essential for finding economic and environmentally friendly hydrogen production processes [1]. Solar energy based-hydrogen production techniques seem to be simpler and more convenient than other methods due to the sustainability and availability of the solar energy [2]. As far as some studies on solar-based multigeneration systems are concerned, Ozturk and Dincer [3] proposed a solar-based multi-generation system consisting of four main sub-systems, namely (i) Rankine cycle, (ii) organic Rankine cycle, (iii) absorption cooling and heating, and (iv) hydrogen production and utilization. The outputs were power, heating, cooling, hot water, hydrogen and oxygen. The energy and exergy efficiency values of the system were calculated to be 52.71% and 57.35%, respectively. Almahdi et al [4] proposed a novel solar thermal energy based multigeneration system and assessed its performance through energy and exergy analysis methods. They reported that the overall energy and exergy efficiencies were 20.7% and 13.7%, respectively. Tukenmez et al [5] proposed and analyzed both energetically and exergetically a solar energy supported plant with outputs of hydrogen, electricity, heating, cooling and hot water. Energetic and exergetic efficiencies of the solar power based combined cycle were reported to be 56.48% and 54.06%, respectively. The main objective of this study is to assess the performance of a solar energy-based hydrogen production system using energy and exergy analysis methods.

MODELING AND ANALYSIS

The considered system is modeled with TRNSYS, as shown in Fig. 1. Main power supply of the system is the solar photovoltaic panel (PV). In order to arrange voltage and current, a controller was used for the system. Electrolyzer and fuel cell are chosen for the continuity and storage of hydrogen production. For evaluating the performance of the system, energy and exergy analysis were performed while sustainable index calculations were also made to provide estimates on how to increase the benefits of the system.

The energy, exergy and sustainability analysis relations are given below [6-8]:

Energy Analysis

The energy balance of the solar PV is given as follows [6].

$$\bar{S}A_S = V_S I_S + \dot{E}n_{S,loss} \quad (1)$$

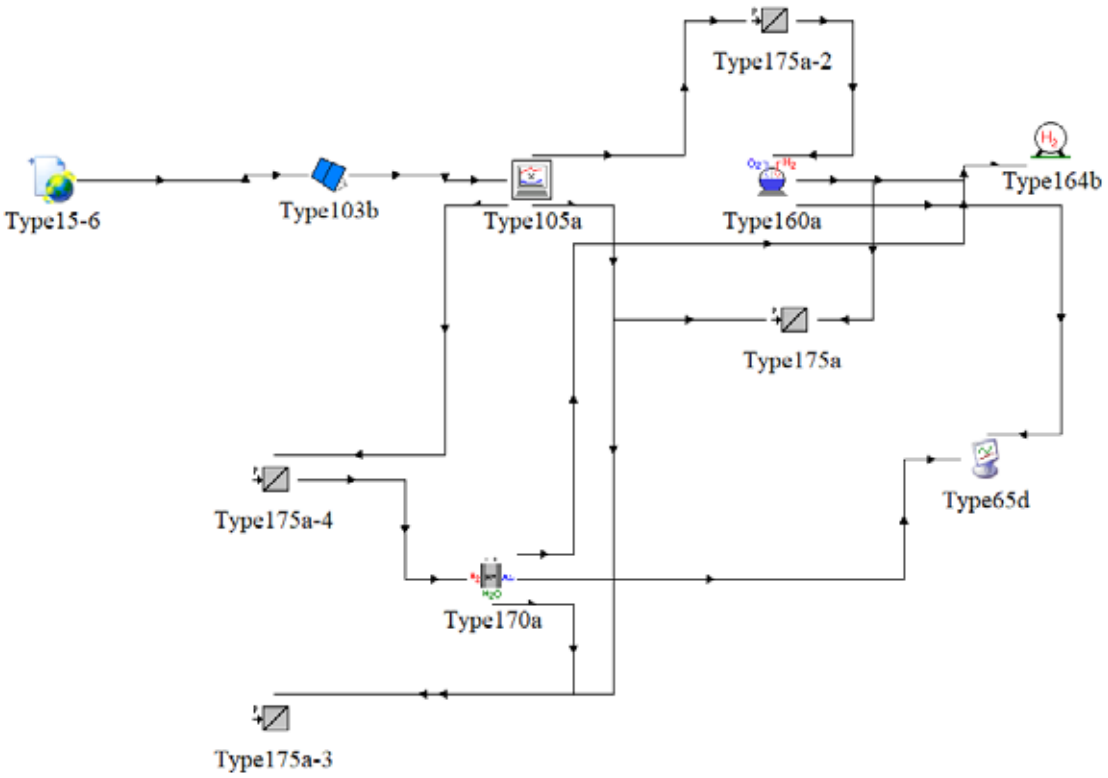

Fig. 1. TRNSYS scheme of the system

The energy balance of the electrolyzer is given by [7]

$$V_{El}I_{El} = \dot{m}_{El,H_2}(LHV)_{H_2} + \dot{E}n_{El,loss} \quad (2)$$

The energy balance of the PEMFC is written as [7]

$$\dot{m}_{FC,H_2}(LHV)_{H_2} = V_{FC}I_{FC} + \dot{E}n_{FC,loss} \quad (3)$$

Exergy Analysis

The exergy balance of the solar PV panel is as follows [6]

$$\bar{S}A_S\left[1 - \frac{4}{3}\left(\frac{T_0}{T_{sun}}\right) + \frac{1}{3}\left(\frac{T_0}{T_{sun}}\right)^4\right] = V_{S,m}I_{S,m} + \dot{Q}_{S,loss,HT}\left(1 - \frac{T_0}{T_{s,panel}}\right) \quad (4)$$

The exergy balance of the electrolyzer is given below [7]

$$V_{El}I_{El} = \dot{m}_{El,H_2}(ex_{ph} + ex_{ch})_{H_2,el} + \dot{E}x_{El,dest} \quad (5)$$

The exergy balance of the PEMFC is obtained from [6]

$$\dot{m}_{FC,H_2}(ex_{ph} + ex_{ch})_{H_2,FC} = V_{FC}I_{FC} + \dot{E}x_{FC,dest} \quad (6)$$

Sustainability Analysis

ψ is the exergetic efficiency. Thus, the sustainability index (SI) is given by [8]

$$SI = \frac{1}{1-\psi} \quad (7)$$

Relative Irreversibility (RI) is directly related to the exergy destruction of the components of the system, as indicated below [8]:

$$RI = \frac{\dot{E}x_{dest,in}}{\dot{E}x_{dest,all}} \quad (8)$$

RESULTS AND DISCUSSION

The energy and exergy analyses of the system along with its components, such as solar PV panel, electrolyzer and PEMFC, were done. Fig. 2 illustrates the energy and exergy efficiency comparison. As seen from the figure, exergy efficiency of the electrolyzer has the maximum value with 60%. The energy efficiency of the PEMFC appears to be higher than the exergy efficiency while the exergy efficiency of the electrolyzer is higher than the energy efficiency. Due to the low energy and exergy efficiencies of the solar PV and the highest exergy destruction rate of 101.688 W, the overall efficiency of the system was also low. Overall exergy destruction rate was calculated as 153.481 W. The SI rates of the components of the system are nearly same in the considered dead state temperature.

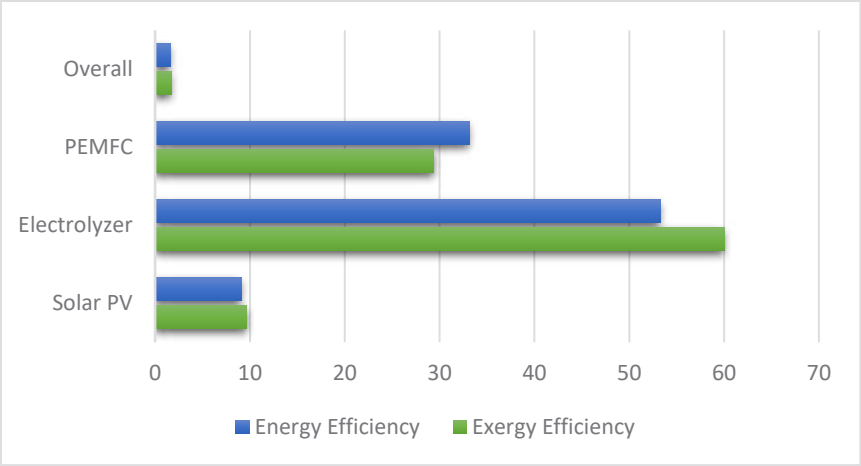

Fig. 2. Efficiency comparison

CONCLUSIONS

Since only solar PVs were chosen as the energy source for the system, the overall energy and exergy efficiencies of the system were determined to be close to each other. Although solar PV is a clean renewable energy source, its exergy destruction value is very high while its exergy efficiency is low. The solar PVs had the highest RI value with 0.66 at the dead state temperature considered.

ABSTRACT

Hydrogen production from water electrolysis has been a topic of keen interest for the research community. Although an exponential growth in water electrolysis was observed, conducting quantitative analysis of literature is still a novelty. Therefore, authors took an initiative to use bibliographic and content analysis techniques to quantitatively analyze literature published on this topic during last 50 years indexed in Web of Science (WoS). A total of 9,277 published articles were extracted from WoS and were analyzed. Further, research evolution and recent hot topics of this field were also highlighted using the content analysis technique. Results shows that more than half of the literature on this topic was published during last fiver years (2017-2021). China followed by USA and Germany are the main research hubs of this field. Furthermore, performance enhancement of hydrogen production from electrolysis by using nanoparticles, nanosheets and nanoarrays are the hot topics of the filed. To pave path of electrolysis to industrial sector, techno-economic analysis is becoming a pivot to research community.

Keywords: Hydrogen, Electrolysis, Research trends, Bibliometric

INTRODUCTION

Due to enormous consumption of energy, which usually stem from non-renewable fossil fuels, world's natural energy resources are depleting [1]. Further, use of these fossil fuels is also a sign of ecological issues such as climate change, emission of pollutant gases, and waste production [2]. Despite these detrimental impacts, around 80% of the world's energy demand is fulfilled by non-renewable energy such as coal, natural gas and oil [3]. Therefore, sustainable, safe, salient and effective approaches needs be to use to meet world's energy demands and avoid exhaustion of non-renewable energy resources and climate change. In this regards, renewable energy resources have got much attention as a clean and green source of energy that can be integrated with existing systems to meet growing energy demands. Intermittent nature of renewable energy resources give rise to a lot of challenges [4]. An electric system powered by renewable energy resources lead to new challenges regarding consumption and storage of extra energy, operation of system, proper management of distributed generation, and incorporation of such energy with automotive sector which are based on electric vehicles. To meet these challenges hydrogen technologies can used which can contribute to the development of clean energy systems [5]. Hydrogen has unique characteristics like light weight, broad inflammability range and higher heating value [5]. Many hydrogen production technologies can be utilized to produce hydrogen, such technologies are thermal, electrolytic and photolytic; the later one uses sunlight to split water via electrochemical and biological materials; while, renewable liquid, coal gasification, and natural gas reforming comes in thermal process technology. Electrolysis of water can also be used to produced pure hydrogen. Using electrolysis technique, many resources can be used to produce hydrogen such natural gas, biomass, nuclear, coal, solar, hydroelectric, wind or geothermal energy.

In the recent years, a steady growth in the hydrogen literature has been observed due to unique characteristics of hydrogen. Hydrogen is being considered a potential fuel of future that has potential to revolutionize the energy sector. Despite this growth in the field, to the best of the authors knowledge, there is no study in the literature that quantitatively evaluates water electrolysis-based hydrogen production. Conducting quantitative analysis has been widely used in other fields of research such as medicine [6], climate change[7], food security [8] and many more. However, there is a gap in the literature to conducting a quantitative literature analysis of hydrogen production from water electrolysis. Authors have attempted to fill this gap by employing two techniques of quantitative literature analysis (bibliographic and content analysis) to map the field of hydrogen production from water electrolysis.

MATERIALS AND METHODS

One of the most authentic and reliable journal databases for searching relevant literature is Web of Sciences. It publishes an excellent quality novel and well-organized research from various disciplines. For this study, relevant keywords, titles, and abstracts were used to extract data from WoS. Data accumulated in the form of research articles,

review articles, letters, books, and book chapters, counted to 10,119 records. The staked data were further refined to make sure the correctness of the bibliometric analysis by excluding records lacking critical info such publication year, author keywords etc. Moreover, articles which were far from the scope of the relevant topic were also excluded manually by observing titles, keywords, abstracts. At the end, 9277 number of to the point or articles which covered the scope of the topic were recognized and exploited for bibliographic analysis. To analysis bibliometric analysis in this study, VOSViewer, Biblioshiny and HistCite software were used.

RESULTS AND DISCUSSION

Publication record

An increasing attention of research towards this topic was observed as represented by increasing number of publications each year. Last five years has been a golden time for the development of this topic as about 59% of total entities were published in last five years. Overall, an exponential growth was observed and it is forested that by 2030 cumulative publication count may reach 23,380 if literature keeps growing at the same rate. Last five decades of this field can be divided into two eras: the introductory era and the development era. In this case, 1972-90 can be referred as introductory era of this field. The very first articles introducing this concept of hydrogen generation by electrolysis were spotted in 1972 [9] and 1973 [10]. Surprisingly, the very first patent was filed in 1982 in USA by POMPEO GARUTI OF ITALY [10]. After this, on average, two articles were published each year until 1990. The major concepts introduced in this era were hydrogen production by solid polymer electrolyte fuel-cell, fusion reactor, alkaline water electrolysis, photovoltaic electrolysis and static feed water electrolysis. Further, hydrogen energy storage, temperature-dependent electrolysis behavior and hydrogen absorption were also introduced in the same era. In development era (1991-2021), the field got matured and an exponential growth was observed in the literature. Various topics were emerged as detailed in section Major research themes.

Major research themes

To find out major research themes in electrolysis research for hydrogen production, keywords analysis was performed. In this analysis, title and abstract of the articles are scanned and most frequent keywords are collected for analysis. In present case, a total of 13, 673 keywords were found out of which only 1.68% appeared more than 15 times and were selected for analysis, see Fig. 1. In Fig. 1, the size of the circle depicts frequency of the keyword and the thickness of the line joining two keywords shows their cooccurrence. Therefore, a bigger circle means higher frequency of apparency of a keyword and thicker line means higher cooccurrence frequency. There are eight different colors in Fig. 1, each depicting a different cluster. Cluster 1 corelates hydrogen production with renewable energy sources and thermodynamic modeling. It was observed that researchers have been active to find environmentally friendly methods of hydrogen production and ensure there is minimum carbon foot print of these technologies. Therefore, using renewable resources as a source of clean energy appeared among top frequent keywords of this field. Among different renewable energy sources, solar energy appears to be widely discussed in conjunction with hydrogen production from electrolysis followed by biomass, wind and geothermal energy. To bring renewable energy-based water electrolysis system to the industrial sector, economic perspective has been a topic of keen interest. To improve economy, researchers have made attempts to optimize system by adopting thermodynamic modeling, life cycle assessment and exergo-economic analysis. Cluster 2 and Clsuter4 sheds light on hydrogen evolution reaction and mainly highlights the significance of catalysts in this process. Although there are two routes of such electrolysis i.e., acidic and alkaline, latter is widely discussed by research community. Developing catalysts for hydrogen evolution reaction has been talk of the town and researchers tested many catalysts for this process. Use of metal organic frame works, nickel phosphide, cobalt, cobalt oxide, Ni foam, graphene, cobalt phosphide, nanoparticles, nanosheets, and nanowires appears among some famous catalysts used by researchers. Cluster 3 provides information about different bio-electrochemical systems used for hydrogen production from water electrolysis. Microbial electrolysis cell and Microbial fuel cell are the examples of such systems that have got enormous attention from research community. In such systems, microbes are used to produce electricity and then this green electricity is used for electrolysis process. This process benefits over others as wastewater is also treated simultaneously making bio-electrochemical process a promising future technology. However, this topic is still in development phase and some challenges spotted are low current density, costly electrode materials and membranes. Cluster 5 and Cluster 6 is all about different membranes used in electrolysis process. Two most widely discussed fuel cells for hydrogen production from water electrolysis are Proton Exchange Membrane Fuel Cell and Solid Oxide Fuel Cell. Membrane development to reduce cost of these fuel cells is a hot topic of last decade. Mass transfer enhancement, material stability and optimal membrane-electrode assembly some widely discussed challenged of this field. Cluster 7 sheds light on photocatalytic electrolysis and solar fuels development. This is one of the cleanest processes to produce hydrogen as it demands only three components water, photoenergy and a catalyst. Although it is a much promising technology, commercialization is still a challenge. In Cluster 8, seawater electrolysis is discussed which has got enormous attention in last century. Using seawater through various means such as desalination for drinking,

agricultural and industrial purposes has been a focal point for years, nevertheless, utilizing sea water for hydrogen production is a much promising technology that has potential to revolutionize future.

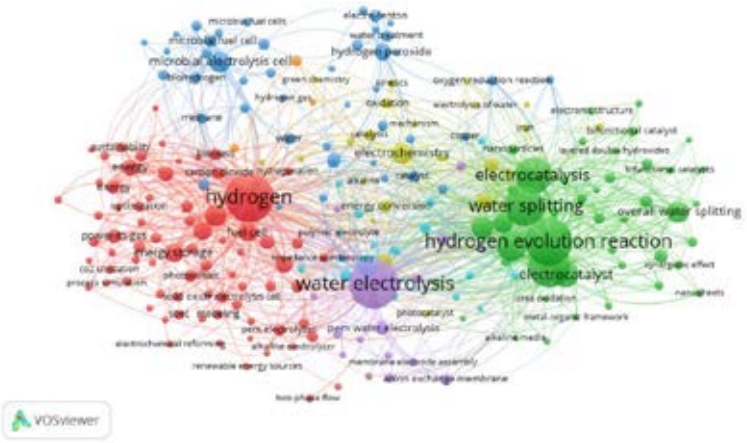

Fig. 1: Major research themes in hydrogen production from water electrolysis

CONCLUSIONS

A quantitative literature analysis of hydrogen production by water electrolysis was performed using Web of Science database. About 9,277 articles published during last five decades were analyzed using bibliographic analysis and content analysis. The analysis reveals that in the early twenty years (1970-90), on an average two articles per year were published whereas in the later years exponential growth was observed. During last five years about 60% of the total literature was published. Using content analysis, eight clusters of most frequent keywords were analyzed. The analysis reveals that electrocatalyst has been a topic of keen interest throughout 50 years of this topic followed by electrodeposition and integration with renewable energy sources. Further, it is reveled that performance enhancement of hydrogen production is a key challenge to the field. To cope with it, researchers have been recently using nanoparticles, nanosheets and nano arrays. The quest of developing an efficient and stable electrocatalysts is still a hot topic. Attempts to commercialise hydrogen production from water electrolyses is also talk of the town and researcher are using techno-economic analysis as a tool to study commercialisation feasibility.

ABSTRACT

Proton exchange membrane (PEM) water electrolyzer (PEMWE) is used to obtain a high amount of hydrogen cleanly from water. However, to make PEMWE common in everyday life, their cost must be reduced, and the performance of these systems must be increased. Thus, alternative materials should be developed to obtain low-cost PEMWE systems. In this study, stainless steel 316L (SS316L) is used as gas diffusion electrode (GDE) materials. The selective laser melting (SLM) method is selected to produce the SS316L electrode. To enhance to SS316L electrodes' corrosion resistance and kinetic activity, SS316L electrodes are coated with Pt different thickness values using electron beam evaporation method (EBM) with a Cr interlayer film. Electrochemical properties of SS316L electrodes have been investigated by cyclic voltammetry (CV), linear sweep voltammetry (LSV), and electrochemical impedance spectroscopy (EIS) techniques. Durability of SS316L electrodes have been conducted by Tafel and chronoamperometry (CA) techniques. The surface morphologies of SS316L electrodes have been characterized by field emission scanning electron microscopy (FE-SEM), energy dispersive X-ray analysis (EDX), X-ray diffractometers (XRD), and X-ray fluorescence (XRF) analysis. As a result, electrochemical performance, kinetic activity, and corrosion resistance of the electrodes are enhanced significantly with Pt-Cr material by EBM coating.

Keywords: Proton Exchange Membrane Electrolyzers, Gas Diffusion Electrode, Selective Laser Melting, Electron Beam Evaporation, SS316L

INTRODUCTION

PEMWEs have an important place in electrochemical hydrogen production systems thanks to their high current density values, fast start up, their ability to operate relatively low temperatures, and achieve higher efficiency values even at low temperatures [1, 2]. In PEMWEs, the anode GDE layers distribute water in the entire active surface area. Performance in PEMWE systems is directly proportional to the amount of water delivered to the catalyst layer [3]. The anode side of the PEMWE has a corrosive environment. Thus, reducing corrosion effects cause higher cell performance due to lower contact resistance, ohmic and activation overpotentials in PEMWEs [4]. Thus, this component of the cell should have high corrosion resistant coating and materials. Generally, Pt-coated Ti mesh structures are preferred as a GDE on the anode side of PEMWEs [5]. When PEMWE costs are compared, 24% of the cell cost is due to membran electrode assembly (MEA) and 48% of these costs are due to GDE and bipolar plates [6]. Corrosion resistant alternatives to Pt coated Ti mesh materials are very crucial to wide spread of these systems. Amon the cheaper options, stainless steel materials are seen as one of the most suitable materials for PEMWE systems due to their accessibility, cheapness , and easy to form [7, 8]. Even they have low corrosion resistance and stability problems it is possible to improve it by a noble or non-noble metal coating [9, 10]. There are several coating methods for anode GDEs like thin film, electrochemical, spin coating, dip coating and electroless methods. Amon them thin film coating provides homogeneous layers on the GDE surfaces. Thus, they are very promising to obtain low cost GDEs. In the literature there are several thin film coating methods. Especially e-beam evaporation methods have some advantageous due to higher temperature evaporation conditions. Thanks to higher temperatures, time effective coatings are possible on the surface of the samples. For example, Park et all. [11] coated the carbon paper with the electron beam evaporation method to reduce Pt loading in the microbial fuel cells (MFC). They are observed that after 45 h of microbial fuel cell (MFC) testing conditions, e-beam coated carbon paper has increased the current density by changing peak intensity in the performance tests. They stated that the potential of e-beam coated Pt electrodes in improving efficiency with the minimal loading of Pt. Raso et all. [12] studied different Pt accumulation methods to reduce metal loading while maintaining their electroactivity. In this study, the behaviour of e-beam Pt coated electrodes for fuel cells were examined and they concluded that MEAs prepared with e-beam evaporated cathodes had clearly higher power density per Pt loading mass. As seen in the literature, electrodes coated with e-

beam evaporation method have been tested in different types of fuel cells for the lower loading of the catalysts. However, according to author's knowledge, SS316L mesh structures are not tested with thin film coating by Pt noble metals. Thus, in this study, SS316L electrodes are produced by SLM method, and these electrodes are coated with different thicknesses of Pt on by the help of a Cr interlayer. Electrode samples are tested in PEMWE simulated acidic environment to observe their electrochemical performance and the stabilization.

MATERIALS AND METHODS

In the experiments, firstly, the best geometry was determined before the coating process. GDE structures with circle, equilateral triangle, square, and rhombus holes were studied in the pressure drop experiments. To measure pressure drop of the GDE samples, 3D printed geometries were placed pressure drop test cell. GDEs with different geometric patterns can be seen in Fig. 1.

(a) (b) (c) (d)

Fig. 1. a) Circle, b) Equilateral triangle, c) Square, d) Rhombus GDE geometries.

100 ml/min water flow was supplied to the pressure drop cell by the help of a water peristaltic pump [13]. For each GDE samples, inlet and outlet pressure was measured. The amount of pressure change (ΔP) and the decrease were calculated proportionally according to the input and output pressure. The inlet pressure of the square geometry GDE was read as 3.866 kPa and the outlet pressure as 2.36 kPa. It exhibited the lowest change at 1.506 kPa ΔP[14]. The low pressure drop means that the PEMWE will better distribute the water sent into it. Thus, since GDE with square geometry will distribute water better than other geometries, square structures are preferred in electrodes designed for coatings.

Electrode samples were designed using SolidWorks software. Pore volume of the electrodes were arranged as 25%. The designed geometries can be seen in Fig. 2.

a) b)

Fig. 2. Electrode sample designs for a) in-situ electrochemical tests and b) corrosion tests

The designed geometries were produced with the SLM method using SS316L material. A cleaning procedure before the coating process were carried out. SS316L samples were kept in an ultrasonic bath for 10 minutes in distilled water, ethanol, acetone, and isopropanol, respectively. After the cleaning procedure, SS316L samples were dried with nitrogen. The samples were coated with 0.5 µm, 1.0 µm, 1.5 µm, and 2.0 µm thick Pt with and without Cr interlayer using electron beam evaporating methods. The coated SS316L electrodes were prepared for electrochemical measurements. The active surface area of the SS316L electrodes was determined to be 25 mm^2 (5 mm x 5 mm). The electrochemical characterization measurements were carried out using Potentiostat-galvanostat (PGSTAT204) with a three-electrode configuration. SS316L electrode was used as the working electrode. Pt wire and Ag/AgCl (3M Saturated) were used as counter electrodes and reference electrodes, respectively. CV, LSV, EIS, Tafel, and CA measurements were analyzed in a 0.5M H_2SO_4 solution. CV measurements were performed at a 50 mV/s scan rate and LSV measurements were conducted at a 10 mV/s scan rate. The EIS measurements were analyzed in a frequency range between 10 kHz to 0.1 Hz at 5mV amplitude. The stability tests of the SS316L electrodes were performed using the Tafel and CA method. Tafel and CA measurements were made using a corrosion test cell. The corrosion cell tests were carried out by keeping the temperature constant at 80°C using a circulator to simulate PEMWE conditions. Surface characterizations of SS316L electrodes were determined by FE-SEM, EDX, EDX Colour Mapping, XRD, and XRF methods.

CONCLUSIONS

In this study, SS316L was coated with Pt as an anode GDE for PEMWEs. By the help of electro beam evaporation method, Pt was coated with 0.5 µm, 1.0 µm, 1.5 µm, and 2.0 µm thickness with Cr interlayer. As a result of surface characterization and electrochemical analyses, the 2.0 µm Pt coated electrode performed as the best electrochemical performance due to higher catalyst content and higher electrochemical surface area. The importance of coating thickness for corrosion resistance has once again been demonstrated.

ABSTRACT

In this experimental study, hydrogen production performance of NaCl, KCl and $CaCl_2$ solutions via electrochemical method through a small scale chloralkali reactor are investigated. A cation exchange membrane is placed in between the anode and cathode chamber to separate the anolyte and catholyte solutions. 316 stainless steel electrodes are used in the experiment due to its economic efficiency. While the anode compartment of the reactor is fed with NaCl, KCl and $CaCl_2$ solutions one by one, the cathode compartment is fed with a low-density NaOH, KOH and $Ca(OH)_2$ base solution depending on the type of salt used in the experiment. Experiments are carried out at cell voltage range of 3 to 5 volts according to three different brine densities (30 g/L, 60 g/L and 90 g/L), three different electrolyte flow rates (0.4 g/s, 0.6 g/s and 0.8 g/s) and three different electrolyte temperatures (30 °C, 50 °C and 70 °C). While a significant amount of hydrogen gas output was observed from the cathode compartment of the reactor, the expected chlorine gas output from the anode compartment was not observed. Since the chlorine gas is very active it reacts with many metals easily. Therefore, chlorine gas produced in the anode chamber caused serious corrosion and contamination on the electrode in this chamber.

Keywords: Hydrogen production, Electrochemical process, Chloralkali reactor, NaCl, KCl, $CaCl_2$.

INTRODUCTION

Due to the harmful effects of non-renewable energy usage on the environment, it has become necessary to meet the world's energy needs from clean energy sources. Hydrogen-based technologies are becoming increasingly important, as hydrogen can be produced and stored with excess electricity produced from renewable sources. When it is necessary, the need for energy can be easily met with stored hydrogen.

Jalali et al. (2009) were studied the effects of various operating parameters on the cell voltage and current efficiency of a laboratory-scale chloralkali cell were at low caustic concentrations (5–22 g/L). These operating parameters are anolyte pH (2–5), cell temperature (25–90 °C), electrolyte velocity (2.2–8.4 cm/s), brine concentration (200–300 g/L) and current density (1–4 kA/m2). Current density and cell temperature were found to be the most striking parameters on the cell voltage.

Rabbani et al. (2014) is discussed the electrochemical model for a newly designed photo electrochemical hydrogen production reactor. According to the results, a minimum voltage is required when the distance between the electrodes becomes a minimum. On the other hand, brine and electrolyte concentrations do not have significant effect on cell voltage.

Main aim of this study is to contribute the process of hydrogen production of salts.

MATERIALS AND METHODS

Fig.1 shows the schematic of the experimental system. Main components of the system are a laboratory scale chloralkali reactor, two peristaltic pumps to adjust the electrolyte flow rate, four containers for electrolyte feeding and dump collection, a graduated cylinder and a power supply. The cathode and anode compartments of the reactor, modeled with the appropriate computer program, are made of Kestamid in CNC machine due to its durability. The cation exchange membrane placed between the anode and cathode compartments of the reactor not only prevents the mixing of electrolytes in the anode and cathode compartments, but also allows positive ions to pass through. Chloralkali process is the electrolysis of NaCl solution producing hydrogen, chlorine and sodium hydroxide. NaCl is usually used in this process. However, salts such as KCl and $CaCl_2$ can also be used. In this case, the Na element leaves its place to the K or Ca element. The first pump sends the prepared salt solution to the anode compartment of the reactor, while the second pump sends the diluted base solution to the cathode compartment. In case of using appropriate electrodes, hydrogen gas is produced in the cathode compartment and chlorine gas is obtained in the anode compartment. Since chlorine gas can react with many metals, the electrode in the anode compartment must be corrosion resistant like platinum metal. However, due to its economy, stainless steel electrodes were used in this experiment. Therefore, no chlorine gas output was observed in the anode

compartment, but serious corrosion effects and contamination were observed on the electrode. On the other hand, an effective hydrogen gas output from the cathode compartment was observed and measurements were made on it.

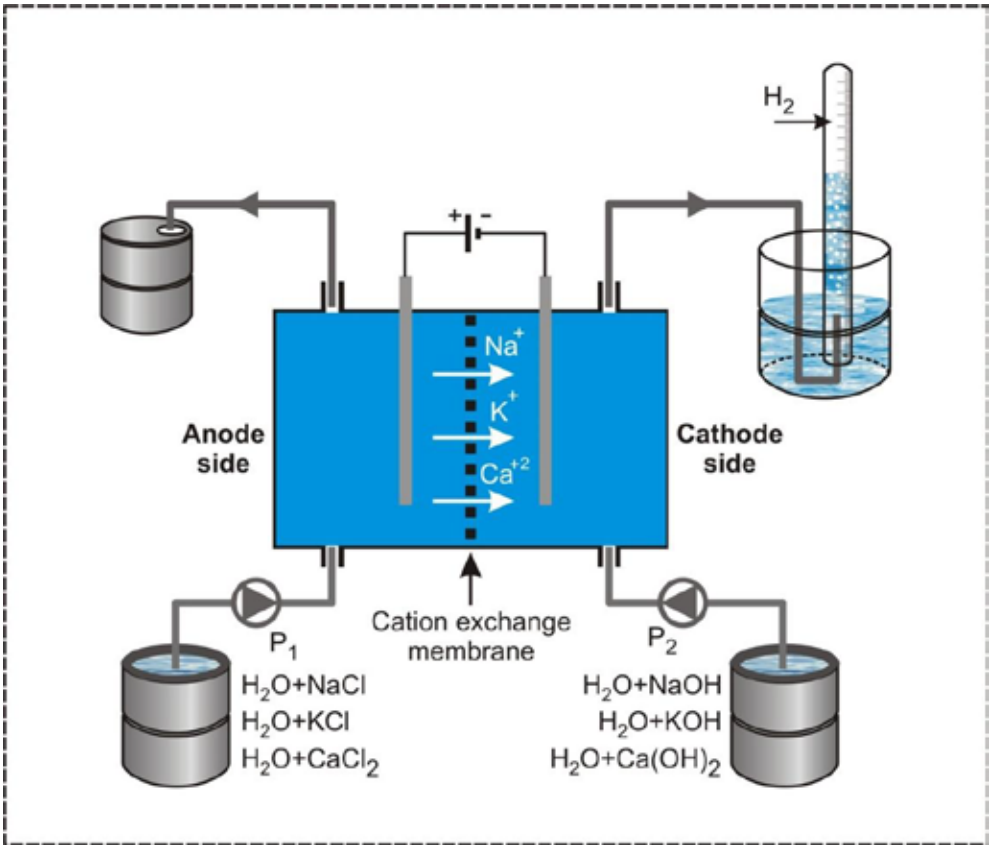

Fig. 1. Schematic of the experimental system.

To assess the system thermodynamically, balance equations should be written.

$$\sum \dot{m}_i = \sum \dot{m}_o \quad (1)$$

$$\dot{Q}_i + \dot{W}_i + \sum \dot{m}_i h = \dot{Q}_o + \dot{W}_o + \sum \dot{m}_o h \quad (2)$$

$$\sum \frac{\dot{Q}}{T_0} + \sum \dot{m}_i s_i + \dot{S}_g = \sum \dot{m}_o s_{\varsigma o} \quad (3)$$

$$\sum \dot{E}x_{Qi} + \sum \dot{E}x_{Wi} + \sum \dot{m}_i ex_i = \sum \dot{E}x_{Qo} + \sum \dot{E}x_{Wo} + \sum \dot{m}_o ex_o + \dot{E}x_{dest} \quad (4)$$

RESULTS AND DISCUSSION

Chlorine production is difficult because it easily reacts with many metals. Since 316 stainless steel electrodes were used in this experiment, corrosion occurred and no free chlorine gas output was observed. No difficulties were encountered in the production of hydrogen and the measurements were made on hydrogen. Experiments were repeated out for three different salt concentrations, three different temperatures and three different flow conditions for each salt.

Fig. 2 shows the hydrogen production rate of NaCl salt at 30, 50 and 70°C. It is clearly seen that the hydrogen production increases with increasing temperature.

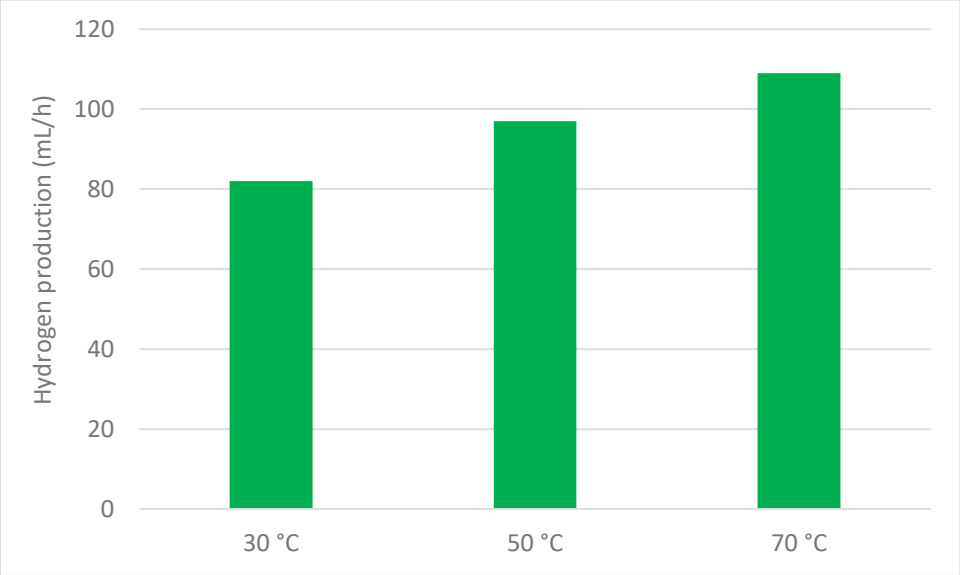

Fig. 2. Hydrogen production at different temperatures.

CONCLUSIONS

In this study, hydrogen production performances of NaCl, KCl and $CaCl_2$ electrolytes via chloralkali reactor are investigated experimentally. For this purpose, a laboratory scale chloralkali reactor is constructed. Experiments were conducted for hydrogen production according to different temperature, salt density and electrolyte flow rate parameters. There was no satisfactory chlorine gas output since the appropriate electrode could not be used. But an effective hydrogen gas output was observed.

ABSTRACT

PEMWE (proton exchange membrane water electrolyzer) can operate at a high current density with a small size to obtain a large mount of hydrogen. However, when PEMWE operate under high current density conditions, lots of air bubbles are generated which causes the reduction of water electrolysis efficiency due to the increase of mass transport loss. In this study, three types of flow channels (single serpentine, double serpentine, and parallel) were designed to reduce mass transport loss and PEMWE performances were compared. Performance was measured with a current density ranging from 0 to 2.0 A/cm^2, and water at 50 and 70 °C was supplied to the anode at 1.5 to 14.1 ml/min, and to the cathode at 1.5 ml/min. Two-phase flow patterns were analyzed using an optical high-speed imaging to understand relationship between flow channel design and cell performance. Among tested channels, the parallel channel had the worst performance because slug flows with Tayler bubbles, that could disturb the water supply, were mainly occurred. Whereas, the single serpentine channel had the best performance because annular flows with a thin liquid film could reduce mass transport loss were dominant.

Keywords: Electrolyzer, Proton exchange membrane water electrolyzer, Flow channel design

INTRODUCTION

The increase in energy consumption with the development of technology leads to the climate change problem due to the greenhouse gas emissions, because most of the energy is commonly obtained from fossil fuels. Hydrogen energy has been received large attention as alternative energy to solve the gas emission problem since it does not emit environmental pollutants and has a high energy density. Although no gas emission occurs in the use of hydrogen energy, greenhouse gases such as CO and CO_2 are also emitted during hydrogen production by the generally employed natural gas reforming method [1,2]. Water electrolysis is a method to obtain hydrogen from water without any emissions of greenhouse gases. Among various methods for water electrolysis, PEMWE (proton exchange membrane water electrolyzer) can generate a relatively large amount of hydrogen with a small size because it can operate under a high current density condition. However, for practical applications of PEMWE at a high current density, the mass transport loss should be reduced. Therefore, in order to improve the performance of PEMWE, it is important to understand two-phase flows related with the water supply and produced gas removal in flow channels and porous transport layer.

Dedigam et al. investigated the relationship between flow and electrochemical performance and they showed that the mass transfer loss decreased by maintaining the slug flow as the flow rate increased [3]. Majasan et al. visualized two-phase flows in channels, and they found that the single serpentine channel had a worse performance than the parallel channel because longer gas slugs were formed [4]. Ito et al evaluated the flow characteristics as flow regime, frictional pressure drop, and flow rate with three kinds of channels (single serpentine, double serpentine, and parallel) [5], and it was confirmed that the mass transport of water can be improved by the parallel channel where bubbly flows with a lower pressure drop were dominated. Although previous studies investigated the relationship between cell performance and two-phase flow behavior during electrolysis, those studies were conducted only with qualitative analysis about the flow characteristics. In this study, flow channels were designed to reduce the mass transport loss of PEMWE, and the relationships between flow characteristics and water electrolysis performance were investigated through quantitative analysis of flows using a optical high-speed imaging.

EXPERIMENTAL

Fig. 1(a) shows the schematic diagram of the experimental set-up used in this study. The transparent window made of a quartz was placed as an endplate to observe the internal flow. As shown in Fig. 1(b), performances of three kinds of flow channels (single serpentine, double serpentine, and parallel) with 3 mm channel width and 2.2 mm rib were compared. Ti mesh with 0.27 mm thickness and 0.1 mm diameter pore size was used as PTL, and Nafion 115 with 25 cm^2 reaction area was employed as MEA. Cell performances were measured by changing the current density from 0 to 2.0 A/cm^2 in intervals of 0.04 A/cm^2 under the cell temperature of 50 and 70 °C. Two-phase flows inside flow channels during PEMWE operations were visualized using a high-speed camera, and images were captured at 125 during 30 s at each operating condition. The length and width of the bubble were obtained after applying image processing technique with Image J and MATLAB software. If water is not sufficiently supplied to the inside of the cell

during the electrochemical reaction, the MEA can dry and shrink, resulting in damage and overvoltage of the MEA [6]. Therefore, water was supplied to the anode at the electro-stoichiometric ratio of 50 corresponding flow rate of 1.5 to 14.1 ml/min. Water was also supplied to the cathode at a fixed flow rate of 1.5 ml/min to prevent drying of the MEA.

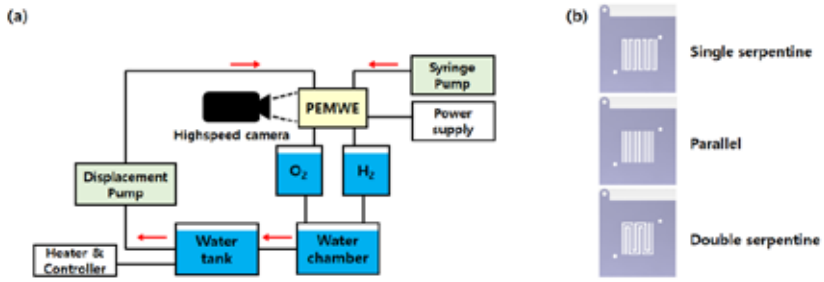

Fig. 1. (a) Schematic diagram of experimental set-up, and (b) designs of flow channels.

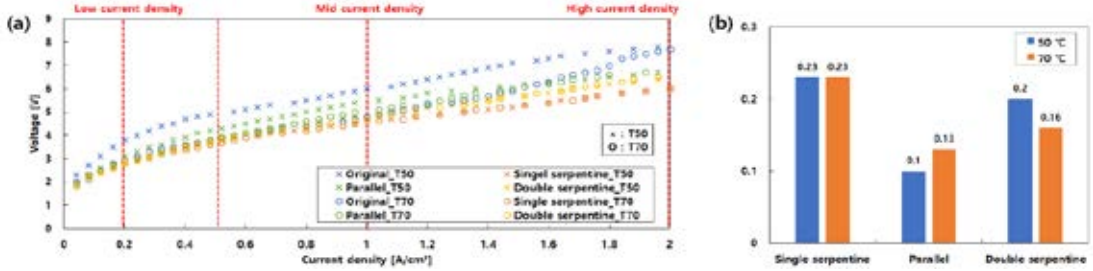

Fig. 2. Comparisons of (a) IV polarization curves, and (b) ratios of voltage drop to that of chamber type at 2.0 A/cm^2.

RESULTS AND DISCUSSION

Fig. 2(a) shows the IV polarization curve. Compared to the performance at 50 °C, the performances in all cases were higher at 70 °C. The voltages at 70 °C and 2.0 A/cm^2 where mass transport loss was dominant were 6 V for single serpentine, 6.5 V for double serpentine, and 6.7 V for parallel, which was 23%, 16%, and 13% lower than that of chamber type having 7.7 V, respectively, as shown in Fig. 2(b). Fig. 3(a) shows the procedure of image processing. Field flat correction was firstly applied with the background image obtained before operations where channels were fully filled with water. Thereafter, threshold correction and noise reduction were employed to classify water and gas regions. Two-phase flow information was analysed only at the straight part of channels marked in the blue box in Fig. 3(a) since it is difficult to distinguish the length and width of gases in regions where the channel direction is switched. Figs. 3(b) and (c) represent the probability density function of the normalized gas length and width, respectively. The length probabilities in Fig. 3(b) show that single and double serpentines have longer gases, and gas streams having same length with channels are generated. In contrast, parallel has a relatively short gases, and most gases have a length of 0.2 times or less of the channel length. The width distributions in Fig. 3(b) have an opposite tendency to the length. The width of most gases in the parallel channel is same with the channel width. While, the single and double serpentines have smaller gas width than the channel width, and highest probabilities for single and double serpentines are observed at the normalized width of about 0.6 and 0.9, respectively. From the width and length, it is known that dominant flows are slug flows with Taylor bubble similar to the channel width for parallel channel and annular flows with thin liquid films on surfaces single serpentine channels, respectively. Double serpentine channel has a mixed flow pattern with slug flows having Taylor bubbles and annular flow. Gas occupies the entire channel width when Taylor bubble flows occur. Therefore, it is difficult to supply enough water to the chemical reaction location through bubble generated regions when gases produced by electric-chemical reactions are discharged to flow channels and Taylor bubbles are emerged. If water is supplied in excess of the flow rate required for the electrochemical reaction of the PEMWE, the small diameter bubbles are discharged without sufficient growth due to the high flow rate. In this study, the water required for the controlled current density was appropriately supplied at constant rate. As a result, Taylor bubbles were generated in parallel channel with relatively low flow rate, disturbing the water supply, and different in previous studies, it had lower performance than other channels. On the other hand, in the annular flow, a gas column is continuously discharged in the middle of the channel, and it is possible to supply water through the edge of the channel. Therefore, gas discharge and water supply can simultaneously occur in the same area for annular flows. This leads to a smooth water supply providing higher cell performance by reducing the mass transport loss as shown in Fig. 2.

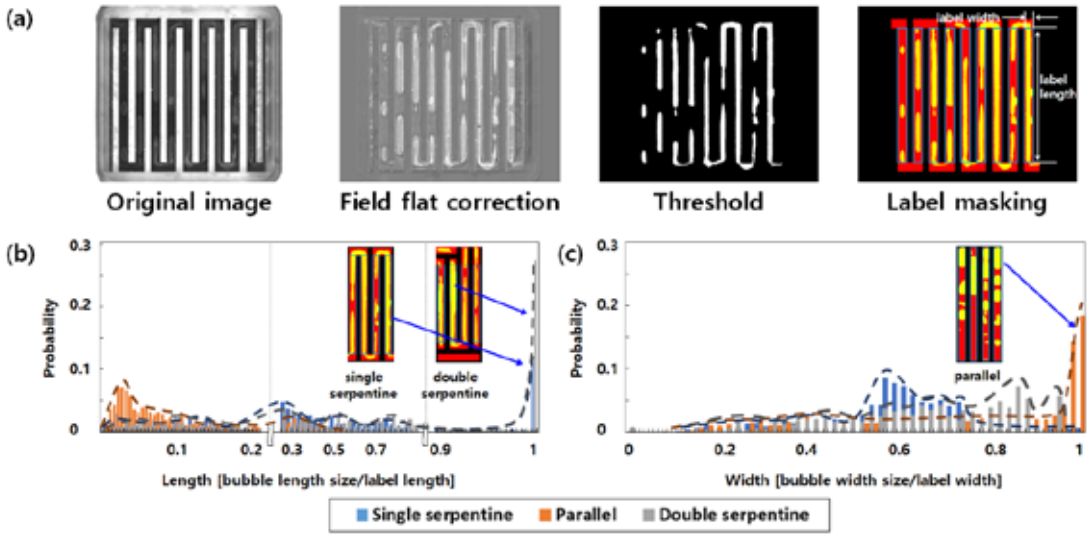

Fig. 3. (a) Image process, (b) probability of length per channel at 2.0 A/cm^2, and (c) probability of width per channel at 2.0 A/cm^2.

CONCLUSIONS

In this study, three kinds of channels were designed for PEMWE, and performances and two-phase flows inside flow channels were compared. Compared to the chamber type, flow channels can improve PEMWE performances, and single serpentine and parallel channels had the best and worst performance among tested channels, respectively. Taylor bubbles which can disturb water supply were dominant in the parallel channel. In contrast, annular flow with thin liquid films, which can reduce the mass transport loss because gas discharge and water supply are smoothly performed, mainly occurred in the single serpentine channel. It is expected that this study would contribute to the design of the flow channel to improve the performance of PEM water electrolysis.

ABSTRACT

In this study, the effect of molybdenum oxide addition on metal catalysts in the reverse water gas shift reaction was investigated. By adding molybdenum to the copper, iron and cobalt supported catalysts, CO_2 conversion rate was improved while maintaining a high CO selectivity. In addition, it was made clear that the addition of molybdenum to ruthenium and nickel supported catalysts containing methane as the main product suppresses the production of methane and improves the selectivity for the reverse water gas shift reaction. The addition of molybdenum oxide from being presumed to suppress complete reduction of CO_2, proceeds highly selectively reverse water gas shift reaction. The addition of molybdenum oxide as a reverse shift reaction catalyst can be expected to be a useful method.

Keywords: Reverse shift reaction, Molybdenum oxide, Zeolite support, Carbon dioxide, Selectivity

INTRODUCTION

The increase in CO_2 in recent years has caused serious climate change and is a problem that greatly affects human society and the global environment. Reducing CO_2 emissions in industrial fields, which accounts for the majority of CO_2 emission sources, has become a major issue [1]. Effective use of CO_2 by converting it into chemical products by catalytic reaction is being promoted. Currently, as a technology to convert CO_2 into chemicals and liquid fuels using H_2, a gas phase catalytic reaction using a solid catalyst is considered. Multiple reaction occur from H_2 and CO_2, the selectivity of the reaction is important to develop a catalyst. As catalysts for RWS reactions, transition metal catalysts such as Cu, Fe and Co and noble metal catalysts such as Ru have been investigated [2].In this study, molybdenum oxide was added to metal catalysts such as Cu, Fe, Co, and Ru, which have a catalytic action on the hydrogenation reaction of CO_2, and the catalytic performance was studied [3]. Catalysts were prepared by co-impregnating these metals and molybdenum oxides and examined for activity using a flow-through integral reactor [4]. In this examination, the effects of H_2 and CO_2 partial pressure on the activity were measured, and the influence of the addition effect of molybdenum oxide was clarified.

MATERIALS AND METHODS

Materials

All materials of catalysts were used as received without further purification. The faujasite-type zeolite (FAU, HSZ-330HUA) was adopted from Tosoh Corporation. Hexaammonium heptamolybdate tetrahydrate $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (GR), copper chloride (II) ($CuCl_2$, GR), hexa-ammine cobalt (III) ($[Co(NH_3)_6]Cl_3$, GR), nickel chloride (II) hexahydrate ($NiCl_2(II)\cdot 6H_2O$, GR), ruthenium chloride hydrate ($RuCl_3$, GR), and hydrochloric acid (HCl, GR) were made use of Wako Pure Chemical Corporation. Anhydrous iron chloride (III) ($FeCl_3$, Trace Metal Basis) was obtained from Sigma Aldrich.

Catalyst preparation

Metal oxide supported catalysts were prepared by incipient wetness impregnation method by using FAU as a support. The metal loading was fixed at 1.0 mmol/g-cat for each catalyst. Prior to impregnation, 1.0 g of FAU was placed in a side-arm flask under vacuum for 30 min at room temperature to remove adsorbed water molecules from the surface. As the impregnation solution, $CuCl_2$ (0.144 g), $FeCl_3$ (0.172 g), $[Co(NH_3)_6]Cl_3$ (0.284 g), $NiCl_2(II)\cdot 6H_2O$ (0.253 g), $RuCl_3$ hydrate (0.231 g) or $(NH_4)6Mo_7O_{24}\cdot 4H_2O$ (0.1953 g) was dissolved into 10 mL of HCl solution (0.01 mol/L). The solution was put into the flask with the FAU and left for 30 min at room temperature. The catalyst was evaporated in a 300 mL round-bottom flask for 1 h, followed by drying overnight in an electric oven at 328 K. Then, the sample was calcined in air at 773 K for 10 h. The obtained catalysts were named M(1)/FAU.M and x refer to element and its content mmol per gram of the catalyst.

Characterization

X-ray diffraction patterns were recorded using a SmartLab diffractometer (Rigaku) equipped with monochromatic Cu Kα radiation at room temperature. The 2θ range from 25° to 75° was scanned using a step size of 0.04° and a counting time of 4 s per step.

Catalytic activity examination for the reverse water gas shift reaction

The reverse water gas shift reaction was carried out in a fixed-bed flow type reactor. α-alumina tube (6 mm inner diameter) was used as the reaction tube. Catalyst (200 mg) diluted with 1.0 g of inert quartz sand were placed in the tube. The catalyst was sandwiched by 1.0 g of pure quartz sand layers. The catalyst was pretreated with a 55% H_2:N_2 mixture at a flow rate of 22.5 mL/min at 873 K for 1 h before the reaction. After pretreatment, the catalyst was set at the reaction temperature in N_2 gas, and the reaction gas (H_2:CO_2:N_2 = 12.5:12.5:10 mL/min, total flow: 35 mL/min) was fed into the reactor with a space velocity of 7000 $mL \cdot h^{-1} \cdot g^{-1}$. The gas lines from the reaction tube to the sampling valves were heated by electric heaters to avoid condensation of products. The products of the reaction were analyzed by two separate on-line GC systems equipped with a thermal conductivity detector (TCD) and a flame ionization detector (FID), respectively. The reaction products were measured as following column and detector: H_2, CO, and CH_4 were measured by GC-TCD with a Molecular Sieve 13X column; CO_2 and H_2O were measured by GC-TCD with a Gaskuropack 54 column (GL Science); and CH_3OH was measured by GC-FID with a Molecular Sieve 13X column. The conversion, yield, and selectivity for each product were calculated using the following equations:

$$\text{CO yield (\%)} = (\text{CO outlet (mol)}) / (\text{CO}_2 \text{ inlet (mol)}) \times 100$$
$$\text{CH}_4 \text{ yield (\%)} = (\text{CH}_4 \text{ outlet (mol)}) / (\text{CO}_2 \text{ inlet (mol)}) \times 100$$
$$\text{CO selectivity (\%)} = (\text{CO outlet (mol)}) / (\text{CO}_2 \text{ inlet-CO}_2 \text{ outlet (mol)}) \times 100$$

RESULTS AND DISCUSSION

Catalytic activity

Fig. 1 shows Cu(1)/FAU, Ru(1)/FAU, Mo(0.8)Cu(0.2)/FAU, Mo(0.8)Ru(0.2)/FAU and Mo(1)/FAU catalysts. The dependence of the reaction rate on the hydrogen partial pressure in the reverse water gas shift reaction was shown. The horizontal axis is the logarithm of the hydrogen partial pressure in the reaction gas, and the vertical axis is the logarithm of the CO_2 conversion rate at the reaction time of 3 hour. The reaction rate at each hydrogen partial pressure was measured, and the logarithm was plotted. In Cu (1)/FAU and Ru(1)/FAU, the slopes of the plots are 0.65 and 0.70. 0.8) Ru(0.2)/FAU were 0.70 and 0.72, respectively. The slope of the plot shows the dependence on the hydrogen partial pressure [5], and the larger the slope value, the stronger the contribution of the hydrogen partial pressure to the reaction rate. By co-supporting with Mo, the value of the slope increased, indicating that the degree to which the hydrogen partial pressure contributes to the reaction rate increased, that is, the ability to activate hydrogen was suppressed. From the XRD measurement results, it is considered that copper and ruthenium exist as metals and molybdenum exists as oxides in the catalyst. It is known that hydrogen is dissociatively adsorbed relatively easily on metal copper or metal ruthenium, and hydrogen atoms exist on the metal. On the other hand, it has been reported that the surface electrostatic field causes a heterogeneous dissociation reaction of hydrogen molecules on oxides such as MoO_2 due to charge separation. From the difference in the dissociation reaction of hydrogen molecules, it is considered that the hydrogen activity on the molybdenum oxide surface is lower than that of metallic copper or metallic ruthenium, and the contribution of hydrogen partial pressure to the reaction rate is increased.

Conversion and Selectivity

Fig. 2 shows the CO_2 conversion and CO selectivity of the series of the catalysts in the reverse water gas shift reaction. Among single metal supported catalysts, Mo(1)/FAU, Cu(1)/FAU, Fe(1)/FAU, Co(1) /FAU have very high CO selectivity in carbon dioxide hydrogenation reaction. The CO selectivity was over 90% for each catalyst. Ru(1)/FAU and Ni(1)/FAU had low CO selectivity of 50% or less in the carbon dioxide hydrogenation reaction, and the main product was CH4. Ru, in particular, has a high hydrogen activity and is known as a catalyst for methanation reactions that reduce CO_2 to CH_4 [6]. Mo(0.8)Cu(0.2)/FAU, Mo(0.8)Fe(0.2)/FAU, Mo(0.8)Co(0.2)/FAU maintain high CO selectivity, CO_2 conversion rate improved. Mo alone showed a high CO_2 conversion rate and was found to work as a selective CO production active site in the CO2 hydrogenation reaction. In particular, CO_2 conversion was improved by co-loading Mo and Cu. It was found that by co-loading with Mo, Mo(0.8)Ru(0.2)FAU and Mo(0.8)Ni(0.2)/FAU decreased in CO_2 conversion but improved in CO selectivity. CO_2 is completely reduced to CH_4 on Ru or Ni which have strong hydrogen activity. And, it is thought that the CO selectivity was improved by co-loading with Mo because the hydrogen activity is suppressed by Mo.

CONCLUSIONS

A reverse shift reaction catalyst with a high CO2 addition rate was developed while maintaining high CO selectivity. While maintaining high CO selectivity, Cu, Fe, the addition of Mo to Co supported catalyst, has succeeded in CO2

conversion rate is improved. The addition of Mo oxide suppresses the activation of hydrogen and promotes the reaction of carbon monoxide generation.

ABSTRACT

The energy crisis, we are facing nowadays requires fast and efficient actions. Indeed, renewable sources are a main pillar, however storage systems are also principal pillars to overcome the intermittent nature of renewable sources. However, and to maintain a fully green system the storage should also be green and eco-friendly. Green to Green ($G2G$) are systems that gathers green sources and green storage. A typical solution is to couple renewable source to fuel cell. In this frame the present paper aims at studying the coupling of two renewable energy systems that are wind turbine and solar chimney to Fuel cell. A case study on the region of Rayak (Lebanon) is performed. Results show that in the first half of the year wind turbine-fuel cell coupling provides higher power supply whereas from June till November, solar chimney-fuel cell coupling is better.
Keywords: Green to Green, G2G, hydrogen, Fuel cell, wind turbine, solar chimney, renewable energy.

INTRODUCTION

Green to Green energy system (*G2G*) [1] is an optimal solution that can be adopted as a long run energy strategy. It allows to gather a green source of energy to a green storage system. On one hand, renewable energy is an efficient solution to reduce the negative impact of the technological development especially on the environmental level. Moreover, renewable energy systems cover wide range of natural sources of energies such as wind energy, solar energy, and geothermal energy. On the other hand, the main disadvantage of renewable energy sources is that they are intermittent and as a matter of fact they induce an oscillation in power supply if they are adopted alone without energy storage system such as super capacitors, batteries and compressed air storage. However, from an environmental point of view, not all storage system can be considered as green. From her is born the concept of (*G2G*) energy systems that could be constructed by coupling a renewable source to a green storage system such as fuel cell in order to obtain a pollution free system including both the source and the storage systems [2]. With this in mind, many works have been devoted to investigate different form of *G2G* energy systems [3]. Ramadan et al [4], suggest a system combining fuel cell and solar thermal system. The solar system is utilized to supply an electrolyser that supplies the fuel cell by hydrogen. Coupling geothermal energy and hydrogen has been also investigated [5]. Hybrid *G2G* energy systems have also been investigated [6]. In the frame of this paper a hybrid system coupling solar chimney, wind turbine and fuel cell is investigated.

MODELING

Green to Green (G2G)

The concept of green to green energy system (*G2G*), represents the simultaneous coupling of a green source to a green storage system. That said, and from an energetic stand point, any system combining a green source to a green storage could be labeled as *G2G*. Indeed, each *G2G* system includes, a green energy source such as wind energy, geothermal energy, solar energy, wave energy and hydropower. Concerning, green storage systems, many technologies can be labeled as green storage such as hydrogen, flywheel, pumped hydro and compressed air.

Coupling

The main contribution of this work is the coupling proposed between Fuel Cell (FC) and SC/WT systems through Hydrogen/Oxygen storage. The concept of coupling consists on using an Electrolyzer to produce Hydrogen and Oxygen from the power generated by SC system and/or WF system as shown in Fig. 1. During sunlight the SC is used to convert thermal energy to electrical power. In presence of wind extra power is produced by the WF. The total power generated by both systems is used to feed the load. The extra energy, if available, is used in the electrolysis process to produce hydrogen and oxygen. When solar radiations and wind speed are insufficient, hydrogen and oxygen are pumped to the FC to supply the load demand.

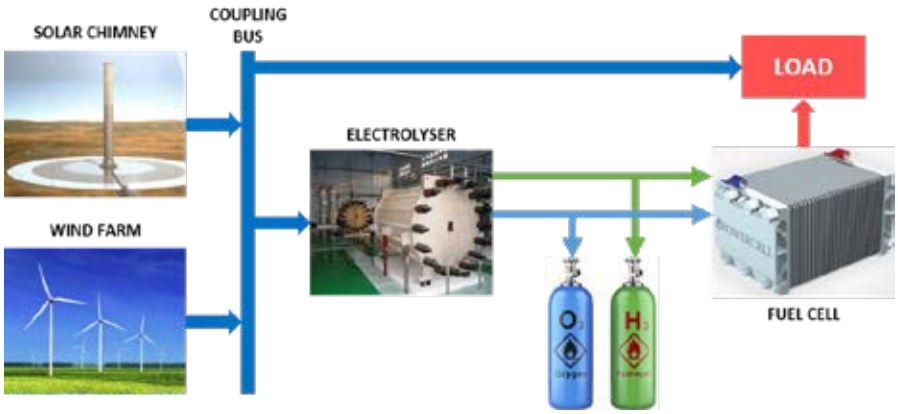

Fig. 1. Coupling Fuel Cell with Solar Chimney and Wind Farm systems.

RESULTS

Hence, coupling WT with SC results in better yearly power that can meet a higher load demand. However, during periods of low load demand with high solar radiations and wind speed there will be exceeds of energy that may be lost if not stored. This work proposes to store the extra energy in form of hydrogen using the electrolyzer. For this end, the AC power produced by the hybrid WT-SC system is converted to DC one using a rectifier before connection to the electrolyzer. Fig. 2 presents the hydrogen production rates of DC powers resulting from WT and SC in the region of Rayak.

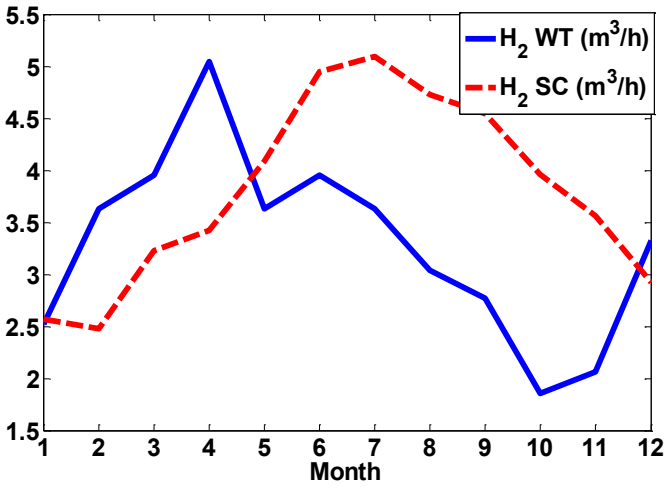

Fig. 2. Hydrogen production rates for WT and SC in Rayak Bekaa

CONCLUSION

Green to Green (*G2G*) energy systems, is the energy solution toward a pollution free environment. Coupling renewable sources to hydrogen is typical application of (*G2G*) systems. In this paper, the potential of coupling solar chimney, wind turbine and hydrogen is investigated. The potential of this coupling is studied in the region of Rayak. Results show that the hydrogen output and thus the output power depends on the period for instance in the first 5 months of the year wind turbine-hydrogen coupling provides higher amount of power whereas, in the second half of the yard solar chimney – hydrogen coupling provides higher amount of power.

ABSTRACT

In this study, a prototype marine vehicle is designed to produce hydrogen from sea water and convert it into electricity and use it as an auxiliary power in the main propulsion, and it is provided to look at this design from an energy perspective. In the designed marine vehicle, the main propulsion power was provided by a diesel generator. In this study, first of all, the requirements were determined, a conceptual design was made, and necessary evaluations were made from the energy perspective. In this study, high-weight hydrogen storage difficulties will be avoided by providing hydrogen production at any time, and costs will decrease in the long run. In addition, it will make great contributions to zero carbon dioxide studies.

Keywords: Hydrogen, Sea Vehicle, Purification, Energy Analyses, Electrolysis

INTRODUCTION

The important percent of hydrogen production handled with water electrolysis. Although it is not easy way to produce directly to hydrogen and it is not widely usage to produce hydrogen from seawater; is a crucial option to produce it. When looked up to the literature, the only work that has become a prototype that produces hydrogen from sea water and uses it for propulsion is the Energy Observer. The Energy Observer is the world's first hydrogen-generating and hydrogen-powered ship. The Energy Observer has a built-in PEM water electrolyzer (PEMWE) powered by a solar panel and wind turbine to produce hydrogen. The PEM water electrolyzer uses purified seawater and converts it to hydrogen. The hydrogen is then compressed and stored and used to power the ship via a Toyota fuel cell stack [1]. A schematic of the Energy Observer ship system is shown in Fig. 1 [1].

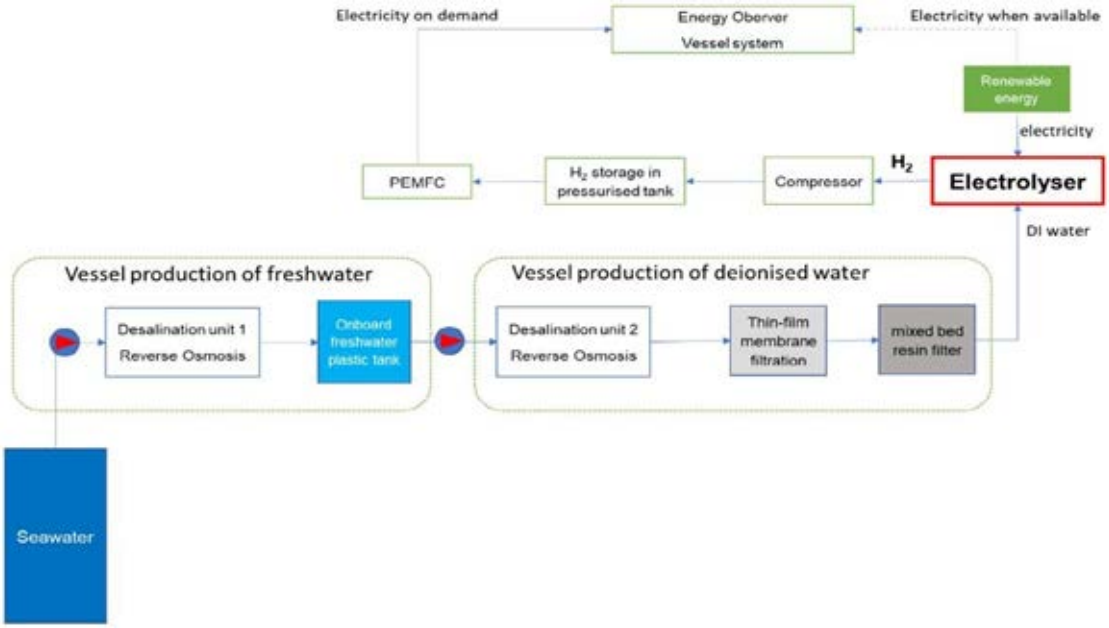

Fig. 1. A schematic of the Energy Observer ship system [1]

Unlike the literature, the hydrogen produced in this study will be used as auxiliary power in the main propulsion. Main power will be provided from diesel generator. In this way, the use of this system will be increased in heavier cargo ships and long-range ships for cargo, etc. purposes. It will also contribute to the literature on the production of hydrogen from sea water and its use in the propulsion system, and the increase of studies will be encouraged.

MATERIALS AND METHODS

In this study, hydrogen production from sea water is planned by purifying sea water, removing all dissolved salts, and giving it to the electrolysis cell. For this, reverse osmosis method, which is the most widely used method commercially, will be used. The conductivity of water, which is the inverse of the resistance with respect to the multiplication and is a measure of the fluid's ability to transmit electric current (the amount of ions in the water), is expressed in microSiemens/centimeter (µS / cm). In addition, an idea about the salinity of the water can be obtained by multiplying the conductivity value by 0.55-0.70. The resistance of the water is expressed as Mega-Ohm per centimeter (MΩ-cm) at 25°C [2]. Sea water is in the range of 40,000 to 100,000 microsiemens [3]. The water to be separated during electrolysis must meet many compositional requirements. These are standardized by the American Society for Testing and Materials (ASTM) Type II deionized (DI) water (resistance 41 MΩ cm), while ASTM Type I DI water (410 MΩ cm) is preferred [4]. The comparative feature is given in Table 1 [5].

Table 1. ASTM Standards (ASTM D1193-91 [5].

Measurement (unit)	Type I	Type II	Type III	Type IV
Resistivity (MΩ-cm)	> 18	> 1	> 4	> 0.2 (200KΩ)
Conductivity (µS/cm)	< 0.056	< 1	< 0.25	< 5.0
pH at 25°C	N/A	N/A	N/A	5.0 – 8.0
Total Organic Carbon (TOC) ppb or µg/L	<50	<50	<200	N/A
Sodium (ppb or µg/L)	< 1	< 5	< 10	< 50
Chloride (ppb or µg/L)	< 1	< 5	< 10	< 50
Silica (ppb or µg/L)	< 3	< 3	< 500	N/A

The designed treatment system and the complete marine propulsion system are given in Figures 2 and 3.

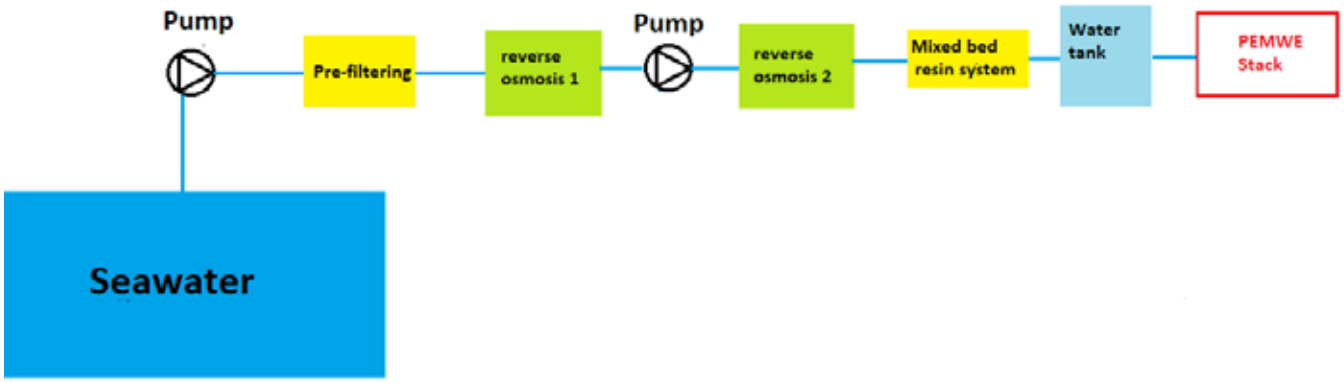

Fig 2. Designed treatment system

First, a pre-filtration is performed to remove very large particles in the seawater and to prevent any damage to the membrane and to prolong its life. In this filtration method, particles are captured using the physical sieving method. Here it is planned to use a sediment filter that captures particles up to 5 µm. Then the desalination of sea water will be carried out using two separate desalination units; both units will remove impurities by reverse osmosis (RO) to remove ions. The reverse osmosis semipermeable membrane (Ex. SW30, Dow Filtec membrane) acts as a barrier for all dissolved salts and inorganic molecules as well as organic molecules with a molecular mass greater than about 100 Daltons. RO units effectively achieve a high salt rejection of 99.2% to 99.5%. After two steps of reverse osmosis, the conductivity of water is expected to be about 3 µs/cm. RO filtrates may not be of the desired quality in single-stage purification. Therefore, two-stage reverse osmosis will be used. After desalination, additional step will be added to further remove impurities (thin film composite membrane).

The sea water treated in the design will be converted to hydrogen by electrolysis and stored in the hydrogen tank. From here, it will be converted into electricity in the fuel cell and feed the electric motor in the propulsion system. This system will be used as auxiliary power. There will be a separate propulsion system powered by a diesel generator as indicated in Figure 3, feeding a separate propeller as the main power. While the electricity produced here rotates the main propeller, a line will be drawn from the electricity produced to meet the electricity needs such as pump, electrolysis etc. Here, it is aimed to reduce the use of fossil fuels by making maximum usage of the fuel cell.

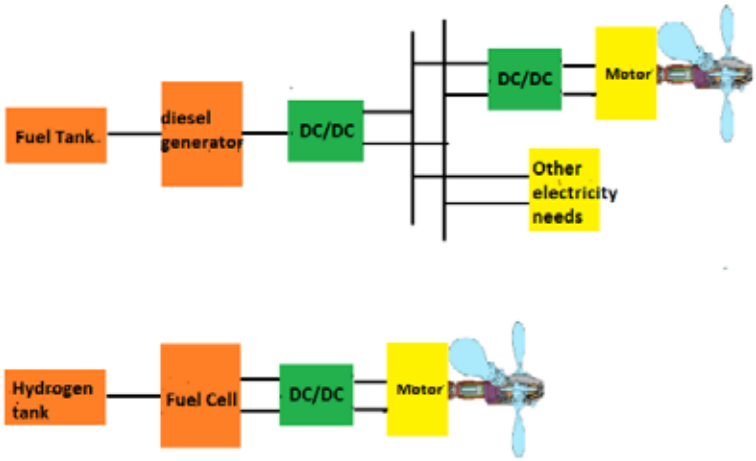

Fig 3. Propulsion system of sea vehicle

After the propulsion elements and the sea water treatment method were determined, the conceptual design stage was started. The paths followed in the conceptual design are as follows. Related formulas are taken from [6]. And the following steps have been followed.

a. Concept design—Feasibility study

At this stage, the mission and requirements were determined, and a feasibility study was carried out. L length, B beam, D side depth, T draft, CB block coefficient, PB powering etc. preliminary estimates of the basic ship dimensions were made. Alternative design solutions were explored.

b. Preliminary design

At this stage, the ship design determined in the first stage was detailed. The main characteristics of the ship, namely length L, beam B, sideboard depth D, draft T, block coefficient CB, and boost PB have been accurately determined. After the ship dimensions were determined, the power of the design materials etc. were determined. The combination of stages a and b is also known as basic design.

CONCLUSION

In this study, high-weight hydrogen storage difficulties were avoided by enabling hydrogen production at any time. Additionality, it will make great contributions to zero carbon dioxide studies. Unlike the literature, the hydrogen produced in this study was used as auxiliary power in the main propulsion. The main power was provided from a diesel generator. In this way, the use of this system will be increased in heavier cargo ships and long-range ships for cargo, etc. purposes. It will also contribute to the literature on the production of hydrogen from sea water and its use in the propulsion system, and the increase of studies will be encouraged.

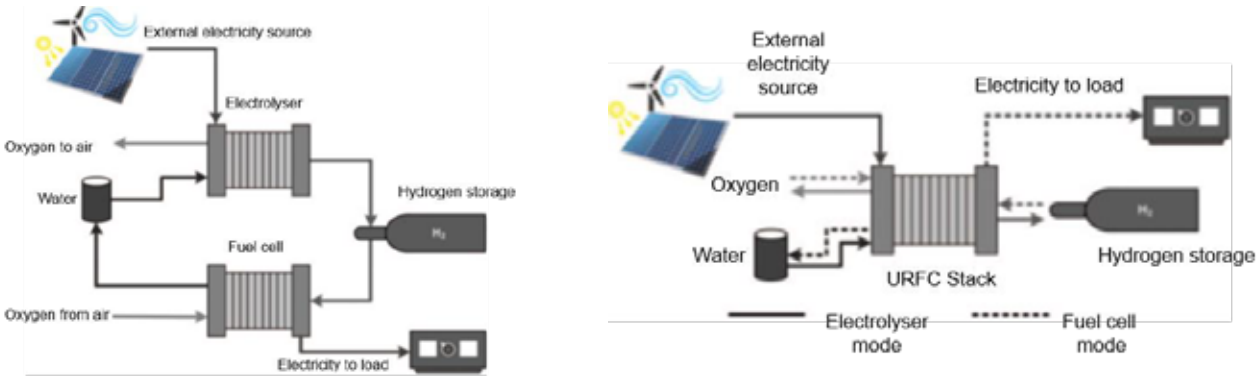
ABSTRACT



A unitized regenerative proton exchange membrane fuel cell (UR-PEMFC) is an electrochemical component that is capable of operating both as electrolyser and fuel cell mode. While UR-PEMFC produces hydrogen and oxygen by decomposing water in the electrolyser mode, it can also produce electricity and heat by using hydrogen as fuel in the fuel cell mode. A reversible system possesses several distinctive advantages for instance, high specific energy, pollution free, and most importantly, the decoupled energy storage capacity with rated power [1]. In this study, the performance of a unitized regenerative fuel cell and stack in electrolyser mode was investigated. The active areas of URFC are 100 cm^2, and the stack has three cell, which has a 100 cm^2 active area. The clamping pressure is optimized for cell and stack by using pressure film. Thus, the contact resistance was minimized, and optimum contact was achieved.

Keywords: Unitized regenerative fuel cell, PEM electrolyser stack, Experimental study

INTRODUCTION

Exhaust emissions from internal combustion engines are the primary source of pollution and are responsible for over 65 percent of global emissions worldwide [2]. As global energy demand is expected to increase continuously in the future, fundamental measures need to meet the growth of energy demand. The UN Framework Convention on Climate Change was adopted by the United Nations Conference on Environment and Development in 1992 to prevent global warming. Since the Kyoto Protocol has concrete action plans, it enforced the international environmental regulations to redeem greenhouse gas emissions [3]. This context supports increasing the interest and needs for renewable energy sources.

Hydrogen is not a primary energy source, but it is clean, efficient, and flexible energy carrier and easily convertible to electricity. Several types of electrolysers, such as, alkaline electrolyser (AEL), polymer electrolyte membrane electrolyser (PEMEL), and high temperature electrolysers (HTEL) are available for hydrogen generation. PEM electrolyser technology is becoming more competitive due to new improvements coming from increased research, developments, and the lower energy demand of the system. The combination of PEMEL and PEMFC into a regenerative fuel cell (RFC) system is an attractive energy storage method. Furthermore, the combination of PEMEL and PEMFC in one unit, the unitized regenerative fuel cell (URFC), provides advantages in system simplicity while compromising efficiency [4].

(a) (b)

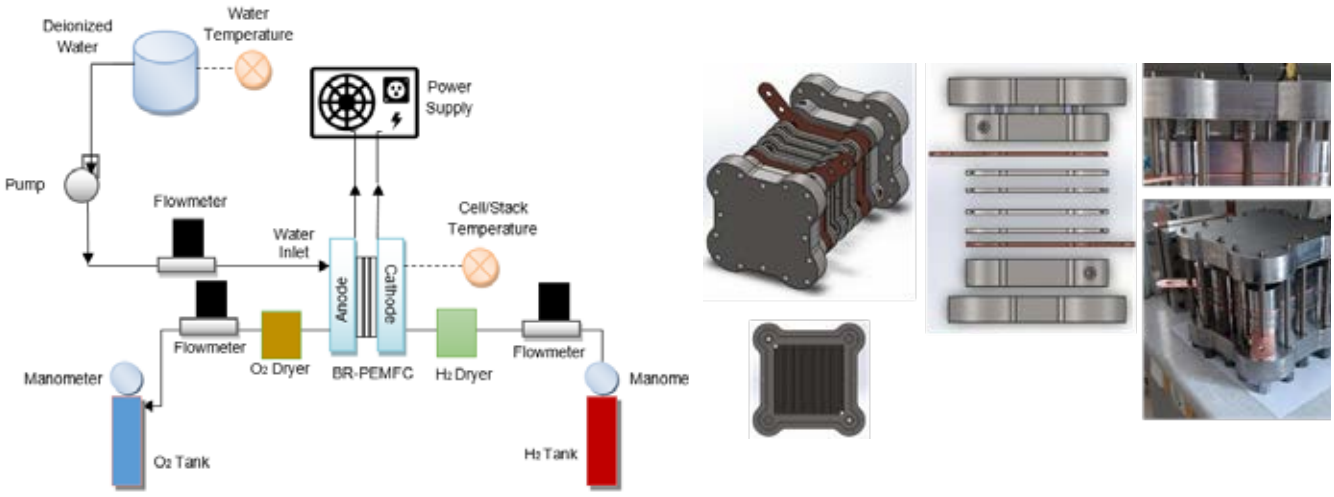


Fig. 1. Schematic diagram of a discrete reversible fuel cell (a), and unitized reversible fuel cell system (b) [5]

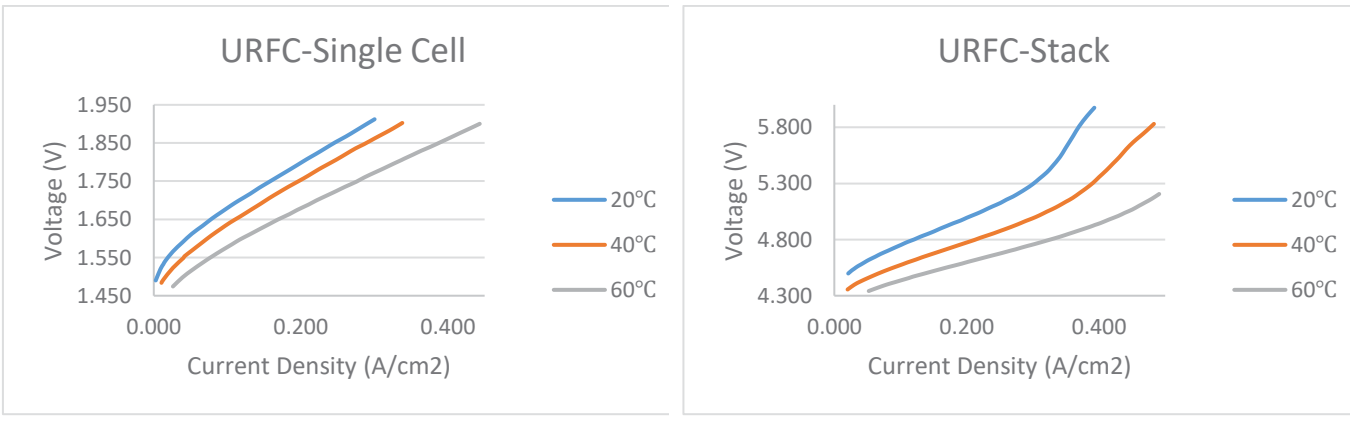
There are two basic types of RFC which are discrete regenerative fuel cells (DRFC) and unitised regenerative fuel cells (URFC). DRFC has separate units to perform the electrolyser and fuel cell, but these two devices are both integrated into a single system, as shown in Figure 1(a). The overall design of a DRFC system consists of a water management system, a control system, and a gas storage system to function as a standalone energy storage unit

[5]. To make a more compact system, the fuel cell and the electrolyser can be unitized into a single electrochemical cell. The URFC system, which can be seen in Figure 1(b), has several advantages against conventional discrete RFC, such as lower capital cost, simpler structure, higher specific energy, and no need for auxiliary heating [1].

EXPERIMENTAL SETUP

Within the scope of this experimental study, two different URFC were considered for different temperatures. One of the URFC has a 100 cm^2 active area, and the other one has three cell which has 100 cm^2 active areas. The experimental setup for the regenerative PEM fuel cell is shown in Fig. 2(a). Also, the bipolar plate flow channel of URFC and stack design can be seen in Fig. 2(b). DC power supply, air conditioning cabinet, ultra pure water, flowmeter, multimeter, and dryer were used to performed electrolyser mode tests. The electrolyser mode of URFC operated 20-60 ℃ to observe the effect of temperature.



(a) (b)

Fig. 2. The experimental setup for URFC

RESULTS AND DISCUSSION

The experimental URFC's electrolyser mode performance data is given in Fig. 3. 10.38 liters of hydrogen gas is produced per hour from a single cell at 60 ℃ and 1,72 V, while 61.65 liters are produced in the stack at the same temperature and 5,2 V. The number of cells in the URFC stack is increased according to the required hydrogen flow and serially to each other. Thus, the hydrogen flow rate obtained from URFC is increased.

(a) (b)

Fig. 3. The URFC cell and stack experimental results

CONCLUSIONS

Storing energy such as hydrogen is becoming very popular. PEM electrolysers have become the favorite way to produce hydrogen, due to their higher operating current densities, high-pressure output, and ability to respond to dynamic demands. UR-PEMFCs provide direct conversion between hydrogen and electricity, and they are sizable systems to

meet the power and energy specifications of a variety of applications. Further research and development are necessary for UR-PEMFCs to become competitive with discrete PEM electrolysers.

ABSTRACT

A thin self-assembly monolayer (SAM) film of Servi Dut Pekmezi (mulberry molasses, Servi MM) was fabricated over a copper electrode (Cu/Servi MM-SAM) in ethanol as solvent. The prepared Cu/Servi MM-SAM electrode was used as cathode in 6 M KOH solution for electrochemical hydrogen gas production. The traditional Servi MM was obtained from Servi village of Bingöl province, Türkiye. In this way, the dissolution and corrosion rate of copper could be reduced as well as electroactive centers coming from the chemical structures of the components of the MM could be supplied for further enhancing the activity of the electrode. It was observed that, the Servi MM-SAM film was not soluble in 6 M KOH solution and the film was very adherent to the metal surface and stable. Modifying the surface improve water splitting activity of the electrode and facilitates the rate of hydrogen gas production.

Keywords: Water Electrolysis, Hydrogen Production, Servi Dut Pekmezi (Mulberry Molasses), Self-Assembly Monolayer Film

INTRODUCTION

Electrolysis of water is one of the most efficient and easy way to produce clean and sustainable hydrogen gas [1,2]. However, cost production must be reduced and the yield of the method should be improved. For this aim, the researchers have been searching for novel electrode materials to be used in electrolysers. Alkaline solutions are generally chosen for this aim since more metals could be used in this medium. On the other hand, many cheaper transition metals, such as copper, cannot be used as electrode materials or electrocatalysts in alkaline solutions since they can easily corrodes. Therefore, enhancing corrosion protection ability and reduce dissolution rate of these metals is essential to use these metals in alkaline or acidic solutions.

Covering metal surface with an organic film may solve this problem. But, the film should also be electroactive. Common conductive polymers could not be used for this aim since they remove from the metal surface during the excess gas evolution in the electrolysis system. Recently, we suggested a new type of organic film called SAM for this aim [3,4] and reported that such organic films could enhance the hydrogen evolution activity of the electrode by facilitating the charge transfer between the metal/solution interface.

In this study, we are reporting a novel SAM film of a natural product, Servi Dut Pekmesi, which is a very healthy and natural product. The most famous mulberry molasses in Turkey is produced completely naturally in Servi village, Bingöl, Türkiye. Servi Dut Pekmezi received a Geographical Indication Certificate by the Turkish Patent and Trademark Office in 2021 and organized by Bingöl Directorate of Provincial Agriculture and Forestry. “Mulberry molasses, which has a high energy-giving feature, is good for fatigue, fatigue and anemia. It has a strengthening effect on the liver and kidneys and is good for hemorrhoids, sciatica and stomach diseases. Its antioxidant compound content supports the body to stay alive and young at all times. It strengthens the body's immune system by removing toxins accumulated in the body. It is edematous and cleans the liver. Mulberry molasses, which is good for arteriosclerosis, ensures the regulation of blood circulation. It regulates the heartbeat and is good for high blood pressure. It has very beneficial effects on smokers due to its cleansing properties of the lungs. This natural product plays an active role against cough” [5].

The Servi Dut Pekmezi modified Cu/Servi MM-SAM electrode was tested as cathode for hydrogen production in 6 M KOH solution. The surface film was characterized by some surface characterization techniques. Its water splitting activity was studied using cathodic polarization and electrochemical impedance spectroscopy (EIS) measurements.

MATERIALS AND METHODS

The Servi MM-SAM films were prepared on a copper specimen in ethanol as solvent. 1000 ppm Servi MM solution in ethanol was used for this aim. 1000 ppm KI was added to the solution in order to facilitated the assembly by synergism.The temperature of the film formation solution was kept at room temperature. The exposure time for the

film formation was 24 hours. The preparation of copper electrode before the measurements was the same as described before in detail [6]. After film formation, the electrode was removed from the solution, cleaned with the same solvent and dried under nitrogen atmosphere.

The structure of the film modified surface was examined with SEM and EDX. Further surface characterizations are ongoing and will be reported in future papers.

Electrochemical activity of the modified electrode for water splitting to produce hydrogen gas was studied in 6 M KOH at 398 K with the help of cathodic current potential curves and EIS. The experiments were performed with a computer controlled CHI instrument. In the polarization studies, the potential of the electrode was scanned between the open circuit potential and hydrogen evolution potential. The EIS data were obtained from 100 kHz to 0.1-0.01 Hz frequency range (based on the over potential). A Pt sheet with dimension of 10mmx10mmx1mm and Ag/Ag/AgCl were used as counter and reference electrodes, respectively.

RESULTS AND DISCUSSION

The Servi-MM-SAM film formed on the metal surface was characterized using SEM and EDX. On Fig. 1, SEM, EDX spectrum and the distribution of C element, which is completely coming from the Servi MM-Sam film are shown. From Fig. 1, it is clearly seen that the Servi MM-SAM film covers the surface completely and adheres very well to the Cu surface. Cu electrode used in this study has not C element content. Therefore, C element is coming from only the composition of the film. Therefore, the distribution of the film was examined by obtaining the distribution of the C element over the metal surface by EDX-mapping. Apparently, the C element, namely the Servi MM-SAM film is distributes over the metal surface perfectly. This is very important for the electrocatalysis studies since water splitting over the electrode is a surface process.

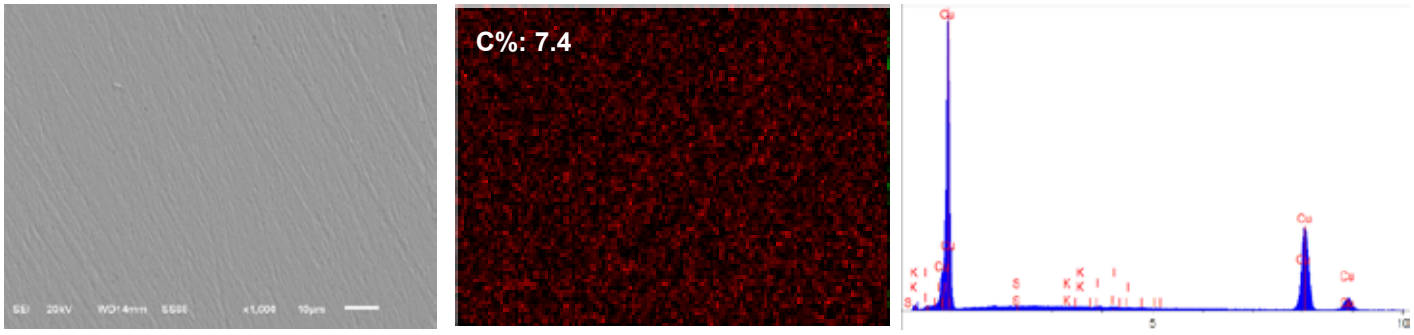

Fig 1. SEM, EDX mapping and EDX spectrum of the Cu/Servi MM-SAM surface

Water splitting activity of the Servi MM-SAM modified electrode was tested in 6 M KOH solution at 298 K. For this aim current-potential and EIS measurements were carried out. The data obtained are shown on Fig. 2 graphically. As it is seen form Fig. 2a, hydrogen gas evolution starts at lower overpotentials at the film modified electrode with respect to the bare Cu. Higher current density, which is directly related to the rate of hydrogen gas evolution reaction, at a specific potential is appeared at the Cu/Servi MM-SAM electrode. Therefore, we can conclude that modifying the copper surface with this natural film enhances its electrocatalytic activity and facilitates water splitting, which results with lower electricity consumption and make the electrolysis cheaper. The enhanced activity of the film can be assigned to the easier charge transfer ability of surface polymeric film.

Of course, the aim of this study is improving a protective as well as electroactive film over the copper metal, improving the stability of the copper and reduce corrosion rate of this metal in alkaline solution. In future studies, the corrosion performance of the electrode will also be reported. We also found that the surface SAM film is stable after the long–time electrolysis. Bu, we could not report these data here due to the limitation of short paper.

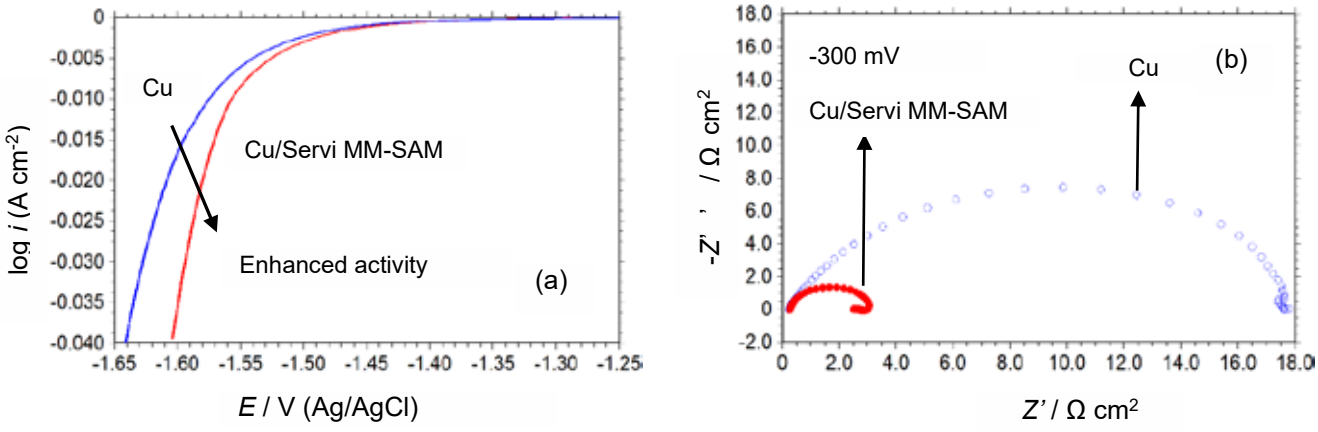

Fig. 3. Cathodic current-potential curves (a) and Nyquist plots of Cu and Cu/Servi MM-SAM electrodes obtained in 6 M KOH solution at 298 K

CONCLUSIONS

A thin Servi MM-SAM film was fabricated over a copper electrode in ethanol as solvent. KI was added to the film formation solution to facilitate the film formation and obtaining better quality film. The prepared Cu/Servi MM-SAM electrode was characterized for 6 M KOH electrolysis to produce hydrogen gas. Following major points were concluded:

- Homogenous and very adherent Servi MM-SAM film was prepared on the copper surface.
- The film has good appearance and nice color which also can be used for decorative aims.
- The film is physically and electrochemically stable.
- The film is promising organic subtract for further modifications and fabricating metal modified electrocatalysts.
- The Cu/Servi MM-SAM electrode has better water splitting activity with respect to the bare copper electrode.
- Further studies are continuing and will be reported later.

ACKNOWLEDGEMENT

The authors are greatly thankful to Bingöl University, Health Sciences Faculty, Occupational Health and Safety Department for experiments and Bingöl University Central Laboratory for characterization measurements.

ABSTRACT

Life cycle carbon footprint of producing hydrogen from spent coffee grounds was calculated. The following scenarios were compared: direct gasification; gasification of biochar produced by carbonization at 300°C and at 500°C; and gasification of hydrochar produced by hydrothermal carbonization. In each scenario, two sub-scenarios for one-step and two-step gasification were also studied, respectively. CCaLC2 software was used with CML2001 methodology, and the functional unit was defined as 1 kg of hydrogen gas produced. Material inputs and emissions were obtained based on experimental data whereas energy consumption of the process was partially adopted from the literature. Hydrogen produced via the two-step gasification of hydrochar obtained as a result of hydrothermal carbonization was found to have the lowest carbon footprint (33.0 kg CO_2eq. per kg H_2) whereas hydrogen produced via direct one-step gasification of spent coffee grounds was found to have the highest carbon footprint (87.0 kg CO_2eq. per kg H_2). The results in general were observed to be in reasonable consistency with the values reported for the carbon footprint of other hydrogen production methods. The main conclusions of the study were the necessity of adding a carbonization step prior to the gasification process, and preferring two-step gasification instead of one-step so that the carbon footprint can be reduced.

Keywords: Hydrogen Production, Carbon Footprint, Spent Coffee Grounds, Carbonization, Gasification

INTRODUCTION

Hydrogen can be produced by several different methods. Conventional methods generally rely on chemical processing of fossil fuels to produce hydrogen. Recently, utilizing biomass to produce hydrogen has become a promising alternative. Hydrogen can be produced from biomass by thermochemical and biochemical processes. Thermochemical processes have technical advantages over the biological processes such as short process time with a relatively high efficiency and high availability for all types of biomass [1]. Different biomass types such as rice straw, palm kernel shell, pine kernel, miscanthus, switchgrass, coffee, grape waste, sawdust and chips, sewage sludge, apricot stones, algae, safflower seed cake have been tested for hydrogen production via gasification. Amongst these options, spent coffee grounds (SCG), which is the solid residue obtained after the roasted coffee brewing process, is especially interesting thanks to its high organic content as well as its widespread availability, as coffee is consumed extensively on a global scale. Furthermore, SCG is normally incinerated or disposed of in landfills, a practice that is considered unsustainable and potentially dangerous for both humans and the ecosystem, due to the fact that SCGs contain significant amounts of compounds with established toxicity [2]. Hence, utilizing SCGs to produce hydrogen appears to be a not only economically but also environmentally beneficial process.

In this study, we calculated the life cycle carbon footprint of utilizing SCGs to produce hydrogen via steam gasification. Details regarding different scenarios that were considered, system boundaries and assumptions can be found in the following sections.

ANALYSIS

Life cycle assessment (LCA) is an effective tool for evaluating a product's environmental burden by quantifying the impacts of all inputs and outputs associated with corresponding production processes. The methodological guidelines of LCA are laid out in the ISO 14040 and ISO 14044 standards. In this study, CCaLC2 LCA software was used to model the system and estimate its carbon footprint (CF) according to the CML 2001 methodology.
Technical details of producing hydrogen from SCG can be found elsewhere [1,3-7]. By using experimental data regarding the mass inputs and outputs and referring to the literature regarding the energy requirements of the process, a life cycle inventory table was prepared. Table 1 below shows the life cycle inventory for the hydrothermal carbonization followed by two-step steam gasification scenario. It must be noted at this stage that while similar tables were prepared for every single scenario, only one sample table was included in the manuscript so as to adhere to the rule on page limitation.

Table 1. Life cycle inventory of hydrogen production via two-step steam gasification of hydrochar obtained by hydrothermal carbonization

Step	Inputs	Outputs / Emissions	Amount	Ecoinvent dataset (as available in CCaLC library)
Hydrothermal carbonization	Water		0.006 kg	Water, ultrapure, at plant
	Electricity		0.216 MJ	Turkish electricity (manually adopted from [8])
	SCG		0.1 kg	-
		CO_2	0.005 kg	Carbon dioxide
		CO	0.001 kg	Carbon monoxide
		Hydrochar	0.1 kg	-
Drying	Hydrochar		0.1 kg	
	Thermal energy		0.15 MJ	Heat, at hard coal industrial furnace 1-10 MW
		Dried hydrochar	0.04 kg	-
Two-step steam gasification	Dried hydrochar		0.04 kg	-
	Nitrogen		0.0047 kg	Nitrogen
	Water		0.000012 kg	Water, ultrapure, at plant
	Thermal energy		0.670 MJ	Heat, at hard coal industrial furnace 1-10 MW
	Electricity		0.00003 MJ	Turkish electricity (manually adopted from [8])
		Hydrogen	0.00436 kg	-
		CO_2	0.047 kg	Carbon dioxide
		CO	0.00239 kg	Carbon monoxide
		Tar	0.0006 kg	Disposal, asphalt, 0.1% water, to sanitary landfill

RESULTS AND DISCUSSION

The results of our analysis can be found in Fig. 1 below.

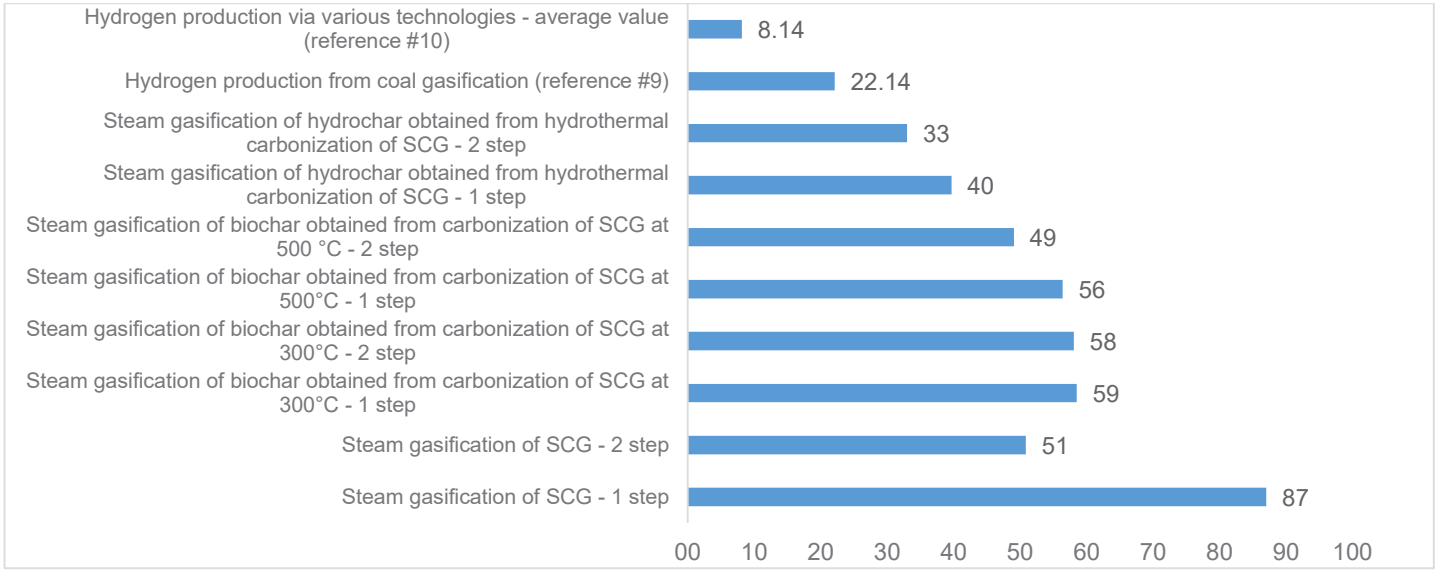

Fig. 1. CF of different hydrogen production from SCG scenarios and comparison with the literature

CF values presented in Fig. 1 were obtained by modelling the life cycle inventory of every single scenario in CCaLC and obtaining the respective CF values, and then calculating the CF value of not utilizing the SCG, i.e. landfilling it as biodegradable waste, and finally taking the difference of the CF value of hydrogen production and the CF value of SCG landfilling. In other words, we also considered the avoided CF as a result of not disposing the SCG.
As shown in the figure, the most environmentally friendly way of producing hydrogen from SCG is the two-step steam gasification of hydrochar obtained from hydrothermal carbonization whereas direct one-step gasification of SCG turned out to be the alternative with the highest carbon footprint. In general, two-step gasification was found to have

a lower carbon footprint compared to one-step gasification for a given process. Interestingly, this is not because of the reduced CO_2 emissions of the two-step gasification process, actually for the same amount of SCG input, the carbon footprint associated with the two-step gasification is on average 5.5% higher than that of one-step gasification. However, hydrogen yield of two-step gasification is significantly higher than that of one-yield gasification due to the improved degradation of the tar [1], with an average increase of 36.2%. Therefore, carbon footprint of producing unit amount of hydrogen turned out to be lower in the case of two-step gasification. Compared to the literature, the carbon footprint of hydrogen production from SCG is generally higher. This can be attributed to the fact that most of the data in this work is experimental and scaling up the process into industrial scale would reduce the energy consumption per unit of mass input, leading to results that would be more consistent with those reported in the literature.

CONCLUSIONS

It was concluded that having a carbonization stage prior to gasification is essential if carbon footprint is to be reduced. Obtaining hydrogen from hydrochar rather than biochar was found to be a more environmentally-friendly option. Two-step gasification was found to have a much lower carbon footprint compared to one-step gasification.

Future work concerning the environmental analysis of hydrogen production from SCG should focus on scaling up the process in order to be able to get more accurate results. Also, a more comprehensive LCA study that covers additional impacts such as acidification, eutrophication, and human toxicity potential can give a clearer idea about the environmental of footprint of utilizing SCG.

THE POTENTIAL OF USING MICROALGAE IN PHOTOBIOREACTORS FOR H_2 PRODUCTION

[1*]*Sergei Markov*

ABSTRACT

Many species of microalgae produce molecular hydrogen (H_2) in reactions catalyzed by the enzymes hydrogenase or nitrogenase. This H_2 production is coupled with photosynthesis. Thus, it is possible to design photobioreactors in which solar energy can be used for the production of H_2. Our research and development efforts were concentrated on designing hollow-fiber photobioreactors incorporating green algae and cyanobacteria. We have continuously for six months operated hollow-fiber photobioreactors for the photoproduction of H_2 from water using two metabolically different species of microalgae. One photobioreactor employed green alga *Chlamydomonas reinhardtii*. Hydrogen production was measured under partial vacuum at the average rate of 6.0 ml • g cell dry weight $^{-1}$ • h^{-1}. Another photobioreactor utilized cyanobacterium *Anabaena variabilis* with average H_2 photoproduction rate of 20 ml • g cell dry weight $^{-1}$ • h^{-1}. In both photobioreactors the duration of H_2 photoproduction was 6 months long.

Keywords: Biohydrogen, Photobioreactors, Hollow-fibers, Microalgae, Cyanobacteria

INTRODUCTION

Some photosynthetic microalgae, including cyanobacteria, can produce molecular hydrogen (H_2) from water using light as an energy source. Biological H_2-production based on photosynthetic water splitting is potentially attractive for industrial applications, because we have plenty of sunlight and water around. The industrial potential of microalgae for H_2 production will eventually be determined by their cultivation techniques [1]. Current production of microalgae for practical purposes is achieved in open “raceway” ponds of some thousand square meters in size [2]. These systems are not suitable for direct H_2 production by microalgae mainly due to H_2 collection. The demand to overcome this limiting factor has led to the development of H_2 production photobioreactors [3]. Photobioreactors are types of closed culture vessels used to grow photosynthetic organisms under controlled conditions with light as the energy source. Many types of photobioreactors are available for algal cultivation, but only few of them are suitable for H_2 production. Some important considerations for designing H_2-producing photobioreactors are the following: they should be simple and energy efficient, they should allow effective gas exchange and be gas tight to avoid the loss of H_2 and efficiently utilize solar energy. A hollow-fiber photobioreactor, specific only for H_2 production by microalgal species, was developed in our laboratory and it is the main subject of current paper. Hollow-fiber bioreactors contain hundreds of hollow fibers with cells attached to them [4]. Hollow fibers are made of semipermeable polymeric membranes, and salts and gases can diffuse freely through them. Microalgal cells, due to their larger size, cannot pass through the membrane, but rather grow on the hollow fiber surfaces as immobilized cells. The large surface-to-volume ratio of the hollow fibers also allows the algal cells to grow to high densities in this type of photobioreactor. Another advantage of photobiorectors containing algal cells immobilized on hollow-fibers is that they can be operated continuously for long periods of time [5].
Two types of metabolically distinct forms of microalgae were used in our photobioreactor: green alga *Chlamydomonas reinhardtii* and cyanobacterium *Anabaena variabilis*.

MATERIALS AND METHODS

Microalgal cultures. Cyanobacterium *A. variabilis* was cultivated in the medium of Allen and Arnon [6] without combined nitrogen. The *Chlamydomonas* CC-503 cw92 (mt+) cell wall-less strain was grown in a Tris-acetate-phosphate medium, pH 7.0 [8]. Both microalgae were cultivated in 250-mL Erlenmeyer flasks with a cell suspension volume of 100 mL. Continuous light was provided by cool white fluorescent lamps (15 µmol · m^{-2} · s^{-1} irradiance at the surface of the culture).
Photobioreactor. Sixty hollow fibers from an AM-40M-5D cartridge (Asahi Kasei Medical CO Ltd, Japan) were sterilized in 20 ppm hypochlorite solution with subsequent rinsing using sterile distilled water, cut into 110 mm lengths, and sealed together at one end with silicone rubber sealant (Aquaria, Dow Corning). To allow light penetration, the hollow fibers were packed into a transparent water-jacketed glass vessel (length, 110 mm; volume, 15 mL). The total surface area of the hollow fibers was 0.002 m^2. Algal cells (9-days old) were also added to the photobioreactor column under sterile conditions as described above. The photobioreactor (Figure 1) was designed in a way that the growth medium was added using a peristaltic pump (LKB 2232 MicroPerpex, Pharmacia LKB Biotechnology, Sweden) from the outside of the fibers within the column. Microalgal cells readily adsorbed to the outer surface of the hollow fibers. The used

growth medium went into the hollow fiber lumens and was pumped back (without being replaced with fresh medium) to the photobioreactor medium
reservoir, in order to create a closed system in which it was possible to measure H_2 production by the cells. Three percent (3%) CO_2 was added periodically to the gas phase (atmospheric levels of O_2 initially) of the photobioreactor reservoir under sterile conditions and maintained at the same level. The photobioreactor was illuminated continuously with cool white fluorescent lamps (45 µmol • m^{-2} • s^{-1} at the top surface of the photobioreactor column). It was operated under room temperature, and the water jacket around the photobioreactor column protected the microalgae from overheating.

Hydrogen production. The photobioreactor column and medium reservoir were vacuum degassed (up to 300 torr) to stimulate H_2 production. Hydrogen production was measured using a Gow-Mac gas chromatograph (Bethlehem, PA) equipped with a molecular sieve 5A column and a thermal conductivity detector. Nitrogen was used as a carrier gas.

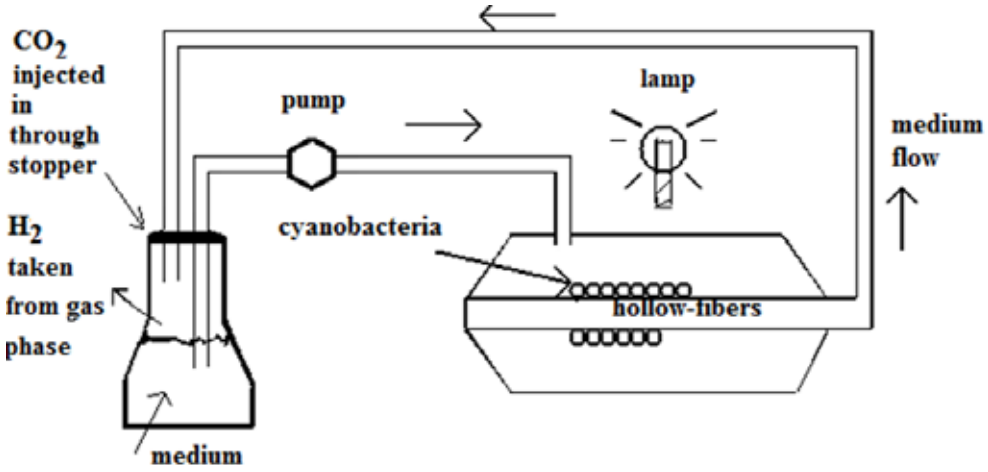

Fig. 1. Schematic representation of a hollow-fiber photobioreactor used for continuous production of H_2 by microalgae.

RESULTS AND DISCUSSION

Photobioreactors H_2 production by green algae

Green algae can produce H_2 from water in reactions catalyzed by the enzyme hydrogenase, but only under anaerobic conditions, because the enzyme is very sensitive to O_2. It very challenging to design photobioreactors for H_2 production by microalgae due to O_2 sensitivity of hydrogenase. Anything that can inhibit photosynthetic O_2 evolution can be useful to stimulate H_2 production by green algae in photobioreactors. One possible solution is to operate photobioreactors under partial vacuum. We produced H_2 in a photobioreactor at rate of 6.0 ml • g cdw^{-1} • h^{-1} continuously for 6 months using immobilized on hollow fibers cells of a green alga *C. reinhardtii* under partial vacuum. Another solution is to stimulate H_2 production in photobioreactors by green algae such as *C. reinhardtii* by photoinhibiting the photosynthetic oxygen-evolving system under high intensity illumination [8]. This high intensity light (more than 2000 µmol • s^{-1} • m^{-2}) is very common in summer in midday in warm climates such US Southern States.

Photobioreactors for H_2 production by cyanobacteria

Cyanobacteria in evolutionary terms are bacteria. They called also blue-green algae because their oxygen evolving photosynthesis is similar to those of algae. In many cyanobacteria specialized cells, heterocysts, are the site of H_2 production. Nitrogenase is the enzyme which catalyzed H_2 production in those cyanobacteria. This enzyme is also very sensitive to O_2. Heterocysts have a number of morphological and biochemical modifications designed to protect the nitrogenase from O_2 inactivation. Thus, compared to green algae, cyanobacteria are unique in their ability to produce H_2 in the presence of O_2. The main function of nitrogenase in cyanobacteria, and other N_2-fixing microorganisms, is to reduce N_2 to NH_3. Simultaneous evolution of H_2 along with N_2 fixation is an inherent property of the enzyme. Under normal conditions the volume of H_2 evolved is only a fourth that of the ammonia synthesized. This low rate of H_2 production is one of the problems of cyanobacterial H_2 production that all applied researchers in this area face. To solve this problem, we operated our photobioreactor under partial vacuum thus reduced the N_2 content (not to lower O_2 concentration as in case of green algae above). The average cyanobacterial H_2 production rate in our photobioreactor was 20 mL • g cdw^{-1} • h^{-1}. The photobioreactor was also operated for 6 months.

CONCLUSIONS

The main advantages of making H_2 by microalgae in our photobioreactors is that this H_2 is coming from water and it is light driven. Although, algal production of H_2 from water is attractive for practical applications, it is very difficult to achieve on a large scale. Rates of H_2 production by algae are much lower compared to bacterial H_2 production (Table 1).

Table 1. Comparative rates of H_2 production by microalgae and bacteria.

Organism	Hydrogen Production Rate in mL H_2 per g of dry weigh per hour	Reference
Microalga Chlamydomonas reinhardtii	up to 6.0	This paper
Cyanobacterium Anabaena variabilis	up to 20	9
Bacterium Enterobacter aerogenes	up to 400	10
Bacterium Rubrivivax gelatinosus	up to 700	11

Our current results demonstrate that it is possible to achieve long-term photobioreactor operation with microalgae immobilized on hollow-fibers. Hollow-fiber bioreactors may have the potential for leading to practical microbial H_2-producing systems in the future. One of the advantages of hollow-fiber photobioreactors is the ability to produce high cell densities, as mentioned above. However, hollow-fiber photobioreactors for H_2 production by microalgae are in their early developments, and are not as yet ready for practical microalgal systems. The price of hollow-fiber photobioreactor construction and operation is crucial factor for further development of these photobioreactors. In general, to improve the economics of H_2 production by microalgae in photobioreactors, H_2 production will have to be combined with synthesis of other useful products, such as single cell protein, specialty chemicals, and other commodities.

ABSTRACT

A unique three-stage integrated system composed of dark fermentation (DF), methanogenesis (M) and photofermentation (PF) in series was developed to maximize the total energy production from unit organic matter (sucrose). The three-stage system aims to minimize the disadvantages of two-stage DF-PF systems and use the advantage of methanogenesis stage via CH_4 production. This study compares the total energy yields (kJ/g soluble chemical oxygen demand, sCOD) of six different reactor configurations, that is, both two-stage DF-M and DF-PF systems to three-stage DF-M-PF systems. Results revealed that three-stage configurations produced a maximum gross heat energy of 13.47-16.11 kJ/g $sCOD_{added}$ and maximum yield equivalence of 9.18-10.80 mol H_2/mol hexose. These values are 14-37% greater than 8 mol H_2/mol hexose, defined to be the economic threshold for application of two-stage DF-PF systems. A methanogenesis stage placed between DF and PF stages was the most significant stage in total energy production.

Keywords: Anaerobic Digestion, Energy, Hydrogen, Methane, Two-stage Systems

INTRODUCTION

Hydrogen is the cleanest energy among other energy sources. When it is produced from wastes via dark fermentation (DF) and photofermentation (PF), it becomes even more valuable because fossil fuels are not used in these processes and the sustainable environment and development approaches are realized. Yet there are some disadvantages of these processes to be economic in application [1]. The major problem in biohydrogen production is the low H_2 production yields and rates leading to the requirement of large volumes and long retention times [2]. The research topics such as development of reactor configurations, sludge immobilization, genetic modifications in microbial cultures, application of two-stage systems, pretreatment of raw materials have been studied to improve H_2 production [1]. The most suitable raw material types, pretreatment methods, operational conditions/modes, culture types and process configurations are still among the topics significant to be investigated. The most effective configuration type for DF-PF integration is still not certain [3].

Two-stage systems are composed of a first-stage DF, which is followed by either PF or a methanogenesis reactor as the second-stage. Anaerobic digestion, where methane is produced via the final methanogenesis (M) step, has been a well-known and widely applied technology all around the world. Yet, its integration into a DF-PF system has not been studied so far. The proposed novel three-stage DF-M-PF system, where the methanogenesis stage will be integrated between DF and PF stages, might have following advantages compared to a DF-PF system. 1) Methanogenesis has higher yields and rates, and is a much more stable process compared to DF; thus, its integration might improve the total energy yield per unit substrate. 2) Biohythane, which is more advantageous compared to sole H_2 and sole CH_4 [4], might be potential to produce in DF-M-PF system. 3) A variety of organics originated from DF stage would be removed in the following M stage. Thus, the effluent of M stage might have lower COD concentration than that of DF; in turn, be more suitable for PF, because PF stage would require less dilution and lower volumes compared to a DF-PF system.

Regarding these potential advantages, a novel three-stage system was developed in a project supported by TUBITAK (Project No: 112M252) [5]. This three-stage system, sequentially composed of DF, M and PF stages, were studied with six configurations differed in operational modes (either in batch, sequencing batch or semi-continuous modes). Two-stage DF-M and DF-PF systems were also operated. This paper, without getting into the details of the reactors' operations, aimed to compare the total energy produced from all two- and three-stage configurations per unit substrate (kJ/g $sCOD_{added}$). It was also aimed to investigate the effect of M stage and three-stage system on energy yield improvement and optimum configuration leading to the highest energy production per unit substrate (sucrose).

MATERIALS AND METHODS

Considering both two- and three-stage systems, six different configurations were compared in this study. Three-stage systems were composed of DF-M-PF in sequence. Two-stage systems were composed of DF-M and DF-PF systems. DF, the first-stage, was performed in sequencing batch reactors (SBRs) in all configurations, and operated at pH of 5.5 and with sucrose at 10 g/L chemical oxygen demand (COD). The effluent of DF was used as the influent of the following stage. In three-stage system, each stage's integration and optimization were gradually applied. This gradual integration involved the conversion of the reactor mode from batch to SBR, which was applied first for M stage and then for PF stage.

Two example configurations are shown in Fig.1a for ***SBR-DF + Batch-M + Batch-PF*** three-stage system and in Fig.1b for ***SBR-DF + SBR-M + SCR-PF*** three-stage system. The operational conditions of each stage shown in Fig.1 are the conditions leading to the maximum energy production from the integrated system. In other words, each stage's operational conditions were previously optimized to achieve the highest energy out of three-stage system. To explain this approach, ***SBR-DF + Batch-M + Batch-PF*** system is selected as an example. In this configuration, for SBR-DF stage, five different operational conditions were investigated [5]. The effluent of each SBR-DF operational condition was collected, stored and then fed to the following triplicate batch M reactors. When the incubation was over, the effluent of each M batch set (run with different DF effluents) was applied as the influent of the following batch PF reactors. In conclusion, SBR-DF + Batch-M + Batch-PF configuration was operated five times for each different DF conditions (five DF effluents). Total energy yields of the three-stage system were calculated for each of the five different DF effluents. The conditions leading to the highest total energy yield from three-stage system were selected as the optimum conditions for DF stage. After setting the optimum DF conditions, the optimization of SBR-M stage was further done in another configuration, where the DF effluent obtained under optimum conditions were applied to the SBR-M. The optimization of PF stage and its conversion from batch PF to semi-continuous reactor PF (SCR-PF) was also performed in another configuration (Fig 1b), following the same approach. All six different configurations studied are shown in Table 1, in Results and Discussion Section. The same reactor codes (such as SBR-DF) indicate that the same operational conditions are valid for that specific reactor type in all configurations (Fig 1).

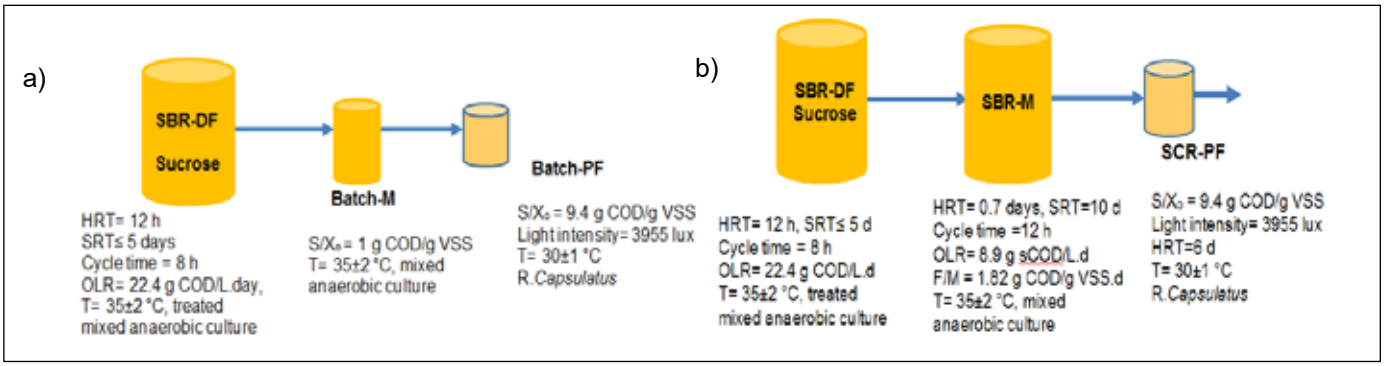

Fig 1. Examples configurations, a) SBR-DF + Batch-M + Batch-PF system, b) SBR-DF + SBR-M + SCR-PF system

In three-stage DF-M-PF system, the incubation period of M stage was shortened in order to remain substrate for the following PF stage; while in two-stage DF-M systems, the incubation period of M stage lasted till the cease of the gas production. In order to compare the total energy yields of each configuration, the yield of each stage was converted to the same unit; that is, g H_2 or g CH_4 produced per g soluble COD (g sCOD) and then the total energy was calculated on the basis of kJ/g sCOD.

RESULTS AND DISCUSSION

The energy yields and its corresponding H_2 yield equivalences obtained from all six configurations are given in Table 1. It is seen that the maximum total(gross) heat energy range of 13.47-16.11 kJ/g $sCOD_{added}$ and maximum yield of 9.18-10.80 mol H_2/mol hexose were obtained via the three-stage configurations (batch, SBR or SCR integrations). These yields are 27-50% greater than the maximum value of 7.2 mol H_2/mol hexose (10.60 kJ/g sCOD) practically obtained so far from two-stage DF-PF systems, and 14-37% greater than 8 mol H_2/mol hexose (11.78 kJ/g sCOD) defined as the economic threshold for application of two-stage DF-PF systems [6].

Among six three-stage configurations, the maximum energy and yield values (16.11 kJ/g sCOD and 10.80 mol H_2/mol hexose) were obtained in SBR-DF + SBR-M + Batch-PF system. This system even produced 7% higher energy yield than that of the theoretical yield (15.12 kJ/g $sCOD_{glucose}$) of a DF-M system. Other three-stage configurations are also of significance for reaching to 89-96% of the energy yield theoretically obtained from a two-stage DF-M system. Considering the energy yields obtained in two-stage DF-M systems (14.64-14.86 kJ/g sCOD),

three-stage systems produced similar energy yields. On the other hand, majority of the three-stage systems had greater energy yields than that of a single-stage anaerobic digestion system where the energy yield would be 13.85 kJ/g $sCOD_{glucose}$. The results also revealed that two-stage DF-M systems are much more advantageous than DF-PF systems.

Table 1. The maximum energy and H_2 equivalence yields obtained from two-stage and three-stage integrated systems

Stage type	Integrated reactors' configurations	Total gross energy of integrated systems [a] (kJ/g $sCOD_{added}$)		Yield Equivalences (Unit H_2/ unit C source) [a]	
		Gross	Net	g H_2/g sCOD	mol H_2/mol hexose
Three-stage systems	SBR-DF + Batch-M + Batch-PF	13.47	11.58	0.095	9.18
	SBR-DF + SBR-M + Batch-PF	16.11	14.11	0.110	10.80
	SBR-DF + SBR-M + SCR-PF	14.55	12.80	0.103	9.90
Two-stage systems	SBR-DF + Batch-M	14.64	13.03	0.103	9.90
	SBR-DF + Batch-PF	9.50	8.00	0.067	6.48
	SBR-DF + SBR-M	14.86	13.23	0.105	10.08

[a] Gross heating values; H_2: 141.8 kJ/g, CH_4: 55.58 kJ/g, Net heating values; H_2:119.47 kJ/g, CH_4: 49.98 kJ/g [7]

CONCLUSIONS

This study revealed that a novel three-stage system, composed of DF-M-PF in sequence, increased the energy obtained from unit organic matter by 7% to 50% compared to the studied two-stage DF-M and DF-PF systems and also theoretical values. More importantly, a methanogenesis stage integrated between DF and PF stages in a two-stage DF-PF system significantly improves the total energy yield, by 27-50%. The main role in energy production was found as M stage in a DF-M-PF system. Therefore, if it is aimed to improve the bioenergy obtained from unit organic matter in a DF-PF system, one should involve the methanogenesis stage and concentrate on optimization of this stage.

Three-stage systems have similar energy yields as that of DF-M systems; thus, seem to be less economical when the additional (a third) reactor's capital and operational costs are considered. However, in-depth economic analysis should also involve the expenses for the treatment of DF-M effluent required to improve the effluent characteristics to the discharge criteria. Three-stage systems would have lower effluent concentrations which will decrease the total operational/management costs. Three-stage systems might be of significance especially for high-strength (> 10 g/L COD) waste's operation, because the effluent of M stage would have higher carbon sources for the subsequent PF stage, which will have in turn higher H_2 yields and more significant role in total energy production.

ABSTRACT

Yard waste, an abundant lignocellulosic biomass, was used as the substrate in a two-stage anaerobic digestion system (TSAD) conducted for hydrogen and methane production. The effect of initial solids concentration (2%, 5% and 8% Total Solids, TS) and pre-treatment options (alkaline, thermal and ultrasound) on H_2 or CH_4 production yield in TSAD were investigated. Batch experiments showed that the highest hydrogen production (30.5 mL H_2/g VS) was observed in alkaline pre-treated (AP) yard waste with 2% TS in the first-stage of TSAD. Alkaline pre-treatment was the best alternative for all three initial TS contents studied in terms of H_2 yields. The highest methane yield (around 40 mL CH_4/g VS), on the other hand, was obtained with thermal pre-treated (TP) yard waste with 2% TS in the second-stage of TSAD. Thermal pre-treatment improved the methane yield for all three TS contents. Overall, this study revealed that, despite the low yield levels, alkaline pre-treatment and 2% initial TS application provided the highest total energy gain from yard wastes in TSAD (2 MJ/kg VS_{addded}) followed by thermal pre-treatment. Independent of the pre-treatment type, the increase in TS contents decreases the yield and the energy production potential from yard wastes.

Keywords: Two-stage Anaerobic Digestion, Dark Fermentation, Biohythane, Yard Waste

INTRODUCTION

In the last two decades, global programs, working on alternative energy, are interested in new and sustainable energy sources since global economy cannot depend on fossil fuels anymore [1]. Biomass is one of the most important renewable energy sources. Yard waste is known as a high potential biomass source. It mainly consists of grass clippings, leaves, cut flowers, potted plants, weeds, bushes, branches and twigs [2]. In recent years, using yard wastes as biomass resource has been supported not only for its abundance but also its contribution to reduce greenhouse gas emissions, encourage regional economies, providing reliable biomass energy sources and limit the competition with food sources [3]. Yet, due to its lignocellulosic nature, pre-treatment or two-stage anaerobic digestion (TSAD) applications might be required for yard wastes to address their solubilization / biodegradability problem.

Hydrogen, has high energy content (141.8 kJ/g), which is 2.75 times higher than other hydrocarbons. For being a clean carbon-free fuel and generating only water after combustion, it is an effective option in researches to address global warming and increasing pollution problems [4]. In conventional anaerobic digestion, i.e. one-stage anaerobic digestion (OSAD), hydrogen can't be observed since it is degraded immediately to produce CO_2 and CH_4 [5]. However, H_2 can be generated individually by maintaining the proper engineering conditions. Lately, H_2 production through dark fermentation (DF) gained interest. The primary drawback is low energy recovery; because it does not reduce organic substrate totally and organic removal is below 20% which gives a low yield value of 10-20% [6]. To destruct all organic acids generated during DF and increase overall energy recovery, TSAD process, involving H_2 production by DF followed by CH_4 by methanogenesis is suggested [5;7]. TSAD is a relatively low-cost alternative to produce a mixture of H_2 (5-20%) and CH_4 (80-95%) labeled as "hythane", and in turn "biohythane" for being generated via biological means [8]. As an energy source, burning hythane is safer and cleaner than methane alone [9].

In this study, TSAD of yard waste (50% grass and 50%-yard trimmings, w/w) was investigated in terms of H_2 and CH_4 production yields. Three different pre-treatment options (alkaline, thermal and ultrasound) and initial total solids concentration (2%, 5% and 8% TS) were also integrated, in order to define optimum conditions leading to the highest energy production per unit solids.

MATERIALS AND METHODS

Inoculum and Substrate: Seed sludge (inoculum) used in all experiments was obtained from Greater Municipality of Ankara Wastewater Treatment Plant's anaerobic digestors. TS amount of inoculum is 6583±27 mg/L, VS is 51±1%. Yard wastes as the substrate, were gathered from METU Campus and sundried within the duties of METU Directorate of Construction and Technical Works. Foreign objects like plastic, branch and metal were sorted. Then,

grass and yard trimming wastes were dried at 40°C for 24 hours, in order to reduce moisture content less than 10% [10]. Size of wastes were reduced with food blender, ground in hammer mill and then screened from 20 mesh screen sieve. Grass and yard trimming wastes were then mixed with 1:1 ratio, sealed in plastic bags and stored at -20°C in order to prevent biological activity prior to use in all experiments. This dried and sieved waste mixture is defined as yard waste in the following text.

Pre-treatments: For alkaline pre-treatment (AP), 1 g yard waste was treated with 20 mL, 2% (w/v) NaOH solution. 5% (w/v) solids loading was achieved and pH was fixed at 12. This mixture was heated at 45°C for 30 minutes on a heater [11]. For thermal pre-treatment (TP), 1 g of yard waste is solubilized in 10 mL distilled water and heated at 120°C and 1.5 atm pressure in an autoclave for 30 minutes [12]. Ultrasound pre-treatment (UP) was done with an ultrasound bath (Sartorius Labsonic-P). The maximum power input of the sonicator was 400 W and sonication frequency was 24 kHz. For each TS% value, 1 g yard waste mixture was mixed with 40 mL distilled water. Without any temperature arrangement, sonication was experienced for 15 minutes.

TSAD experiments: In the first-stage of TSAD experiments, batch reactors with total volume of 110 mL and effective volume of 60 mL were used. Experiments were performed with four different batch set-ups, including blank, control and test reactors of raw and pretreated yard waste mixtures, individually. All reactors were composed of specified basal medium (BM) [13], pretreated or not-pre-treated yard waste with certain TS% amounts (2%, 5% and 8%) and inoculum. Inoculum was heat pre-treated for 1 hour at 105°C. Substrate/Inoculum ratio (S/I) was set as 4. Initial pH values were adjusted to 7. In the second-stage of TSAD (i.e. methanogenesis step), DF reactors were filtered and, these filtrates were used as substrate of methanogenesis stage. Batch reactors with 50 mL total volume and 30 mL effective volume were used. Proper amount of inoculum seed, basal medium and water were added in order to arrange S/I as 1 in the reactors. Initial pH values were set to 7. For both stages, after sealing with rubber stoppers, reactors were flushed with 100% N_2 gas for 5 minutes, placed on a shaker at 175 rpm in a hot room at 35±2°C. Daily biogas production and gas composition analyses were performed in order to determine the hydrogen and methane production potential of the reactors.

RESULTS AND DISCUSSION

- According to the results shown in Table 1, the highest H_2 yield was obtained with AP 2% test reactor as 30.5 mL H_2/g VS in the first-stage of TSAD. As solids percentage increases, H_2 yields generally decrease. AP was found as the best alternative in producing high H_2 yields from yard wastes for all solid contents studied.
- Maximum H_2 yield increases were obtained for 2% TS in all pre-treatment options. Compared to no pre-treatment (NP) case, AP increased H_2 yields for 2%, 5% and 8% TS by 73%, 48% and 85.5%, respectively.
- CH_4 production was also observed during DF in all test reactors, indicating the ineffective heat pre-treatment of inoculum and also intrinsic microorganisms potential to exist in the yard waste mix and contributing to CH_4 generation. Hydrogenotrophic methanogenesis as well as homoacetogenesis might have led to lower H_2 yields.
- For all three solid concentrations, the highest methane yield (~ 40 mL CH_4/g VS) was obtained with TP 2% test reactor in the second-stage. TP was found as the best alternative among others in terms of CH_4 yields. However, obtained CH_4 yield results are very low, compared to the theoretical methane yield (395 mL CH_4/g VS). This was attributed to the potential inhibitory by-products of DF and pretreatment methods, which remains to be researched.
- Overall, cumulative yield data shows that AP 2% reactor provides the optimum total energy gain in TSAD with yard waste, since there was additional methane production coming from the first-stage of TSAD, originated from intrinsic microorganisms which has not been exposed to heat pre-treatment.

CONCLUSIONS

This study revealed that alkaline pre-treatment is the optimum option leading to the highest H_2 production yields compared to thermal and ultrasound pre-treatment options. Alkaline pre-treatment improved the H_2 yields by 48-85% compared to the no pre-treatment case. The filtered effluent of the first-stage of TSAD, i.e. DF step, was used as the substrate of the second-stage (i.e. methanogenesis). In second-stage, thermal pre-treatment was found as the option leading to the highest CH_4 production for all three TS concentrations studied. Yet, it should be noted that the total CH_4 production from alkaline pre-treated waste was even greater than that of thermal pre-treated waste, because methane was also observed during DF step. Nevertheless, the total energy obtained from two-stage anaerobic digestion of yard waste achieved 0.3-2.00 MJ/kg VS_{added} of energy production. The highest total energy production per unit solids was obtained in alkaline pre-treated yard waste with 2% TS content. This study also revealed that lower initial solids concentrations (2% TS) enable to apply all pre-treatment options efficiently; but at higher TS%, gaining feasible yields and, in turn, energy productions become harder.

Table 1. Cumulative hydrogen and methane yields and related energy productions in each reactor type

Pre-treated yard waste [a]	TS, %	Yields (mL H_2 or CH_4 /g VS)			Energy (MJ/kg VS $_{added}$) [b]

A THERMOSIPHON BASED PHOTOBIOREACTOR FOR PHOTOFERMENTATIVE HYDROGEN PRODUCTION

[1] Bovinille Anye Cho, [1] Calizé Bosman, [1]Steven Bradshaw [1] Robert W. M. Pott*
[1]Department of Process Engineering, Stellenbosch University, South Africa

ABSTRACT

Photofermentation is a process driven by, primarily, anaerobic photosynthetic bacteria. Significant advances have been made in the field with regards hydrogen productivity using these organisms, however, comparatively little work has been to develop reactors optimised for photofermentation. This paper presents a novel photobioreactor, designed with anaerobic photosynthetic organisms in mind: the thermosiphon photobioreactor (TPBR). This reactor utilises absorbed light to drive passive circulation, potentially reducing operating costs, and allowing for continuous hydrogen production. The prototype reactor's thermal and hydrodynamic performance was investigated using Computational Fluid Dynamics (CFD) and validated with experimentation. Using *Rhodopsueduomonas palustris* as an exemplary photofermentative organism, the TPBR operation was demonstrated at laboratory scale. Hydrogen production and bacterial growth were shown to be in line with that seen in test bioreactors. The CFD results demonstrated good agreement with experimental data, indicating that the model has functionality in predicting fluid operation in this reactor. Further, the TPBR demonstrated excellent liquid circulation with up to 88% of the microbial cells kept in free suspension, using only passive circulation. The TPBR is demonstrated as an anaerobic photobioreactor system entirely agitated using passive circulation, which has the potential to be used as a low energy-input reactor for photosynthetic organism cultivation.

Keywords: Thermosiphon Photobioreactor (TPBR), Photosynthetic Bacteria, Biohydrogen, Photofermentation

INTRODUCTION

The photosynthetic bacterium *Rhodopseudomonas palustris* demonstrates an exceptional metabolic diversity, consuming many compounds which other organisms find toxic [1]. Its metabolism makes it useful for the degradation of recalcitrant organic wastes, and the purification of industrial waste waters. Furthermore, it is robust and is therefore an attractive organism for use in industrial bioprocesses. *R. palustris* combines its metabolic diversity with the ability to produce high purity hydrogen, through the action of the enzyme nitrogenase. This biohydrogen can then be used in fuel cell for the production of electricity, or other hydrogen reliant processes [2,3].

Hydrogen is regarded as a clean, high energy fuel and is particularly useful in fuel cells owing to very high conversion efficiencies. Currently most hydrogen is produced by steam reforming of natural gas, which, rather than reducing the use of fossil fuels and carbon emissions, merely shifts them to an earlier production step[4]. Therefore methods for producing hydrogen which are not dependent on fossil feed-stocks are needed, such as the reforming of biomass, the electrolysis of water and biological hydrogen production [5].The biological production of hydrogen has a number of advantages over the biological production of other fuels and chemicals. For example, it circumvents the problem of producing a dilute aqueous product stream, which then requires significant purification, likely to be needed if the substrate were converted to liquid-phase products in a biological process, such as ethanol, or butanol. Hydrogen is relatively insoluble in water and so partitions almost entirely into the gas phase, significantly reducing purification costs compared with the production of a soluble biochemical [6,7].

Since its photometabolism is significantly different to that of microalgae (for which most photobioreactors (PBRs) are designed), a novel PBR can be designed to optimize hydrogen production and waste organics degradation. Because the metabolism of *R. palustris* requires incident light to drive the reformation of organic compounds to hydrogen, we can use this absorption as a driver for fluid mixing, utilising the thermosiphon effect, which is the physical effect of fluid flowing because of density differences due to temperature effects. The design of a PBR on the thermosiphon effect has not been described in the literature previously, although thermosiphons are commonly utilised in solar water heating systems [8,9].

This paper aims to demonstrate the utility of a novel photobioreactor, which utilises the thermosiphon effect to drive passive circulation, for the cultivation of anaerobic photosynthetic bacteria. A CFD tool is developed to understand the fluid flows, velocities and temperatures in the reactor, and experiments are conducted to examine the hydrogen production and cell circulation developed in the reactor.

MATERIALS AND METHODS

Bacteria and culture methods

Rhodopseudomonas palustris strain NCIB 11774 was obtained from ATCC (ATCC® 17007™) and grown in modified *Rhodospirillacea* minimal medium consisting of (/L): 0.57g KH2PO4, 1.86g K2HPO4, 0.4g NaCl, 0.2g yeast extract, 0.25g Na2S2O3.5H2O, 0.2g MgSO4.7H2O, 0.05g CaCl2.2H2O, 0.005g Ferric citrate, 0.002g para-aminobenzoic acid. Growth medium was adjusted to pH 7.2 before autoclaving, with subsequent addition of sterile glycerol and glutamate and 1ml per litre trace element solution as per [7].

Test Photobioreactor setup

Cultures were grown in 500 ml bioreactors comprised of borosilicate reagent bottles and lids fitted with gastight stainless-steel liquid and gas sampling tubes; sterilised by autoclave. Anaerobic conditions were induced by sparging cultures with argon through a 0.2 µm PTFE filter for 10 min. Agitation was provided by magnetic stirring at ±200 RPM with 50mm PTFE coated stirrer bars and illumination by 100W tungsten-filament incandescent lightbulbs. Irradiance intensity was calibrated to 200 W/m2 (± 20) in the wavelengths between 500 – 1100 nm, corresponding to the range utilised by *R. palustris*, using a compact spectrometer with cosine correcting probe (RGB photonics Qmini VIS-NIR). Temperature was controlled by immersion of bioreactors in a water-filled glass tank fitted with heating circulator and cooling as required to maintain temperature at 35°C ± 0.2°C. Gas produced was collected by displacement of water in inverted 1L measuring cylinders connected to each gas sampling port with low hydrogen-permeability tubing (Tygon E-3603, Saint-Gobain) and one-way check valves.

TPBR prototype setup and operation

A 1-L working volume laboratory scaleTPBR was designed and fabricated from glass (denoted in Figure 1), adapted from thermosiphon designed for solar water heating, and that published by [8]. Specifically the reactor was modified to meet the purpose of photosynthetic microorganism cultivation. For significantly more detail see: [10].

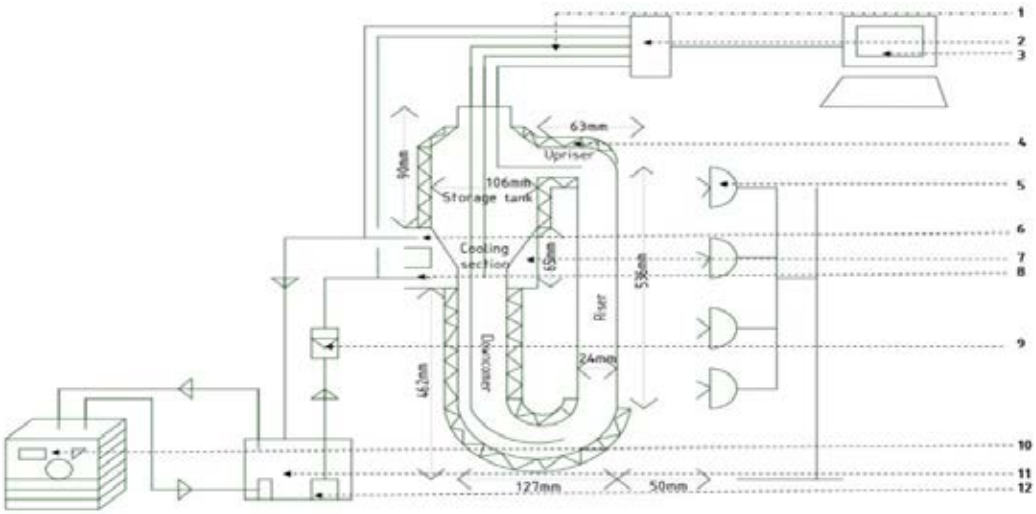

Figure 1: Schematic diagram of the experimental setup: (1) Thermocouples, (2) Data acquisition unit, (3) Computer, (4) Thermal insulation (5) Halogen lamps, (6) Cooling water outlet, (7) Cooling water inlet, (8) cooling section (9) Rotameter, (10) water Chiller, (11) Reservoir, and (12). Submersible water pump.

Circulation experiments were conducted with water, and heat treated bacterial cells, to determine temperature and velocity gradients within the TPBR. Additionally, growth and hydrogen production experiments were conducted with living *R. palustris*, at an initial loading rate of Kg/m^3. Illumination was provided by four halogen lamps (150 watt each, EUROLUX FS13B), to simulate sunlight. These lights illuminated the riser. Cooling was provided by a cooling jacket with circulating cooled water at 0.5L/min, 17°C. The thermocouples (RTD, PT100, Simplex, and Class A) within the reactor were connected to a 4 channel data-acquisition unit (WIKA Instruments REB(TR40)) with data recorded at intervals of 60s. Gas production was monitored via an inverted measuring cylinder in water, and the gas composition determined using gas chromatography. The biomass concentration was determined using optical density measurements at 660nm, tracked against a cell dry weight-OD calibration curve.

RESULTS AND DISCUSSION

The results of the CFD simulations adequately represented the physical thermosiphon experimentation.
shows the flow profile within the TPBR, with the greatest

velocity achieved at the light-side wall – unsurprisingly, as this is the area where most light energy is converted into heat, giving rise to the thermosiphon buoyancy effect. The simulation indicates that the circulation velocity is sufficient for biomass circulation; a finding which is strengthened by experiments in the laboratory scale thermosiphon showing good cell circulation. Nonetheless, there are potential limitations; for instance, if the thermosiphon operates on sunlight, then during the night the thermosiphon effect will dissipate, fluid will no longer circulate, and the cells will settle.

In this work, CFD modeling and experiments have been used to support the development of a thermosiphon photobioreactor (TBPR), where fluid circulation is achieved by temperature difference arising from light absorption.

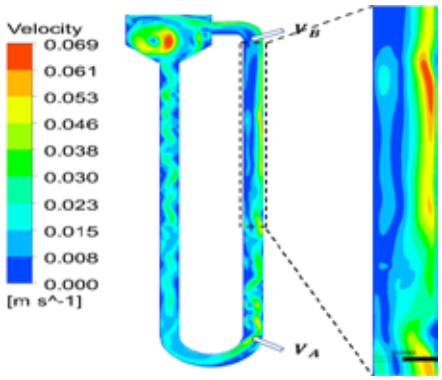

Figure 2: Velocity contours of the CFD simulations showing the two velocity notation points and the riser's flow profile.

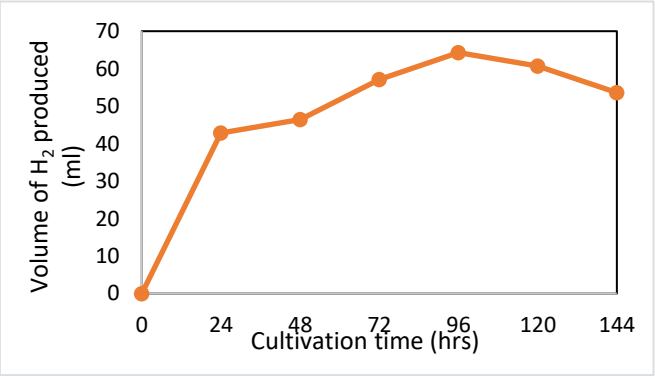

Figure 3: hydrogen production within the TPBR by *R. palustris* cultivated on 50mM glycerol

The hydrogen production of *R. palustris* in the TPBR compares well with that in normal test photobioreactors, with specific hydrogen production rates of around 5 $ml.g_{DCW}^{-1}.h^{-1}$. Indeed the hydrogen production appeared to improve cell circulation, by hydrogen bubbles coming out of solution in the riser, and adding to the heat-aided buoyancy effect. A larger scale TPBR has been fabricated, and is currently under assessment for its passive circulation with and without photofermentative bacteria present – instead of a cooling loop, in this larger reactors' case a set of metal cooling fins has been used (a more water-wise solution to cooling); similar velocities have been achieved in this reactor.

CONCLUSIONS

This paper has outlined the development, fabrication, experimentation and modeling of a novel photobioreactor, designed for use with photofermentative bacteria: the thermosiphon photobioreactor. The reactor was successfully fabricated, tested, and modelled using CFD, with good agreement between modelled and experimental validation. Sufficient flow velocities are achieved, within the temperature limits of the organism, and using simulated sunlight, for cell suspension. Hydrogen production experiments have shown the organisms continue to produce hydrogen at a comparable rate in these reactors, as opposed to normal test photobioreactors. Larger scale experiments indicate good cell circulation when using heating fins instead of cooling water, and these larger TPBRs have shown good hydrogen production under environmental conditions.

ABSTRACT

Decarbonizing the economy has become one of the main concerns in Colombia, where hydrogen (H_2) plays an outstanding role. H_2 is obtained through different pathways, including water electrolysis or by thermochemical pathways such as the ethanol steam reforming (ESR). The latter process is an interesting alternative for those areas where residual biomass is highly available. The non-centrifugal sugar agroindustry has an important role in the Colombian economy and produces different residual biomass that can be employed to produce H_2 by coupling alcoholic fermentation and ESR. Herein, the technical and environmental assessment of the conversion of sugarcane press-mud, a residual biomass of this sector, into H_2 was performed. Technical analysis revealed that sugarcane press-mud should be pretreated under hydrothermal conditions and fermented with a pH of 4.5 to decrease fusel alcohol which have a negative impact during ESR. In terms of environmental impact, H_2 could be used as energy vector to produce heat and replace sugarcane bagasse to mitigate greenhouse gases emissions. Therefore, the upgrading of sugarcane press-mud into H_2 will have a positive impact on climate change and this technology could be employed to decarbonize the Colombian economy.

INTRODUCTION

Overcoming the issues associated with climate change is aligned with the United Nations agenda and Sustainable Development Goals (SDG). Indeed, SDG 7 seeks to ensure access to affordable, reliable, sustainable, and modern energy for all. In addition, one of the main targets of SDG 7 is: *"By 2030, expand infrastructure and upgrade technology for supplying modern and sustainable energy services for all in developing countries".* Recently, Colombia stablished the Energy National Plan 2020-2050 that aims to move towards into a clean energy system where hydrogen (H_2) has become the main actor in the energy transition [1]. H_2 is an energy vector that could be employed to produce either heat or power without direct emissions of greenhouse gases by using fuel cells. These devices are affordable for rural areas where power grid is unavailable [2]. H_2 could be produced by water electrolysis boosted by solar and wind power. However, in areas where solar and wind are scarce, the use of other sources could be employed. Colombia, as an agricultural country, produces larger amount of residual biomass that could be upgraded into H_2. Among agro-industrial sectors, non-centrifugal sugar plays an outstanding role within the social and economic development of Colombia. During non-centrifugal sugar production, different residual biomass is yielded, including leaves, buds, bagasse, and sugarcane press-mud. The latter has been used for producing H_2 by coupling alcoholic fermentation and ethanol steam reforming (ESR), where the yields ranged between 4.0 to 6.0 g H_2/kg sugarcane press-mud [3]. One of the main issues associated with the conversion of biomass to H_2 by ESR is the presence of impurities (e.g., fusel alcohol and acetic acid) that limit the conversion of ethanol [4]. Hence, it is key to develop alternatives to mitigate those compounds to enhance H_2 by ESR. Recently, we assessed the effect of both pre-treatment and fermentation conditions on the production of bioethanol for its further conversion into H_2. According to those preliminary results, addition of nitric acid had a strong influence on the production of impurities during sugarcane press-mud fermentation [3]. Besides, the pH during fermentation also had an effect on the formation of impurities [4]. Based on the above, the next step is to design the complete process to produce H_2 from sugarcane press-mud with aim to be used in a non-centrifugal sugar facility. Therefore, the aim of this study was to determine the environmental benefits on the use of H_2 within a non-centrifugal sugar facility.

MATERIALS AND METHODS

Bioethanol production

Bioethanol was obtained through the pretreatment, fermentation, and distillation of sugarcane press-mud by using a stainless-steel Alembic of 24 L. The alembic was coupled with a stirrer. Two factors were assessed: type of pretreatment (i.e., hydrothermal and acid hydrolysis) and pH of fermentation (i.e., 4.5 and 5.5). Pretreatment of sugarcane press-mud was carried out at 70 °C for 2 h. Afterwards, alembic was cooled down, and supplemented with nutrients, as reported elsewhere [3]. Fermentation was performed using a *S. cerevisiae* yeast strain, previously propagated and activated in

YPD (yeast extract 10 g/L, peptone 20 g/L, and glucose 20 g/L), at room temperature and 200 rpm for 42 h. After fermentation, bioethanol was distilled until the steam-to-ethanol ratio was 4.2:1.0. Ethanol concentration was monitored using a digital refractometer (Anton Paar, Graz, Austria). Fusel alcohol was quantified by gas chromatography (GC) [4].

Syngas production and environmental analysis

Syngas production was carried out in a pilot plan scale which is formed by two reactors in series. The former reactor converts the bioethanol into syngas at 750 °C over a washcoated monolith of $RhPt/CeO_2$-SiO_2. The second reactor removes the carbon monoxide at 260 °C over a washcoated monolith of $AuCu/CeO_2$. Syngas was quantified by GC [5]. Environmental analysis was carried out through the Life Cycle Assessment (LCA) and following the ISO 14040/14044 guidelines [6]. The aim of the LCA is to determine the environmental benefits on the use of H_2 for the non-centrifugal sugar agro industry. Hence, the functional unit was set to 1 ton of non-centrifugal sugar. Life cycle inventory was gathered from interviews in a non-centrifugal sugar facility and experimental data obtained at pilot plant scale level. Impacts were calculated in terms of carbon footprint by using the ILCD midpoint methodology impact assessment.

RESULTS

Bioethanol production

Table 1 shows the ethanol profile after the pretreatment, fermentation, and distillation of sugarcane press-mud. According to Table 1, sample S3, which was pretreated under acid hydrolysis conditions and fermented with a pH of 4.5, delivered both the lowest ethanol (6.05 wt.%) and fusel alcohol concentration (631.8 ppm). While sample S2 yielded the highest ethanol concentration with low fusel alcohol concentration in comparison with the other samples. Sample S2 was pretreated under hydrothermal conditions and fermented at a pH of 4.5. Under acid hydrolysis conditions, H^+ boosts the decomposition of sucrose into glucose. Besides, the formation of organic acids, such as acetic acid, uronic acid, and formic acid, are also yielded. Those acids affect the central metabolism of yeast, and consequently reduce the ethanol concentration [4], [7]. Concerning the formation of fusel alcohol, at low pH values, fusel alcohol formation is inhibited since the key enzymes involved in the Ehrlich metabolic pathway are strongly affect under acidic conditions [8]. Therefore, sugarcane press-mud should be pretreated under hydrothermal conditions and fermented at a pH of 4.5 to produce a bioethanol stream with high ethanol content and less fusel alcohol concentration.

Table 1. Bioethanol profile after distillation

Sample	**S1**	**S2**	**S3**	**S4**
Pretreatment	Hydrothermal	Hydrothermal	Acid hydrolysis	Acid hydrolysis
Fermentation pH	5.5	4.5	4.5	5.5
Ethanol (wt.%)	6.86	7.20	6.05	6.78
Fusel alcohol (ppm)	810.5	793.8	631.8	807.1

Syngas production and environmental analysis

Syngas was obtained through ESR in a pilot plant scale. The H_2 yield was 3.2 mol H_2/mol ethanol whose composition at 750 °C was 29.5 mol.% H_2, 8.4 mol.% CO, 11.6 mol.%, CH_4, 0.1 mol.% CO_2, and 50.4 mol.% N_2. Afterwards, CO was removed at 260 °C, and the clean syngas composition was 25 mol.% H_2, 13 mol.% CH_4, 17 mol.% CO_2, and 45 mol.% N_2. This clean syngas could be fed into a HT-PEMFC to produce power that could substitute the fossil energy used during sugarcane milling or to be used as heat source to avoid the use of sugarcane bagasse. Environmental analysis is shown in Figure 1. Accordingly, non-centrifugal sugar industry has a carbon footprint of -2.57 kg CO_2-eq/kg non-centrifugal sugar. The negative value indicates environmental savings due to the carbon capture during sugarcane growth in the harvest stage. However, the upgrading of sugarcane press-mud into H_2, for its further use as energy source to avoid the use of diesel, will result in a higher carbon footprint. Furthermore, Figure 1 also shows that using H_2 as heat source to avoid the use of sugarcane bagasse will result in 5% environmental savings, since greenhouse gases are not directly emitted to the atmosphere. Hence, the upgrading of sugarcane press-mud into H_2 will have environmental benefits in the non-centrifugal sugar facility.

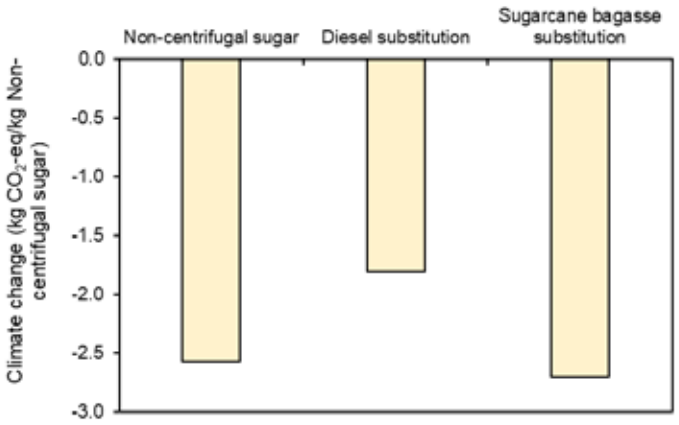

Figure 1. Climate change on the use of H_2 in a on-centrifugal sugar facility

CONCLUSIONS

Conversion of sugarcane press-mud into H_2 by coupling alcoholic fermentation and ethanol steam reforming would have a positive environmental impact if H_2 is directly employed as thermal source. Further studies must seek to design a complete non-centrifugal sugar facility where H_2 is integrated as energy vector. Besides, alternatives on the valorization of other residual biomass would be determined in order to move towards a low-carbon economy.

ACKNOWLEDGEMENT

The authors are grateful to Panelas Don Pedro for supplying the sugarcane press-mud samples. ABSTRACT

Photofermentation of cheap feedstock using sunlight is a promising route for sustainable hydrogen production. While successful laboratory and pilot-scale hydrogen production examples have been demonstrated, the economic feasibility remains to be improved. In this study, a preliminary techno-economic analysis of photobiological hydrogen production was performed, taking into consideration current production technologies.

First, several hydrogen production technologies were investigated and their costs were compiled from literature. The results show that conventional steam reforming of natural gas still offers the least cost. Future trajectories and prices for natural gas were investigated worldwide and for Turkey. In view of the fact that natural gas is a fossil-fuel, predictions show a continuously increasing unit price.

The cost of photobiological hydrogen production was based on an existing outdoor, pilot-scale photobioreactor design. The annual capital cost and operating costs of the plant were calculated as 195 USD/year and 33 USD/year, respectively. Overall, the specific hydrogen production cost was found as 3.8 USD/mol (1890 USD/kg H_2). While this cost is currently unfeasible, it can be decreased via the use of more productive strains combined with valorization of side-products and concurrent treatment of waste.

Keywords: Photofermentation, Biohydrogen, Economic Analysis

INTRODUCTION

Hydrogen is a clean and efficient energy carrier. The energy stored in the hydrogen can be extracted via several devices such as boilers, turbines, internal combustion engines or fuel cells. However for a viable and sustainable hydrogen economy, hydrogen has to be produced using renewable resources. Hydrogen can be produced biologically and renewably using several different types of microorganisms. Photofermentative production using purple non-sulfur bacteria (PNSB) is favorable because of its high theoretical conversion yield, high purity of produced hydrogen, the capability of PNSB to use a wide portion of the light spectrum and their ability to utilize wastes. Pilot-scale photobiological hydrogen production has been demonstrated using both suspension [1] and immobilized [2] cultures. However, to obtain better insight on the prospects of this method, an economic analysis is also necessary. This study highlights the results of a preliminary cost analysis for this purpose.

METHODS

Cost Estimation Methodology

The method utilized by Urbaniec and Grabarczyk [3] was adopted for this study. The fixed and capital costs are evaluated to estimate the price per unit of product, which in this case is hydrogen. The fixed component of the costs includes land and equipment, whereas the operating cost includes maintenance, power and raw materials.

Case Study

An existing 20 L pilot-scale photobioreactor system was selected as the model. The glass reactor has a stacked U-tube geometry, and is combined with a circulation pump, a cooler and a gas collector to constitute a compact, integrated system that can operate outdoors. The bacterial species is R. capsulatus, and the carbon source for hydrogen production is molasses, which is a sugar-rich carbon source that also includes essential nutrients such as amino acids and iron. The molasses is diluted to a concentration of 5 mM sucrose, based on previous studies [1].

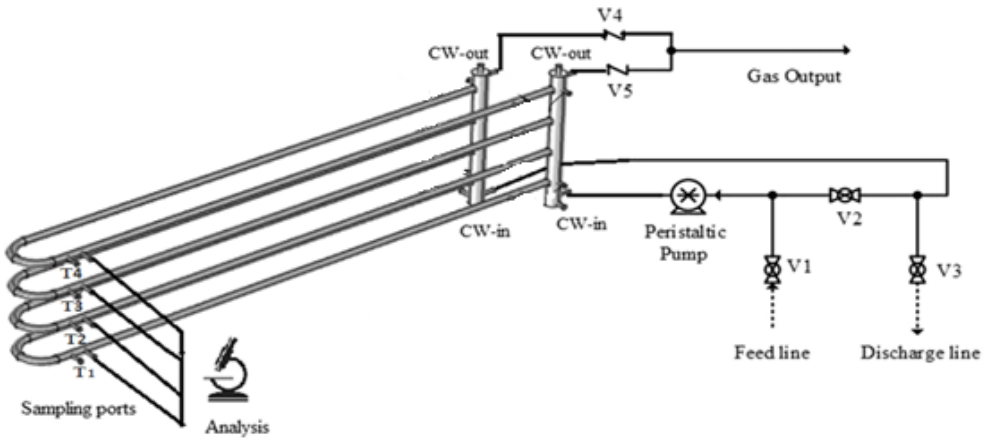

Fig. 1. The Photobioreactor Setup

Assumptions and Data

The reactor setup is assumed to occupy 200 m^2 on non-arable land. All cost data were based on market prices for Turkey. For the photobioreactor system components, the costs were based on the existing custom-manufactured pilot-scale glass photobioreactor, and off-the-shelf prices for the pump and chiller unit. The operating costs are for the electricity used to operate the chiller and the pump, and the water cost to dilute the molasses. The cooling duty of the chiller was based on the incident solar radiation during summer months and a coefficient of performance based on the Carnot efficiency. A life of 15 years was assumed for the plant. The total plant cost was estimated as the sum of the land and equipment costs, i.e. the Lang factor was assumed to be 1.0.

RESULTS AND DISCUSSION

The results of the analysis are summarized in the Table 1 below. Annual capital cost was calculated from the land price and total equipment price as 800 USD/year, whereas the operating cost, composed of maintenance, water, power, chemicals and molasses feedstock was 34 USD/year. Based on our prior studies, a hydrogen production rate of 0.17 mol/day can be achieved in a 20 L reactor operating under natural sunlight. As a result, specific hydrogen production cost was found as 3.8 USD/mol or 1890 USD/kg H_2.

Table 1. Summary of Cost Estimation

Specific Hydrogen Cost	Fixed Capital Cost (195 USD/year)	Total Equipment Cost (2900 USD)
		Land Price (34 USD)
(1890 USD/kg H_2)	Operating Cost (34 USD/year)	Maintenance Cost (16 USD/year)
		Power Cost (2.6 USD/year)
		Chemical Cost (11 USD/year)
		Molasses (4 USD/year)
		Water (0.15 USD/year)

CONCLUSIONS

Compared with current technologies, it is obvious that if photofermentative hydrogen production is to become an economically viable path, the unit cost needs to be decreased considerably, even for improved economies for larger scales. This can be achieved via the reduction of equipment cost e.g. by using passive cooling systems, the use of more productive strains combined with valorization of side-products and treatment of waste material favorable for hydrogen production.

ABSTRACT

In this study two strains of *Rhodobacter capsulatus* were compared in terms of efficiency of hydrogen (H_2) and poly-β-hydroxybutyrate (PHB) synthesis. One strain of *R. capsulatus* (YO3 (*hup*$^-$)) lacked the uptake hydrogenase enzyme, while the other was its wild type (WT). Both strains were grown in a medium with high carbon and minimal nitrogen. The H_2 and PHB contents of the reactors were all measured at the end of the experiment. The cell concentration measurements show that the growth trends were similar in both strains. The maximum H_2 productivities of the YO3 (*hup*$^-$) strain and WT strain were found as 0.534 mmol/(L.h) and 0.323 mmol/(L.h), respectively. While the PHB amount of the YO3 (*hup*$^-$) strain was 11.7%, the PHB amount of the WT strain was 10.1%. More studies will be conducted to further optimize the H_2 and PHB production, and to understand the partition of resources towards H_2 and PHB.

Keywords: Hydrogen, Poly-β-hydroxybutyrate (PHB), *Rhodobacter Capsulatus*, Acetate

INTRODUCTION

Due to the limited reserves and adverse environmental effects of fossil fuels, alternative energy sources have been intensively researched and among various renewable energy sources, hydrogen (H_2) receives attention for being a clean and efficient fuel. There are a variety of ways to produce hydrogen, and photobiological H_2 production is known as an environmentally harmless method [1]. Among various microorganisms, purple non-sulphur bacteria (PNSB), a subclass of photosynthetic bacteria, are suitable for large-scale production. Also, these species can utilize a wide variety of substrates and their substrate conversion efficiencies are high [2].

During biohydrogen production, one of the major by-products is poly-β-hydroxybutyrate (PHB). PHB is a biodegradable and biocompatible polymer that is used as a storage material by the bacteria and is a commercially valuable bioplastic. Like hydrogen, PHB is produced effectively at a high carbon to nitrogen ratio (C/N). The enzymes nitrogenase and hydrogenase are primarily involved in hydrogen production and consumption pathways. It is of interest to investigate the differences between H_2 and PHB production in the presence and absence of these enzymes in host species.

Several studies have investigated the co-production of PHB and H_2 in PNSB [3-5]. Various species, carbon sources and concentrations have been investigated for PHB production [6-8]. In the present study, the relationship between H_2 and PHB production was investigated in wild type (WT) and mutant (YO3 (*hup*-)) strains of *R. capsulatus*. The major difference between these strains is that the uptake hydrogenase gene of the YO3 strain was deleted [9]. Thus, this study indirectly reveals the effects of the uptake hydrogenase enzyme on both H_2 and PHB production.

MATERIALS AND METHODS

Bacteria, growth, and PHB production media

R. capsulatus YO3 (*hup*$^-$) and R. *capsulatus* WT were grown in the Biebl and Pfenning (BP) defined medium [10]. In this growth medium, 20 mM acetate and 10 mM glutamate were used as carbon and nitrogen sources, respectively. For PHB and H_2 production medium, 65 mM acetate and 2 mM glutamate were used. Vitamins, Fe-citrate and trace elements were added to the medium and pH was adjusted to 6.4 [5].

Bioreactor Start-up and Analytical Methods

Bacteria were inoculated (10% v/v) into 50 mL reactors, and four replicates were set up for each bacterial strain. Reactors were flushed with Argon for 3 minutes to provide anaerobic conditions. Temperature was kept constant at 30 ^oC and the light intensity was set to 2500-2600 lux. The batch operation of the reactors lasted 11 days.

Gas amount and composition, pH, and optical density (OD) measurements were performed daily. For these measurements, a gas chromatograph (GC, Agilent Technologies 6890N) equipped with a Supelco 1010 column, a pH

meter (Ezdo MP-103), and a UV spectrophotometer (Shimadzu UV-1800) were used. To control the light intensity, a lux meter (Lutron LX-105 Light Meter) was used regularly.

The protocol of PHB analysis was taken from Özsoy et al. [5]. At end of the experiment, to obtain the cell pellets, each reactor content was centrifuged at 13,000 rpm for 20 minutes. The supernatant was removed, and the cell pellets were placed into a freeze drier (Christ alpha 1-4 LD plus) for 24 hours. After freeze drying, weights of the pellets were recorded and added into 2 mL chloroform, then mixed with 2mL of acidic methanol solution (15% of H_2SO_4). The mixture was heated at 100°C for 4 hours. The reaction time was adapted from Braunegg [11]. Following the heating, 1 mL of distilled water was added into each mixture and vortexed for 10 minutes to separate phases. The lower phase, which contained methyl ester of 3-hydroxybutyrate, was filtered with a PTFE filter (22 µm, 13 mm Millipore). Concentration of PHB was determined via GC analysis [5].

RESULTS AND DISCUSSION

The biomass concentrations and cumulative H_2 productions of both strains are displayed in Figures 1 and 2, respectively. The growth trends were observed to be quite similar for both strains (Fig.1). The maximum biomass concentration for the WT was 0.849 g dcw/L, while the maximum biomass value was 0.850 g dcw/L for the YO3 type. A similar biomass concentration was observed for the YO3 type in the study of Oflaz et al. [12]. On the other hand, there is a difference in biomass concentration trend compared to another study by Özsoy et al. that used both acetate and the *R. capsulatus* WT, where the maximum biomass concentration was obtained as 0.85 g dcw/Lc [5]. However, the maximum biomass concentration in the present study was reached in 3 days, whereas study of Özsoy et al. did not attain maximum biomass concentration until day 6. By considering the H_2 (Fig. 2) and PHB (Fig.3) production results, it can be speculated that in the present study, bacterial metabolism might have shifted early on towards cell growth.

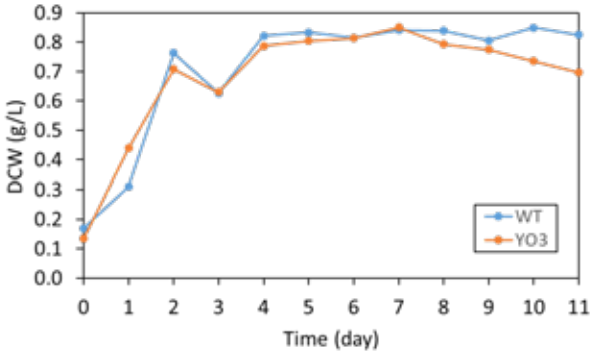

Fig.1. Biomass concentration

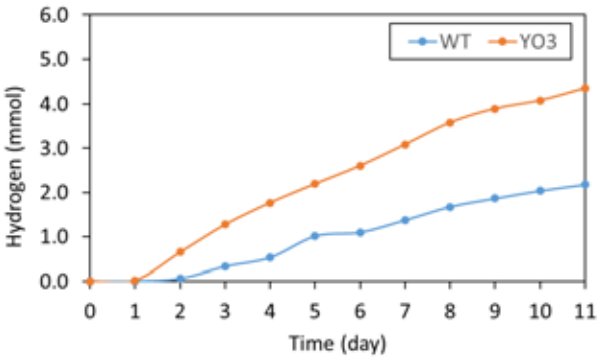

Fig.2. Cumulative hydrogen production

The cumulative H_2 production of the YO3 strain is twice that of produced H_2 by WT strain (Fig.2). This result was expected since YO3 strain is an uptake hydrogenase gene deleted mutant strain of *R. capsulatus* [9]; thus, the produced hydrogen cannot be recycled. The maximum molar H_2 productivities of YO3 and WT strains were found as 0.534 mmol/(L.h) and 0.323 (mmol/L.h), respectively. For the WT strain, Özsoy et al. [5] reported the molar productivity and cumulative molar H_2 production as 0.350 mmol/(L.h) and 11.4 mmol for 65 mM acetate and 120 mL reactor volume.

The final PHB content of the cells were determined at the end of the experiment. While the average PHB amount of the WT strain was 10.1±1% (as percentage of cell dry weight), the average PHB amount of the YO3 strain was 11.7±2.6% (Fig.3). It can be suggested that the presence of the uptake hydrogenase enzyme has a significant impact on H_2 production but its effect is relatively low for PHB production under the conditions studied. In particular, it is probable that the PHB produced could have been consumed in the later stages of the batch operation. In the literature, mixed results have been found regarding the relation of PHB to H_2 production based on differences in strains and operational conditions [13] and more investigation is necessary to determine and optimize the relation for our strains as well.

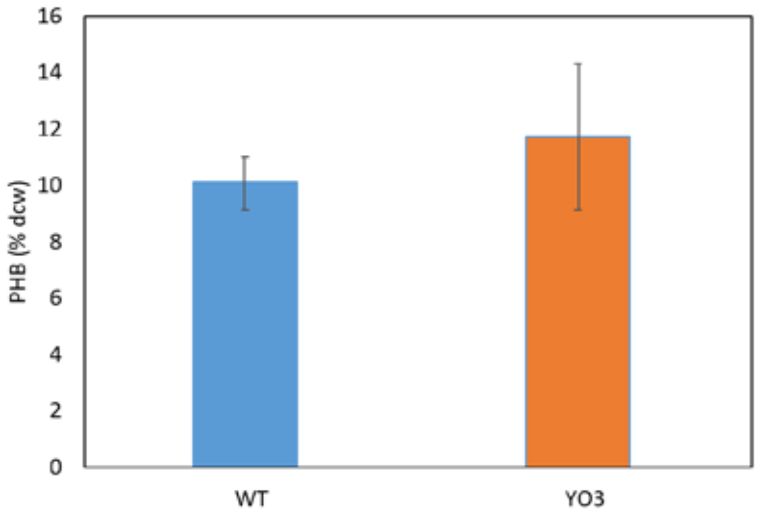

Fig.3. Final PHB content of cells (as percent dry cell weight) in the two strains

CONCLUSIONS

PHB and H_2 production in *R. capsulatus* YO3 and *R. capsulatus* WT under a nitrogen-limited environment was investigated. For both bacterial strains, the variation of pH and dry cell weights were similar. For the YO3 strain, the highest molar H_2 productivity was found as 0.534 mmol/(L.h) and this value was 1.65 times of the productivity of the wild strain. Since YO3 has no uptake hydrogenase enzyme, which consumes hydrogen, the increased H_2 production in this strain was an expected outcome. PHB accumulation in the YO3 strain was slightly higher than the wild strain. Further investigation is necessary to elucidate the details of the relation between H_2 and PHB production in these strains.

ABSTRACT

Microalgae have been drawn great attention due to their biohydrogen production potentials. In this study, we investigated biohydrogen production potentials of *Chlamydomonas reinhardtii* strains as D1 protein mutant strain D240-41, PGRL1 single mutant PGRL1 mt (+), PGRL1 double mutant PGRL1xΔnd4 Véro. Biohydrogen productions were carried out according to HS-HS strategy. This new strategy is based on performing hydrogen production by completing two successive phases, aerobic and anaerobic. In the first phase, the cultures were cultivated in HS medium under aerobic condition, then in the second phase they were transferred to anaerobic photobioreactors containing fresh HS medium. As result, we observed that all strains were able to produce hydrogen during this new HS-HS strategy.

Keywords: Biohydrogen*, Chlamydomonas Reinhardtii*, *C. Reinhardtii* Mutants, Photobioreactor, HS

INTRODUCTION

The concerns on energy demand are increasing rapidly. At this point, hydrogen is seen as our new energy source thanks to its high gravimetric energy density and ability to provides energy conversion without producing carbon-based emissions [1]. The researches have been proved that hydrogen can be obtained through biologically process. In these processes, microorganisms are considered as a bioconverters which use light energy and water to convert them to hydrogen via hydrogenase and nitrogenase enzymes [2]. In this respect, microalgae are more advantageous than plants due to their ability to be easily grown in closed systems in a wide variety of climatic conditions on lands that are not suitable for agriculture [3,4] Additionally, they can exhibit high hydrogen yields in a specially designed photobioreactor that can allow hydrogen retention [5].

Microalgal hydrogen production can be evaluated from two aspects, process development and genetic applications. In process development studies, the researchers have been focused on both producing high amount of starch and avoiding the hydrogenase enzyme inactivation caused by oxygen. For this purpose, a two-stage strategy has been developed, which includes microalgal cultivation in sulfur containing Tris-Acetate-Phosphate (TAP) medium under aerobic condition and biohydrogen production in sulfur-free TAP-S medium under anaerobic condition [6,7]. However, there is always a risk that photosynthetic mechanism disruptions will be occurred irreversibly. For this reason, new strategies are being developed for microalgal photoautotrophic hydrogen production without exposing the cultures to sulfur starvation [8–11]. From a genetic application perspective, the aim of the studies was to obtain microalgae species with increased biohydrogen production potential. According to this view, mutations have been carried out on chloroplast and mitochondria, since both organelles respond in continue communication to many different stimuli originating from the environment.

In our previous study, we investigated biohydrogen production potentials of *C. reinhardtii* strains as CC124, D1 protein mutants (D240, D239-40, D240-41), PGRL1 single mutants PGRL1 mt (-), PGRL1 mt (+), PGRL1 double mutants PGRL1xΔnd4 Véro, PGRL1xΔnd4 1130, mitochondrial mutant AOX, and control strains as WT and T-1. Biohydrogen productions were carried out based on TAP-TAP(-S) strategy in 1 L magnetically-mixed Roux-type Photo-bioreactors (PBRs). D240-41, PGRL1xΔnd4 Véro and PGRL1 mt (+) were selected as the most hydrogen productive strains, which attained the total biohydrogen amount of 152.05 mL/L, 170 mL/L and 143.04 mL/L, respectively. Then, biohydrogen productions were performed in 2.5 L continuous stirred-tank photobioreactors (CSTR) with these opted strains. It was observed that, D240-41, PGRL1xΔnd4 Véro and PGRL1 mt (+) produced 409.5 mL/L, 309.2 mL/L and 259.8 mL/L hydrogen, respectively. Also, a new strategy named as HS-HS strategy that came from the name of Sueoka's High Salt (HS) medium was developed. In this strategy, the cultures were first cultivated in HS medium under aerobic condition, then they were transferred to fresh HS medium and biohydrogen productions were performed under anaerobic condition. Most importantly, it was observed that all strains have ability to produce hydrogen in capped vials (50 mL) based on this strategy.

In this study, D1 protein mutant strain D240-41, PGRL1 single mutant PGRL1 mt (+), PGRL1 double mutant PGRL1xΔnd4 Véro, which was selected as the most effective hydrogen producers according to our above-mentioned study, was used. Now, their biohydrogen production potentials of them is being investigated in photobioreactor.

MATERIALS AND METHODS

C. reinhardtii strains cultivation

Among *C. reinhardtii* mutant strains D240 had single deletion at amino acid residue 240, PGRL1 mt (+) had single mutation at PGRL1 protein and PGRL1xΔnd4 Véro have also mutated in mitochondrial complex I gene Δnd4 in addition to this mutation. The strains were incubated in 250 mL erlenmeyer flasks containing HS medium [9]. Cultivations were started at pH 7.2 ± 0.2 and performed at 21±2℃, 100 rpm with continuous illuminating on top sides 40-45 $\mu E*m^{-2}*s^{-1}$ for 10 days.

Microalgal Biohydrogen Production

Biohydrogen production will be performed based on HS-HS strategy. In the first stage, once the culture reached its logarithmic phase in erlenmeyer scale will be transferred into the photobioreactor containing HS medium. The inoculation volume will be determined according to the initial chlorophyll concentration of 4±1 mg chlorophyll/L [12]. The culture will be aerated with gas mixture includes air-CO2 (v/v; 97/3). The microalgal biomass production will be performed under aerobic condition. Then, the culture in logarithmic phase will be inoculated to the photobioreactor which capped with plug. The inoculant amount will be arranged based on to reach 12 mg/L as the initial chlorophyll content in fresh HS medium [13]. The biohydrogen production will be started after flushing the culture with N_2 and incubated it in dark for 4 hours.

Both biomass and biohydrogen productions will be started at pH 7.8±0.2 and performed at 21±2℃, 40-45 $\mu E*m^{-2}*s^{-1}$ (on two sides) [14]. All productions will be monitored for 8 days.

Analytical methods

The microalgal growth phases were followed by according to daily taken samples. pH value detection, cell counting, dry weight measurement and optical density determination (at 560 nm and 750 nm) were performed. Photosynthetic activity will be detected by photosynthetic activity device. The chlorophyll-a determination will be performed according to our previous studies [15,16].

Biohydrogen production will be monitored via gas chromatography (GC). In addition, the hydrogen production will be also followed through utilizing a Proton-Exchange Membrane (PEM) fuel cell as described in our previous study [14].

RESULTS AND DISCUSSION

Microalgal cultivation

Microalgae strains reached their stationary phase in very close times to each other (Fig. 1). It has been known that high salt concentration can increase the photo-inhibition mechanisms [17]. As a result, decreased direct electron transfer from photosystem (PS) II to PS I can be observed [18]. Also, it was mentioned as decreased PSII activity causes more work falls on the PSI, and thus on the PGRL1 molecule [19]. This may explain that D240 strain, which has mutation only in the D1 protein complex of PS II, produced highest amount of biomass.

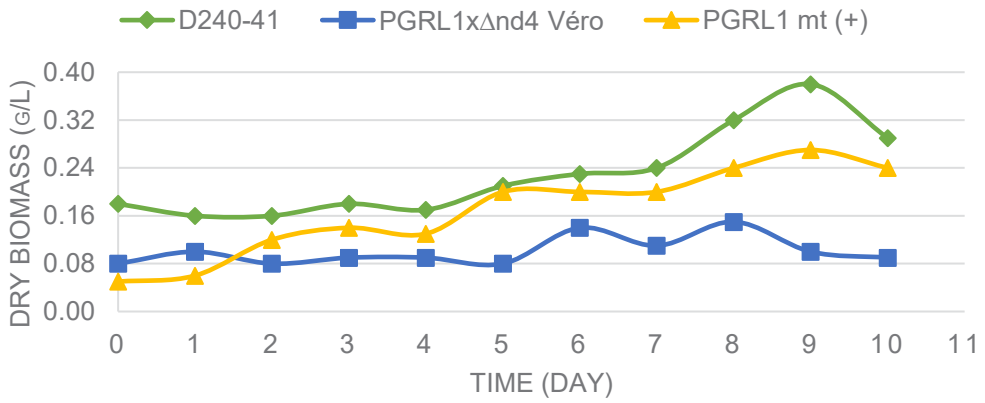

Figure 1. Microalgal growth of microalgae strains.

In addition, it is known that chloroplast and mitochondria are in constant communication to respond to many different stimuli from the environment [13]. Therefore, in considering the PGRL1 mutants, single point mutant PGRL1 mt (+) produced higher amount of biomass than PGRL1xΔnd4 Véro mutant strain. This can be explained as PGRL1xΔnd4 Véro, which has mutations in both chloroplast and mitochondrial organelles, was more affected by this stress condition.

CONCLUSIONS

In this study, it was proven that hydrogen producer PGRL1xΔnd4 Véro, D240-41 and PGRL1 mt (+) mutant strains can be cultivated in HS medium. Briefly, HS-HS strategy offers advantages such as (1) no need for washing the culture with the medium which used in anaerobic condition while transferring the culture from aerobic condition to anaerobic condition, (2) low risk of contamination as no organic carbon source (acetate) is used and (3) allows the cultures to still be photosynthetically active.

ABSTRACT

Hydrogen, a carbon-free clean fuel and a strong alternative to conventional fossil energy sources, has many production strategies including biological routes, acknowledged as sustainable and environmentally friendly. The hydrogen yields acquired by those routes with either pure or mixed cultures are predominantly dependent on the environmental factors. Accordingly, in the literature, statistical experimental designs were proven to be useful to understand the effects of independent parameters including macro and micro nutrients, organic or inorganic substrates, pH and temperature. Within this scope, the aim of this study was to optimize the bio-H_2 yields using the Box-Behnken design (BBD) with 3 different independent parameters (temperature(^oC), pH and inorganic substrate (CO volume (mL)) with a comparative approach using both mixed and pure thermophilic cultures isolated from Izmir hot springs. The maximum H_2 yields were reported as 0.13 mmol H_2/mmol CO for mixed cultures at pH 7, 60^oC and 15 mL CO addition whereas the pure culture reached 2.5 fold higher yields by 0.46 mmol H_2/mmol CO. The results demonstrated the effectiveness of the utilization of the statistical design of experiments to improve the bioproduction yields via local thermophilic isolates.

Keywords: Biohydrogen, Box-Behnken Design, Water-Gas Shift reaction

INTRODUCTION

Carbon-based energy sources, fossil fuels, and accumulation of greenhouse gasses via consumption of fossil fuels in the industrialized world is imprinting unwanted and inevitable traces on the environment day by day. Worldwide CO_2 emissions are expected to increase over 33 billion tonnes by 2022 [1]. In the time of the emerging environmental crisis, the search for clean, renewable, and carbon-free energy sources that can reduce the energy burden of the industry is deemed to be crucial and the production of carbon-free energy sources such as hydrogen gas using sustainable and green routes, in particular, biotechnological routes, are vital. Hydrogen production using biological sources is divided into five categories; direct and indirect photolysis, photo-fermentation, anaerobic fermentation and water gas shift [2]. Water-gas shift (WGS) reaction is regulated by the metabolisms of carboxydotrophic hydrogenogenic microorganisms that can use CO gas as a carbon and electron source, and in the presence of H_2O converting it into molecular hydrogen (H_2)[3].

Mixed or pure cultures of microorganisms able to perform WGS can be used for the production of biohydrogen, both having their own advantages and disadvantages. Mixed cultures are reported to be more economically viable as sterilization requirements in pure culture processes are eliminated [4] however, the dynamics of the microbial consortia must be taken into consideration, such as the presence of H_2 consuming bacteria is known to decrease the H_2 production yields and the necessity of pre-treatment to eliminate these microorganisms should be taken into consideration [5].

This is the first report in the literature with local isolates collected from Izmir hot springs to demonstrate the optimization of H_2 yields employing Box-Behnken Design with a comparative approach using mixed and pure cultures.

MATERIALS AND METHODS

Microbial Cultures

Local isolates were collected from Doğanbey geothermal hot springs in Seferihisar, Izmir (38°07'32.8"N 26°54'35.8"E). The hot spring possesses a thermophilic (77.3^oC) environment with a pH of 6.42 and an oxidation reduction potential (ORP) of 43,8 mV. These parameters were recorded by a portable multiparameter meter (Milwaukee, USA). The samples were taken into sterile flasks aseptically and transported in thermal bags to the laboratory. The samples were cultivated under anaerobic conditions at incrementing temperatures (55, 60 and 65^oC) with a previously defined basal media [6-7]. All experiments were conducted in 50 mL serum bottles. Each bottle was filled with 27 mL anaerobic medium and flushed with pure N_2 gas for 30 seconds to provide anaerobic conditions.

The bottles were sealed with rubber septa and aluminum crimp caps then autoclaved at 121 °C for 15 min. Following sterilization, 3 mL of inoculum was added to each bottle. Stock cultures from previous studies were used as inoculum for all experiments. After inoculation, CO gas was added to the serum bottles using a gas-tight syringe with 3 different volumes as shown in Table 1.

Box-Behnken Design

Box–Behnken design ensures modeling of the response surface that was commonly used for fermentative hydrogen production processes [8-10]. The design was used to ensure maximizing hydrogen production yields to that end, three factors, namely temperature, pH and the CO addition were selected and three levels of each factor, which corresponds to low, middle and high for the variables (Table 1) were employed (Design Expert v13, USA). These factors and levels were selected according to literature [11-12] and results from previously conducted experiments. A set of 17 experiments were performed to comparatively analyze the effects of variables on hydrogen production yields. The values of each experiment that results in the maximum value of response (hydrogen production yield) was selected as optimal conditions. 5 validation experiments were carried out for each culture condition.

Table1. Factors and levels selected for the Box-Behnken Design (Design Expert v13, USA).

Factors and levels selected for the Box-Behnken Design			
Factors	Levels		
	1 (Low)	2 (Medium)	3 (High)
1 Temperature (°C)	55	60	65
2 pH	5.0	7.0	9.0
3 CO feed (mL)	5	10	15

Gas Analysis

In order to measure the quantity of H_2 produced and CO consumed, 1000 µL of samples were taken from the headspace of the bottles with a gas tight syringe (Hamilton, Nevada) at 0-3rd-7th-10th days of the experiments and analyzed with Gas Chromatography (Shimadzu, Nexis GC-2030, Japan). The device is equipped with a Restek ShinCarbon ST 100/120 packed column and TCD (Thermal Conductivity Detector). The temperature of the injector, column and detector were 150, 60 and 150°C, respectively. N_2 was used as a carrier gas. The hydrogen yield was expressed as a percentage of the H_2 gas produced per CO gas consumed (mol/mol).

RESULTS AND DISCUSSION

As reported in Figures 1 and 2, the significant results obtained with a fit to a quadratic model ($p<0,05$) in this study, reported maximum hydrogen yields of 0.46 mmol H_2/mmol CO (%) (8.02% H_2) using pure cultures and 0.13 mmol H_2/mmol CO (2.16% H_2) for mixed cultures with following conditions: pH 9, 60°C and 15 mL CO addition. The hydrogen production in the headspace was successfully improved compared to the authors' previously reported studies [13]. Biohydrogen production yields with the use of an organic substrate (e.g. glucose) were reported as 2.3 mol H_2/mol glucose for mixed cultures [14] and 1.35 mol H_2/mol glucose [15] for pure cultures. In the case of using an inorganic substrate, such as CO gas with application of the WGS pathway, biohydrogen production yields were reported to range between 0.606-0.808 mmol H_2/mmol CO [16]. As observed, the hydrogen production potential could remarkably be increased by altering operational conditions.

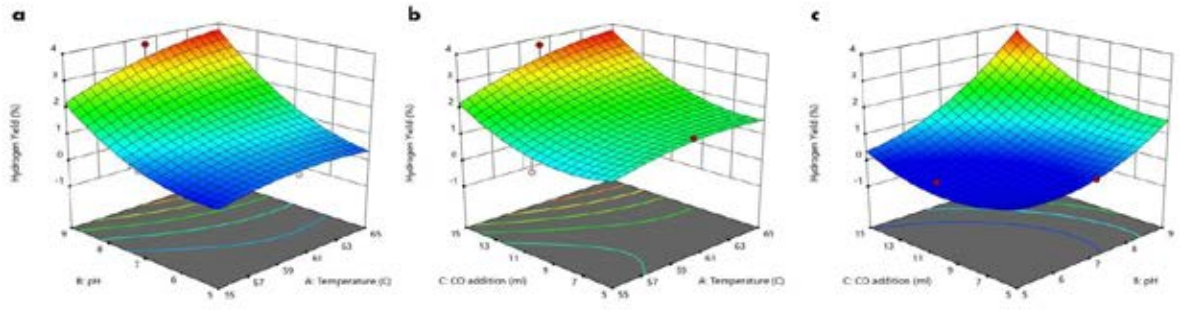

Figure 1. Effects of different parameters on the hydrogen yield for pure culture. (a) temperature (y-axis) and pH (x-axis) (b) CO addition (y-axis) and temperature(x-axis) (c) CO addition (y-axis) and pH(x-axis).

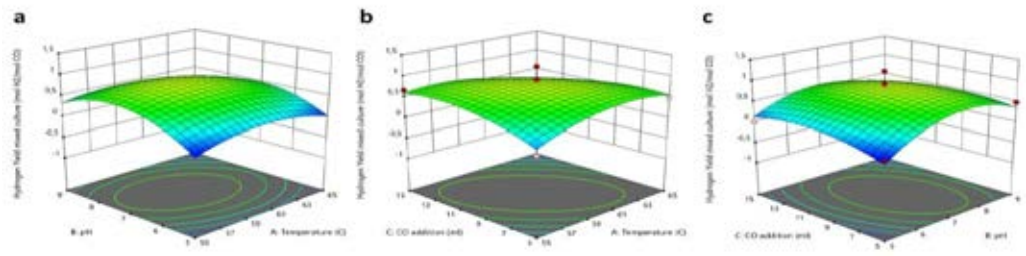

Figure 2. Effects of different parameters on the hydrogen yield for mixed culture (a) temperature (y-axis) and pH (x-axis) (b) CO addition (y-axis) and temperature (x-axis) (c) CO addition (y-axis) and pH(x-axis).

CONCLUSIONS

The results of the current study proved the effective optimization of the isolated cultures with the BBD tool reaching a 4 fold higher H_2 production in the headspace gas than the preliminary values obtained prior to optimization. The biohydrogen production yield from CO with the pure culture was significantly higher compared to the mixed culture. This can be explained by the microbial dynamics within the mixed culture, as both H_2 producing and H_2 consuming strains could be present at the same time. Overall, the CO fermentation of the local isolates in this study represent a promising alternative to the conventional fermentation processes.

ABSTRACT

Hydrogen as a clean environmental friendly fuel has the potential to meet energy demand of the world. High organic carbon wastes can be used for biohydrogen production reducing raw material cost. In the energy sector the utilization of green market wastes (GMW) offers certain advantages to produce high value-added products with low cost. An important factor affecting biohydrogen production is temperature. In this study, the GWM (a mixture of lettuce, parsley, spring onion and dill) was used for biohydrogen production by dark fermentation using pretreated anaerobic sludge. Hydrogen production potential at mesophilic conditions (37°C, initial pH 7.2) at different initial substrate concentrations varying between 1000-5000 g wb was utilized. After mesophilic experiments, 5000 g wb was conducted to thermophilic conditions to compare the effect of temperature.

The highest CHF (8.9 L) and the highest yield (0.012 mol H_2/ g TOC) was obtained with 5000 g wet weight in mesophilic conditions. Thermophilic conditions gave higher CHF (14.2 L) when compared with mesophilic one. Thermophilic conditions gave 1.6 times higher yield than mesophilic conditions; demonstrating suitability for organic substrates having high density.

Keywords: Biohydrogen Production, Green Waste, Thermophilic, Mesophilic, Dark Fermentation

INTRODUCTION

Hydrogen, which is a clean and environmental friendly fuel, draws attention as the biggest alternative to fossil fuels in meeting the energy demand in the world [1]. A wide variety of substrates such as algae biomass, cellulose-based biomass, food waste, fruit and vegetable waste, organic waste and wastewater are used to produce biohydrogen by dark fermentation [2]. Market waste is an ideal substrate for biohydrogen production due to its high organic carbon concentrations and its readily degradable in nature [3]. Moreover, the use of waste substrates in energy production reduces the cost of raw materials [1].

The pretreatment method applied to the substrate is effective in increasing the hydrogen yield. Physical, chemical, enzymatic pretreatments are the most common ones but it increases the overall operation cost of production [2]. Therefore partial hydrolysis of the substrate or consolidated fermentation could be a solution to this problem [4,5]. One of the important factors affecting biohydrogen production in dark fermentation is the process temperature. Thermophilic conditions (42–75°C) offer advantages over mesophilic one, such as elimination of hydrogen-consuming bacteria [6], efficient conversion of simple sugars to hydrogen. Hence the biohydrogen production yield and productivity is found higher in thermophilic conditions [7]. For instance, Toledo-Cervantes et al. (2020), reported 1.7 times higher hydrogen production under thermophilic conditions when compared with mesophilic conditions [8].

The utilization of green market wastes in the energy sector offers certain advantages to produce high value-added products with low cost such as biohydrogen. By considering this fact, the aim of this study is to valorize the green waste for biohydrogen production by dark fermentation using mixed culture. For this purpose hydrogen production potential at mesophilic conditions (37°C) at different initial substrate concentrations varying between 1000-5000 g wet matter was evaluated. After mesophilic experiments, the substrate concentration giving the highest hydrogen production potential was conducted to thermophilic conditions to compare the effect of temperature.

MATERIALS AND METHODS

Substrate preparation

The green wastes made up of lettuce, parsley, spring onion and dill were collected from city markets in İzmir/Turkey. They were first chopped then mixed and finally blended. Partial hydrolysis of the substrate was conducted by applying heat (T>100°C) in a pressurized vessel for 30 minutes. The mixture had a characteristic of 94% moisture content, 0.523 g TOC/g dry matter and 7.16 g TOC/L in the liquid fraction, 10.95 g/L total sugar concentration of hydrolyzed waste liquor, 2940 mg/L total nitrogen, 298.5 mg/L total phosphorus.

Experimental set up

Serum bottles were used for batch dark fermentation experiments. Silicone stoppers and caps were used to prevent gas leakage. The substrate concentration varying between 1000 to 5000 g wet basis were subjected to fermentation. Mesophilic and thermophilic dark fermentations were carried out with pretreated anaerobic sludge. The fermentation media contained 2.8 g L^{-1} K_2HPO_4, 3.9 g L^{-1} KH_2PO_4, 0.05 g L^{-1} $FeSO_4.7H_2O$ and 0.1 g L^{-1} L-cysteine. The initial pH of the fermentation media was adjusted to 7.2 and autoclaved at 121°C for 15 min. Anaerobic conditions were maintained by passing nitrogen gas from head space of the bottles. 10% (v/v) inoculation was applied. The bottles were placed in an incubator at 37°C for mesophilic experiments and 55°C for thermophilic experiments.

Organism

The anaerobic sludge was taken from anaerobic wastewater treatment plant's acidogenic phase from PAKMAYA, İzmir, Turkey. In order to select the spore forming hydrogen producing bacteria, the sludge was heated over 100°C for 1 hour at pH 5. The pretreated anaerobic sludge was inoculated (10% v/v) in a media containing 10 g L^{-1} glucose, 2.8 g L^{-1} K_2HPO_4, 3.9 g L^{-1} KH_2PO_4, 0.25 g L^{-1} $MgSO_4$, 10 g L^{-1} peptone, 0.6 g L^{-1} yeast extract and 0.1 g L^{-1} L-cysteine. Anaerobic conditions were achieved by passing nitrogen gas through the medium prior to cultivation. The organisms were incubated at 37°C and 55°C an initial pH of 7.2. The cultivated organisms were incubated for 2 days and used as inoculum.

Analytical Methods

Samples were taken daily and centrifuged at 8000 rpm. pH analysis, total sugar concentration, simple sugar composition and total volatile fatty acid (TVFA) concentration were performed in the clear supernatant. The Dubois method [9] was used to measure total sugar concentration. Simple sugars and TVFA concentrations were determined by using HPLC with RID and UV detectors, respectively [10]. TOC was analysed with initial and final dry mass substrates.

Hydrogen gas samples were taken daily from the head space of the bottles. Hydrogen concentration was measured by using a GC with TCD, and total gas volume by water displacement method [10]. Cumulative hydrogen formation (CHF), yield, volumetric hydrogen production rate were calculated according to the [11].

RESULTS AND DISCUSSION

Batch dark fermentation experiments were carried out to evaluate the effects of substrate concentration (1000 g to 5000 g wet basis) on biohydrogen production. Fig. 1 gives the final CHF and Fig. 2 gives the hydrogen production yields for different substrate concentrations at mesophilic conditions. CHF and the hydrogen yield (mol H_2/ g TOC) increased with substrate concentration. The highest CHF (8.9 L) and the highest yield (0.012 mol H_2/g TOC) was obtained with 5000 g wet weight.

Fig. 3 shows the time-dependent variation of thermophilic and mesophilic CHF and TS in the liquor with 5000 g substrate. At the end of the fermentation period CHF was 14.2 L and 8.9 L in thermophilic and mesophilic conditions, respectively. The initial total sugar concentrations in the liquor phase of the substrate was 26.5 g/L and 12.8 g/L due to partial hydrolysis via heat. The substrate was simultaneously converted into simple sugars during the fermentation period and consumed by bacteria. At the end of the fermentation period the TS in the liquid phase was under 2.5 g/L in both conditions. The main VFAs were acetic and butyric acid. The total VFA concentration was 15.8 g/L in mesophilic conditions while it was 39.8 g/L in thermophilic conditions. Thermophilic conditions helped bacteria to convert simple sugars into VFA's faster than mesophilic conditions effecting positively hydrogen production yields.

Table 1 shows the comparison of mesophilic and thermophilic biohydrogen production in terms of CHF, yields. Depending on the increase of temperature, the hydrogen yield per mole of glucose increased 3.3 times. This may be related to the fact that sugar degradation and hydrolysis take place more effectively as the temperature increases. In the light of all these results, it has been observed that the production and yield performance of biohydrogen production in thermophilic conditions is higher than in mesophilic conditions when high density of organic waste substrate is used with dark fermentation.

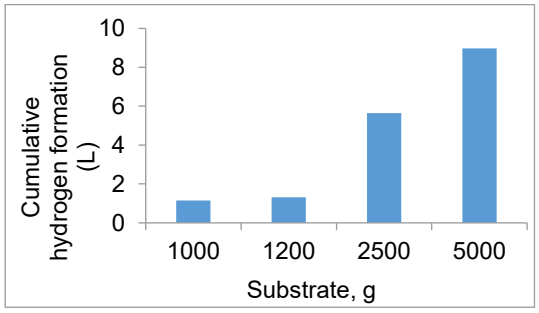

Fig. 1. Cumulative hydrogen formation at different amount of substrates

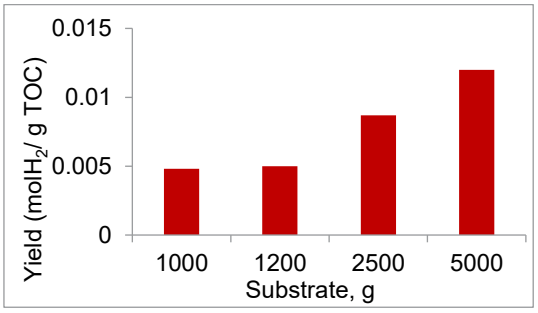

Fig. 2. Variation of hydrogen yield based on g TOC with different amount of substrates.

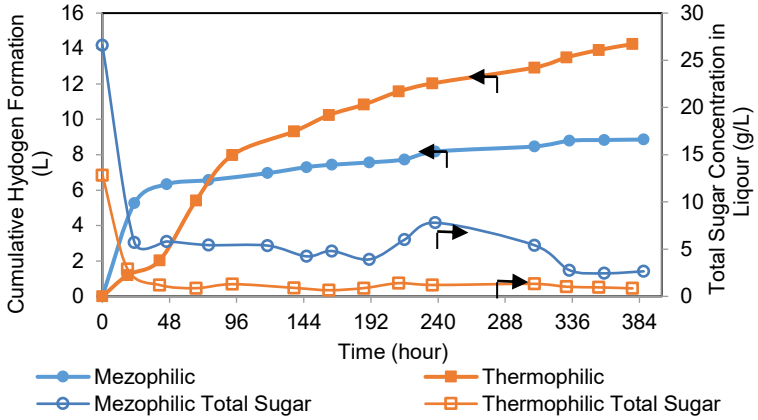

Fig. 3. Time dependent variation of CHF and total sugar (TS) concentrations in the liquor of mesophilic and thermophilic experiments with 5000 g wet basis substrate concentration.

Table 1. Comparison of mesophilic and thermophilic hydrogen production

	Mesophilic fermentation (5000 g)	**Thermophilic fermentation (5000 g)**
CHF (mmol H_2)	348	549
Yield (mol H_2/ mol total sugar)	0.43	1.42
Yield (mol H_2/ g TOC)	0.012	0.018
Yield (mL H_2/ g dry matter)	29.5	47.5

CONCLUSIONS

Batch dark fermentation experiments were carried out to evaluate the effects of substrate concentration (1000 g to 5000 g wb) on biohydrogen production. The substrate concentration that gave the highest biohydrogen production potential in mesophilic conditions was compared with thermophilic conditions to understand the effects of temperature on hydrogen production. The highest CHF (8.9 L) and the highest yield (0.012 mol H2/ g TOC) was obtained with 5000 g wet weight in mesophilic conditions. Thermophilic conditions gave higher CHF (14.2 L) when compared with mesophilic one. The main VFAs were acetic and butyric acid in both conditions. Thermophilic conditions helped bacteria to convert simple sugars into VFA's faster than mesophilic conditions effecting positively hydrogen production yields. In terms of hydrogen production yields per g dry matter thermophilic conditions gave 1.6 times higher yield than mesophilic conditions; demonstrating suitability for organic substrates having high density.

ABSTRACT

The growing demand for energy worldwide requires a transition towards clean and renewable energy sources in order to mitigate the negative effects of greenhouse gases. During the last decade, hydrogen has been included in multiple national energy roadmaps as a promising alternative to traditional fossil fuels due to its energy content and conversion efficiency. This study aims to assess different biohydrogen production routes from organic solid waste in order to select the best cost-effective alternative for the city of Cartagena, Colombia. Therefore, six different criteria were defined using the Analytical Hierarchy Process (AHP). Subsequently, these criteria were used in order to compare seven biohydrogen production routes. The results obtained in this study suggest that the production of hydrogen through the biogas steam reforming process could be an attractive technology compared to other methods.

Keywords: Biohydrogen, Biogas Steam Reforming, Anaerobic Digestion, Colombia, Analytical Hierarchy Process (AHP).

INTRODUCTION

Hydrogen is an element widely used at industrial level with around 60 million tons produced every year that are mainly used in oil refining and ammonia production [1]. However, the production of hydrogen is limited since this element does not exist by itself in nature and requires complex processes to obtain it [1], [2]. Most of the current hydrogen production worldwide is based on fossil fuels [3]. However, there is a growing interest in producing hydrogen from renewable sources in order to avoid the generation of greenhouse gases during the process. Biohydrogen production from organic solid waste and wastewater is a promising alternative for the development of a sustainable hydrogen production chain [2]. Technologies that use waste generated by human production to generate energy are a great alternative. In this study, the following technologies were reviewed: thermo-chemical gasification, supercritical conversion, biogas steam reforming, direct bio-photolysis, indirect bio-photolysis, photo-fermentation and dark fermentation [4]. Although photosynthetic hydrogen production is a theoretically good technique for converting solar energy into hydrogen using photosynthetic bacteria, putting it into reality is problematic due to poor light utilization efficiency and complex hydrogen reactors development. Hydrogen production from agriculture residue is reported to be more cost-effective than the photosynthetic hydrogen production. Fermentative hydrogen production is more feasible and thus widely used. However, fermentative hydrogen and steam Reforming production have the advantage of rapid hydrogen production rate and a simpler operation [4]. This study aims to assess and compare the different biohydrogen production routes from organic solid waste in order to select the best cost-effective alternative for the city of Cartagena, Colombia. This city, located on the northwest of Colombia, produces approximately 0.57 kg/inhabitant of urban solid waste each day, i.e., 190,273 tons/year [5]. Therefore, the amount of biogas produce by urban solid waste in this area of the country evidences its potential use for energy applications.

METHODOLOGY

The selection of the best cost-effective biohydrogen production route was based on the Analytical Hierarchy Process (AHP). This is a decision-aiding method developed by Saaty [6] that aims to quantify relative priorities for a given set of alternatives on a ratio scale. Furthermore, the consistency of alternative comparisons in the decision-making process. The AHP method aligns well with decision-maker behaviour because a decision-maker relies on judgements on knowledge and experience before making decisions. This approach's strength is that it collects physical and intangible aspects in a systematic manner and gives a structured yet relatively straightforward solution to decision-making challenges [6]. Six different selection criteria were defined by the authors based on previous studies [4]: cost, process yield, environmental impact, complexity, sizing, and environmental and occupational risk.

Table 1. Alternative selection criteria

Criteria	Cost	Environmental impact	Complexity	Sizing	Yield	Environmental and occupational risk	Criteria value	Total
Cost	0.14	0.14	0.22	0.11	0.09	0.12	0.14	14%
Environmental impact	0.25	0.25	0.22	0.40	0.29	0.20	0.27	28%
Complexity	0.08	0.15	0.13	0.10	0.29	0.11	0.15	16%
Sizing	0.09	0.05	0.11	0.08	0.06	0.11	0.08	9%
Yield	0.16	0.10	0.05	0.14	0.11	0.20	0.13	13%
Environmental and occupational risk	0.25	0.28	0.25	0.15	0.12	0.22	0.21	21%

The alternatives considered in the selection analysis were thermo-chemical gasification, supercritical conversion, steam reforming, direct bio-photolysis, indirect bio-photolysis, photo-fermentation and dark fermentation.

Table 2. Biohydrogen production routes assessment

	Cost	Environmental impact	Complexity	Sizing	Yield	Environmental and occupational risk	Total
Thermo-chemical gasification	1.51	0.32	0.65	1.64	1.10	0.90	6.12
Supercritical conversion	1.35	0.33	0.68	1.84	1.24	0.92	6.36
Biogas steam reforming	**1.13**	**0.34**	**0.70**	**2.11**	**1.42**	**1.02**	**6.74**
Direct bio-photolysis	0.83	0.61	0.96	1.72	1.16	0.52	5.81
Indirect bio-photolysis	0.78	0.62	0.99	1.63	1.10	0.45	5.58
Photo-fermentation	0.76	0.65	1.09	1.41	0.95	0.46	5.32
Dark fermentation	0.70	0.74	1.23	1.37	0.93	0.46	5.42

RESULTS AND DISCUSSIONS

The biohydrogen production routes assessment is shown in table 2. It was obtained that the best cost-effective alternative was the biogas steam reforming process. The selected process was used to estimate the output production for the city of Cartagena based on energy balances. The energy balance (Eb) was calculated using the following equations [7]:

$$Eb = Eout - Ein \quad (1)$$

$$Eout = 2.752 \times 0.535 \times 0.96 \times 0.8 \times MBiogas \times LHVH2 \quad (2)$$

$$Ein = ERSU + EDigestion + EDigestion - sep + ELiquid.dig + ESolid.dig + Ebiomethane + EH2 \quad (3)$$

Applying the selected production process could result in a total biohydrogen production of approximately 1697 tons each year. The required energy input is nearly 554 TJ/year, and this is mainly because of the huge amount of biogas required in the process.

CONCLUSIONS

In this study, different existing technologies used to produce hydrogen from biogas were assessed applying the Analytical Hierarchy Process (AHP). The biogas steam reforming alternative was selected and seems to be the best cost-effective of all the alternatives evaluated. In a future review, it would be essential to incorporate additional aspects, such as social components in order to estimate the overall sustainability of biogas routes, especially considering that innovation in the transformation of biogas into hydrogen is still in a developing stage.

ABSTRACT

Animal manure is an abundant, renewable, and cost-effective resource that is rich in valuable organic matter. In this work, utilization of unpretreated cattle manure (UCM) at high loadings (15, 25 and 50 g VS/L) as the sole carbon source for biohydrogen production by hyperthermophilic *Caldicellulosiruptor bescii* was examined. To enhance biohydrogen production, *C. bescii* was adapted to lower concentrations of UCM, which showed a significant increase in biohydrogen production compared to non-adapted *C. bescii*. The highest H_2 yield achieved from adaptation operation using 15 g VS/L of UCM as 161.3 ± 1.6 mL H_2/g VS_{added}, followed by 25 g VS/L as 89.1 ± 2.6 mL H_2/g VS_{added}. The achieved yields are the highest dark fermentative H_2 yields reported in the literature when unpretreated animal manure has been used for dark fermentation. A striking enhancement has been achieved via laboratory culture adaptation of the cellulolytic hyperthermophilic bacterium. Biohydrogen production has been improved by 124% at 15g VS/L and by 142% at 25 g VS/L compared to non-adapted culture of *C. bescii*. Even though the impact of inhibition was lowered by adaptation, the yield was still low in comparison to other concentrations studied.

Keywords: Manure, Hyperthermophilic, Biohydrogen, Laboratory Culture Adaptation, *Caldicellulosiruptor Bescii*

INTRODUCTION

Overuse of fossil fuels has contributed to dramatic exhaustion of natural resources, resulting in environmental pollution and greenhouse gas emissions. The efforts for developing alternative energy resources have been increased with a specific focus on renewable, sustainable, and cost-effective resources. Hydrogen (H_2) is proposed as a superior and clean energy carrier since its combustion generates only water vapor, and it has a substantial energy yield (122 kJ/g) approximately 3 times higher than any hydrocarbon fuels [1,2]. Yet, about 95% of H_2 generation is currently dependent on fossil fuels, thus, there is an urgent need to develop sustainable renewable hydrogen production methods [3]. Dark fermentation (DF) is a promising method for biohydrogen production through biomass conversion in the absence of light and oxygen. H_2 production via DF provides several benefits as low energy requirements, easier reactor design thus cost-effectiveness, and the use of various organic wastes as carbon source. The efficiency of the process is highly dependent on the activity of microorganisms, and the feedstock [4]. Among different microorganisms, hyperthermophiles are exceptional candidates for biohydrogen production and hyperthermophilic processes offer advantages such as minimal risk of contamination and significantly boosted reaction kinetics [5]. *Caldicellulosiruptor bescii*, a member of hyperthermophilic cellulolytic bacterial genus of *Caldicellulosiruptor*, has been identified as an excellent candidate for biohydrogen production from a wide range of polysaccharides, as well as unpretreated plant biomass [6,7]. Further, *C. bescii* has a superior ability to metabolize multiple six carbon and five carbon sugars simultaneously, owing to the absence of carbon catabolite repression mechanism (CCR). This is a very important feature for processing of various substrates. Formerly, we demonstrated that *C. bescii* can use pretreated wastewater biosolids [8] and cattle manure and their combinations at low concentration as the sole carbon source to produce biohydrogen [9]. However, the cost of pretreatment contributes up to 20% of biofuel generation cost; hence, our current focus is on the development of an efficient biohydrogen production process that does not require any pretreatment [10].

Use of widely accessible waste materials without any pretreatment, as a sole carbon source, is the key point to make the biohydrogen production sustainable and cost-efficient. Animal manure has an important potential as a renewable feedstock due to its abundance and low cost. Recently it was estimated that in EU more than 1.2 billion tons of animal manure is generated annually and cattle manure accounts for more than half of this amount [11]. Moreover, it is estimated that energy potential of cattle manure when used for biohydrogen production is about 10.6% of domestic crude oil supply of Turkey per year [9]. To utilize the untapped potential of cattle manure, we investigated its utilization by *C. bescii* at high organic loadings and without any pretreatment. The experiments were designed to assess the impact of culture adaptation on biohydrogen production yield.

MATERIALS AND METHODS

Inoculum and feedstock

C. bescii (DSM 6725) as an active culture was purchased from Germany Collection of Microorganisms and Cell Cultures (DSMZ), Braunschweig, Germany. It was grown as described elsewhere using crystalline cellulose as the carbon source with little modification as 1.5 g/L of $Na_2S.9H_2O$ was replaced with 0.5 g/L of L-cysteine and titanium citrate was removed from the media [8]. Cattle manure samples were obtained from Polres biogas plant in Polatlı, Ankara, Turkey. The sample was blended for 15 min and stored at 4 ˚C. The chemical oxygen demand (COD) analysis for manure was resulted as 123.9 ± 9.9 g/L. Total solids (TS) and volatile solids (VS) concentrations were 112.60 ± 1.91 mg/g and 79.4% ± 0.1% of TS, respectively. The fiber content analysis resulted as 50% of total fiber composition including 19.11% of cellulose, 18.42% of hemicellulose, and 12.47% of lignin, indicating this is a suitable substrate for *C. bescii*.

Experimental design and reactor operation

In this study, there were two sets: batch (non-adapted) and adaptation reactors. In Set 1, all reactors were inoculated with *C. bescii that was* grown in 5 g/L of crystalline cellulose for 15-18 hours (repeated for three consecutive cycles). In Set 2, *C. bescii* was first grown in 5 g/L of crystalline cellulose; then, active inoculum was adapted to lower concentration of UCM. To achieve, adaptive laboratory evolution (ALE) process serial batch cultivations were applied [12]. In the second cycle of ALE, carbon source for growth was replaced with 5 g VS/L of UCM and serial batch cultivations in this media has been repeated for a total of three cycles. *C. bescii* adapted to UCM was put into Set 2 reactors as an inoculum.

In each set, four types of reactors were operated as (i) blank, (ii) pure substrate control, (iii) cattle manure reactors, and (v) negative control. In brief, the aim of blank (B) was to define the background metabolic products. Pure feedstock control (PC) feeding with 5 g/L of crystalline cellulose were operated to prove the activity of *C. bescii*. Target feedstock, *i.e.* unpretreated cattle manure, reactors were operated as test reactors, fed with different manure concentrations (15, 25 and 50 g VS/L). Negative controls (NC) were fed with corresponding cattle manure concentrations without any *C. bescii* inoculum to determine any metabolic product generation due to the presence of native microorganisms of UCM.

Batch reactors used in this study have a total volume of 60 mL (an effective volume of 30 mL). Triplicate reactors were incubated in a water bath at 75 ˚C for 44 days in Set 1 and for 32 days for Set 2. Hydrogen was measured periodically during incubation and other metabolic products such as acetic acid have been measured at the end of operation.

Analytical methods

Characterization of cattle manure was achieved by using standard methods for total solids (Method 2540B), volatile solids (Method 2540E) and total COD (Method 5220D). Manure fiber analysis was conducted at Nutrilab (Konya, Turkey) [13]. The total gas generation was measured by liquid displacement method in the serum bottles. The content of the produced gas and quantification of volatile fatty acids (VFA) were analyzed as described elsewhere [14]. H_2 production values were given at standard temperature and pressure (STP) (0 °C and 1 atm).

The modified Gompertz equation (Eq. (1)) was used to compare H_2 production performance of different reactors [15].

$$H(t) = P.exp\{-exp[\frac{R_m.e}{P}(\lambda - t) + 1]\} \quad (1)$$

H(t) = H_2 generation (mL); P = maximum H_2 generation (mL); R_m = H_2 generation rate (mL/day); e = 2.71828; λ = lag-phase time (d); t = time (d). Data analysis was performed using Excel for Windows 8.0 software (Microsoft, USA).

RESULTS AND DISCUSSION

Hydrogen production from all reactors were given as net H_2 production at STP by subtracting the production in blank reactors. In batch-pure control reactors, average net H_2 production was 7.0 ± 0.4 mL H_2 proving that inoculated *C. bescii* was active. In the first set, 32.5 ± 0.6 mL H_2 was produced in 15 g VS/L reactors and 27.6 ± 2.9 mL H_2 was produced in 25 g VS/L added reactors (Fig. 1A). In the reactors containing 50 g VS/L of cattle manure, there was no hydrogen production, which is a clear proof of inhibition effect of cattle manure at this high loading. The highest H_2 yield from UCM for batch reactors was 72.2 ± 1.3 mL H_2/g VS_{added} achieved from 15 g VS/L, which indicates that there is a moderate inhibition at higher loadings of UCM (Table 1).

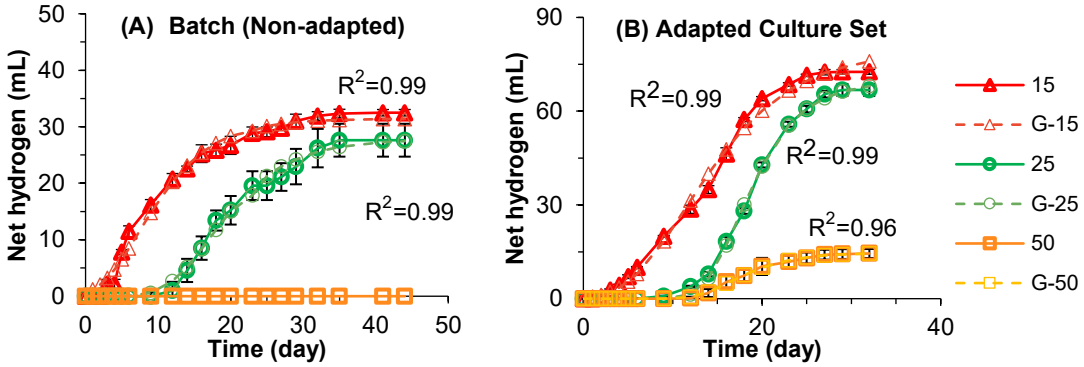

Figure 1. Average net hydrogen production (A) batch (non-adapted) reactors; (B) adapted reactors (15: 15 g VS/L of UCM; 25: 25 g VS/L of UCM, 50: 50 g VS/L of UCM; G: Gompertz model fitting)

Table 1. Hydrogen yields

	Batch (Non-adapted) Set			Adapted Culture Set		
Concentration (g VS/L)	15	25	50	15	25	50
Yield (mL H_2/g VS)	72.2 ± 1.3	36.8 ± 3.9	-	161.3 ± 1.6	89.1 ± 2.6	36.8 ± 3.9

Although biohydrogen production from UCM was significant with non-adapted culture, a considerable decrease on H_2 yield (~ 50%) was observed at higher loadings. To overcome this problem and produce H_2 more efficiently at industrially relevant concentrations of UCM, adaptation of *C. bescii* to UCM has been performed. Adapted inoculum showed a significant H_2 production in PC reactors (including 5 g/L of crystalline cellulose). The net average H_2 production of PC reactor was 14.2 ± 1.1 mL H_2, which is about 2 times higher than batch PC reactors (data not shown). This may be explained by the additional carbon source from growth reactors that is introduced to the reactor or adapted *C. bescii* can effectively degrade pure substrate. The adapted inoculum reactors containing 15, 25 and 50 g VS/L produced H_2 in the order of 72.6 ± 0.7 mL H_2, 66.8 ± 1.9 mL H_2 and 14.5 ± 1.5 mL H_2 (Fig. 1B). Adaptation of *C. bescii* enhanced H_2 generation from UCM significantly at which the enhancements for biohydrogen generation are 123.5% and 141.8% for 15 and 25 g VS/L compared to non-adapted culture of *C. bescii*. For adapted reactors, hydrogen yields were also increased to 161.3 ± 1.6 mL H_2/g VS_{added}, 89.1 ± 2.6 mL H_2/g VS_{added} and 36.8 ± 3.9 mL H_2/g VS_{added} for 15, 25 and 50 g VS/L. Yet, even with adaptation as the load was increased yield decreased. Nevertheless, here we report the highest dark fermentative yields obtained in the literature when unpretreated animal manure was used as a sole carbon source [16–19].

Modified-Gompertz model was run for data analysis to compare hydrogen production rate and lag-phase additional to the yield. The highest volumetric H_2 generation rate was 6.5 ± 0.3 mL H_2/day obtained from 25 g VS/L in adaptation operation. It is followed by adapted 15 g VS/L reactors with 4.4 ± 0.1 mL H_2/day. We have also checked the solubilization of UCM to assess the extent of biodegradation. The degree of solubilization was 73.1% for 15 gVS/L UCM and 57.1% for 25 g VS/L UCM with the adapted culture. These solubilization results are about 2 times higher than any other real feedstock solubilization that were used by *C. bescii* [20–22].

CONCLUSIONS

It is proved that hyperthermophilic bacterium *C. bescii* has an ability to degrade UCM at high loadings to produce biohydrogen. With the adaptation of *C. bescii* to UCM, biohydrogen production was significantly enhanced for all concentrations (15 - 25 g VS/L) about 2.2-2.4 times compared to non-adaptive operation. Even though there is an inhibition at 50 g VS/L of cattle manure loading, adaptation of inoculum has supported to decrease the negative effect, and enhanced biohydrogen generation. The results presented here indicate that *C. bescii* can be used as a microbial factory to process complex materials such as UCM for enhanced biohydrogen production and can be adapted to industrially relevant loads.

ABSTRACT

Biohydrogen production at extremely thermophilic conditions (>70°C) has a high potential as it provides increased reaction rates, enhanced feedstock solubilization, and lower risk of contamination. Hyperthermophilic cellulolytic bacteria *Caldicellulosiruptor bescii* is capable of utilizing cattle manure as the sole carbon source and produce hydrogen with a superior yield in comparison to other dark fermentation (DF) processes. Yet, acetic acid produced as an end product of DF remain unused in the system. Hyperthermophilic microbial electrolysis cells (MECs) offer a great potential to further process soluble DF products by employment of electro-active microorganisms with no need for chilling. In this study, *C. bescii* was used to produce hydrogen from untreated cattle manure and DF effluent was rich in acetate, thus sufficient for feeding to electro-active hyperthermophiles. Therefore, we designed experiments to process DF effluent of *C. bescii* based bioprocess in hyperthermophilic (80 – 85 °C) MECs to evaluate the potential of sequential operation of DF and MECs at hyperthermophilic conditions for the first time in the literature. To this purpose, experiments were conducted in single chamber MECs with an applied voltage of 0.7 V and inoculated with recently proven electro-active archaea, namely, *Geoglobus acetivorans* and *Ferroglobus placidus.* Hydrogen production rate of the sequential operation was around 0.11 ± 0.02 m^3 H_2/m^3/day, to which MECs contributed significantly as 0.08 ± 0.01 m^3 H_2/m^3/day. This study is the first report of sequential application of DF and MECs at hyperthermophilic conditions and presents a proof-of-concept.

Keywords: Dark Fermentation, Hydrogen, Microbial Electrolysis Cells, Electrohydrogenesis, Hyperthermophilic

INTRODUCTION

Microbial electrolysis cells (MECs) is a bioelectrochemical reactor used to produce hydrogen (H_2) from different feedstocks such as organic acids and complex substrates as dark fermentation effluents and wastewater [1–3]. The production of H_2 in MECs, known as electrohydrogenesis, depends on the anode biofilm possessing electro-active characteristics, which metabolize organic material and generate electrical current via transfer of electrons to the anode [4]. The electrons are then consumed at the cathode, where H_2 evolution reaction ($2H^+ + 2e^- \rightarrow H_2$) takes place upon application of an external voltage [4]. The external voltage is needed, because the reaction on the cathode is non-spontaneous. For example, bioelectrochemical acetate oxidation, a typical product generated during fermentation of organic materials, leads to a potential around -0.28 V, yet H_2 production requires a potential around -0.42 V [5]. Therefore, a minimum of 0.14 V is necessary to produce H_2 in MECs, yet in practice at least 0.5 V is applied, because of the electrode overpotentials and losses resulted from MEC materials [5]. Still, the required energy during electrohydrogenesis is significantly lower in comparison to what is needed (~1.8 V) water electrolysis process [6].

Dark fermentation (DF), on the other hand, is a widely used biohydrogen production process that offers a simple reactor operation and applicability to a variety of complex wastes [7]. Operation of bioreactors for processes such as DF and electrohydrogenesis at extremely thermophilic conditions (>70°C) has a higher application potential than mesophilic operations, specifically for industrial applications elevated temperature accelerates the rate of reactions, improves the degradation of insoluble substrates, minimize contamination risk and lowers the solubility of oxygen enabling easier maintenance of anaerobic conditions [8,9]. Recently, we have reported that *Caldicellulosiruptor bescii* can utilize various feedstocks such as wastewater biosolids and cattle manure with the highest fermentative yields of 86 mL H_2/g VS for biosolids and 106 mL H_2/g VS for cattle manure at 78 °C with pretreatment [10,11]. Biohydrogen production from cattle manure by *C. bescii* not only produce H_2, but also produce acetic acid in significant quantities and hence could potentially be used for further H_2 production in hyperthermophilic MECs operated at similar temperatures without the need for chilling [11]. So far there are only four hyperthermophilic species that are proven to be electro-active [12–15]. Among those, three of them namely *Ferroglobus placidus*, *Geoglobus ahangari* and *Geoglobus acetivorans* belongs to the family of Archaeoglobaceae and we have demonstrated that these iron reducing archaeal cultures possess electro-active properties and can produce electrical current in MECs, when fed with pure acetate at elevated temperatures ~ 80 ˚C [14,15]. The promising results of our proof-of-concept work with electro-active hyperthermophiles directed us to further examine the possibility of feeding DF effluent to hyperthermophilic MECs for further H_2 production. Therefore, in our current investigation experiments were designed

to assess the potential of sequential process of DF and MEC reactors at hyperthermophilic conditions and to determine the best fit culture for this process.

MATERIALS AND METHODS

Microorganisms and growth conditions

Active cultures of *C. bescii* (DSM 6725), *G. acetivorans* (DSM 21716) and *F. placidus* (DSM10642) were purchased from the German Resource Centre for Biological Material (DSMZ). *C. bescii* was grown in a media, where crystalline cellulose was used as carbon source at 75 °C as detailed elsewhere [11]. *G. acetivorans* and *F. placidus* were grown with acetate (10 mM) as electron donor and ferric citrate (56 mM) as electron acceptor at 80 °C and *at* 85 °C, respectively [14].

MEC configuration and reactor operation

MECs used in this study were constructed as single chamber with an active volume of 5 mL (total volume: 8 mL), called Mini MECs [14]. Anode was a graphite block (1 cm wide, 1.5 cm long and 0.3 cm deep). The stainless-steel mesh (1 cm wide and 1.5 cm long) was used as a cathode. All MECs were made oxygen free by purging with the mixture of N_2:CO_2 (80%:20%) gas and sterilization was completed by autoclaving before use. The hyperthermophilic medium without ferric citrate (electron acceptor) was filled into MECs inside an anaerobic chamber and the active culture of *G. acetivorans* (or *F. placidus*) were inoculated as 20% volume. The operation of all MECs were performed as fed-batch cycles and continuously a 0.7 V was applied to each MEC. Current generation was observed during the reactor operation, and the content of H_2 was analyzed at the end of each cycle. After the current drops by ~60% of its peak value, a new cycle was started by replacing MEC media including electron donor. A multimeter was used to record voltage measurements across 10 Ω resistor that is put in between the power supply and the anode, over the anode cable and measurements were taken at 10 min intervals [14]. Current was calculated using the data stored by applying Ohm's law. To find current density (A/m^2) current was normalized to total anode area. The impact of switching from pure acetate to acetate produced via DF process was tested using similar reactors (named as Midi MECs) constructed in larger size with a total volume of 25 mL (15 mL of active volume). A similar protocol was followed to produce Midi MECs, by inserting slightly larger electrodes (1 cm wide, 2 cm long and 0.3 cm deep anodes, 2 cm long and 1.0 cm wide cathodes) to larger size serum bottles.

Experimental design and calculations

DF reactors have been operated as batch reactors (60 mL of total volume and active volume of 30 mL) fed with 15 g VS/L of unpretreated cattle manure. Triplicate reactors were operated for 44 days, and H_2 production was analyzed periodically during incubation, and liquid metabolic products *e.g.* acetic acid was measured at the end of operation. There were two sets of experiments with MECs in this study. In the first set, Midi MECs were used only by *G. acetivorans* inoculation. Midi MECs were operated for 90 days reactors with a feed of pure acetate in concentrations ranging between 10 mM and 20 mM, and biofilm formation was monitored via cyclic voltammetry along with current generation. After this initial biofilm growth with pure acetate, feed was switched to filtered DF effluent as a carbon source, where the other medium components e.g. vitamin, trace element kept the same as in the original hyperthermophilic medium. DF effluent has been diluted to provide acetate concentrations of 10 mM and 20 mM acetate, and H_2 production has been monitored for four cycles, presented as cycle 1 – 4 in Midi MECs. The second set was conducted in Mini MECs with pure culture of *G. acetivorans*, pure culture of *F. placidus* and their co-culture. This time Mini MECs have been started directly by feeding DF effluent containing medium at a concentration of 10 mM acetate to assess whether there is an impact of DF on the initial biofilm growth and to assess hydrogen production rate (HPR) for three cycles. All MECs were operated in duplicate.

Coulombic efficiency, C_E, is calculated by Eq. 1 by dividing total coulombs (nC_E) and to the total Coulombs found from acetate consumption (n_{th}) by considering eight electrons per acetate. The calculation of cathodic recovery, r_{cat} (%), was achieved by Eq. 2, which gives relative the moles of H_2 recovered (n_R) (mole H_2) to that possible from the measured current (n_E). Eq. 3 was used to calculate the HPR, where J_V (A/m^3) is volumetric current density averaged over 6 hours, c_g (mol/L) is the concentration of gas at reactor T and P, F is the Faraday' constant (96,485 C/mol.e^-), and 43.2 is for unit conversion factor. The multiplication of C_E and r_{cat} provides the overall hydrogen recovery (R_{H2}) [5].

$$C_E\,(\%) = \frac{n_{C_E}}{n_{th}} = 100 \times \frac{\int_{t=0}^{t} I\,dt}{n_{th}} \quad (1)$$

$$r_{cat}\,(\%) = 100 \times \frac{n_R}{n_E} = 100 \times \frac{n_R}{\frac{\int_{t=0}^{t} I\,dt}{2F}} \quad (2)$$

$$HPR\left(\frac{m^3 H_2}{m^3\ active\ volume.day}\right) = \frac{43.2\ J_V\ r_{cat}}{F\ c_g(T)} \quad (3)$$

RESULTS AND DISCUSSION

H_2 production in DF reactors fed with 15 g VS/L of untreated cattle manure produced 32.5 ± 0.6 mL of H_2 with a yield of 72.2 mL H_2/g VS and a HPR of 0.03 $m^3/m^3/d$. The other major end product of *C. bescii* fermentation of cattle manure was acetic acid and produced as 54.4 ± 1.6 mM. There was also lower amounts of lactic acid, butyric acid and propionic acid at concentrations of 6.4 ± 0.5 mM, 7.5 ± 0.1, and 3.0 ± 0.2, respectively. No other volatile fatty acids were observed at the end of operation. The yield obtained here is considerably higher (about 3 times) than the studies using unpretreated animal manure as a sole carbon source [16–18]. Similar to our studies with pretreatment [10,11], the yield obtained here is the maximum dark fermentative H_2 yield when solely unpretreated animal manure is used for H_2 production.

DF effluent was first fed for four cycles to Midi MECs, in which biofilm formation was completed by pure acetate. In the first cycle, current density peaked around 0.32 ± 0.02 A/m^2 corresponding to > 65% of peak current density recorded by pure acetate (data not shown). It was decreased to 0.23 ± 0.03 A/m^2 in two subsequent cycles when the dosage was doubled, which may be due to the need of adaptation of biofilm to DF effluent as it contains other constituents, for instance, lactic acid present in DF effluent is not degradable by *G. acetivorans* [15]. When DF effluent was fed at a 10 mM acetate concentration, ~ 80% of acetate has been consumed and in cycles with 20 mM initial acetate concentration ~ 55% consumption has been recorded (Figure 1). Over four cycles of operation HPR did not change significantly, with average of 0.08 ± 0.01 m^3 H_2/m^3/day. C_E decreased from 150% to ~ 77% indicating that utilization of hydrogen by *G. acetivorans* in membraneless MECs was reduced over multiple DF cycles. Regardless, average R_{H2} in MECs was 65%.

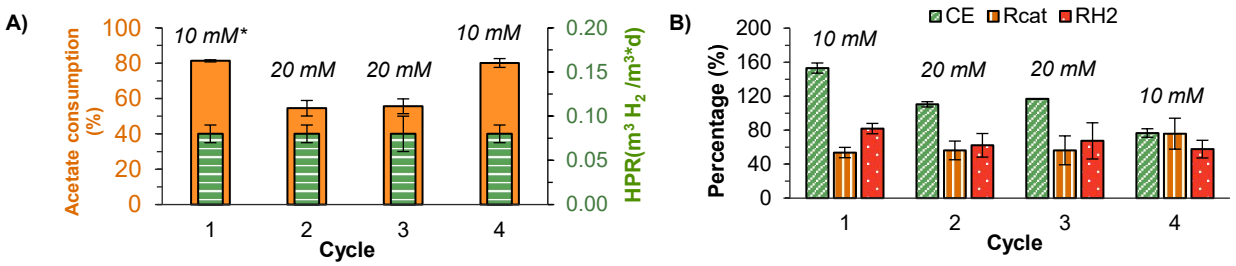

Figure 1. A) HPR and acetate consumption B) C_E, r_{cat}, and RH_2 in Midi MECs fed with DF effluent (*initial acetate concentration)

Further, DF effluent was directly used in Mini MECs inoculated by *G. acetivorans*, *F. placidus* and their co-culture and HPR recorded with these cultures is presented in Figure 2. By the third cycle of operation all MECs produced hydrogen with similar rates around 0.09 m^3 H_2/m^3/day.

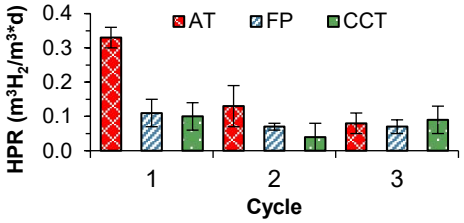

Figure 2. HPR in Mini MECs of directly fed with DF effluent *G. acetivorans* (AT), *F. placidus* (FP) and co-culture (CCT)

CONCLUSIONS

For the first time in the literature, it is proven that H_2 production could be enhanced by sequential operation of a hyperthermophilic DF process followed by hyperthermophilic MECs that were fed with DF effluent. HPR of series application of DF and electrohydrogenesis was 0.11 ± 0.02 m^3 H_2/m^3/day, which is 325% higher than DF process alone. Similar HPRs around 0.08 ± 0.01 m^3 H_2/m^3/day was achieved independent of hyperthermophilic culture used and overall H_2 yield is now further increased to 104.2 mL H_2/g VS. Yet, HPR is still small and optimization of MEC conditions is required to increase rate and the overall yield of H_2 from unpretreated cattle manure.

ABSTRACT

In this study, mesophilic batch fermentation experiments were conducted to investigate the effects of varying C/N ratios on biohydrogen production. The fermentable sugar was obtained from microwave hydrolyzed waste Fig (*Ficus carica*) which is a Mediterranean fruit rich in sugar. The initial total sugar (TS) was kept constant at 40 g/L and nitrogen concentration was varied to adjust the C/N between 25 -150. A control experiment without external nitrogen addition was also conducted to evaluate if the nitrogen content of hydrolyzed fig sustains biohydrogen production. The highest cumulative hydrogen volume of CHV = 861 ml and volumetric production of 4.3 $L/L_{reactor}$ were obtained at C/N=50. The yield varied between 0.9 and 1.1 mol H_2/ mol TS $_{consumed}$ for C/N= 25-100. The highest production rates achieved were 11.5 ml/h and 57.5 ml/L h at C/N=50. Thus, the best ratio in terms of substrate conversion to hydrogen is C/N=50 which can be evaluated as the nitrogen-limited condition. The nitrogen content of the hydrolyzed waste fig is not sufficient for efficient biohydrogen production and external nitrogen addition is required to obtain a higher production rate.

Keywords: Fig, Biohydrogen, Microwave, Hydrolysis, Total Sugar Production.

INTRODUCTION

Biohydrogen research stemmed from the rising interest in renewable energy. It is a fermentation-based, microbial mediated value-added product and it forms an integral part of the production, promotion, and sustainability of green energy technologies. Researchers like Veeramalini and co-authors classified biohydrogen production technologies into "photo-fermentation, bio-pyrolysis, microbial electrolysis cell, microbial fuel cell, and dark fermentation" [1]. Enterobacter, Escherichia, and Clostridium are important microbial genera with high biohydrogen production potential [2]. Biohydrogen fermentation substrates pre-treatment is highly necessary. Pre-treatment makes fermentable sugar readily available for microbial utilization, thereby enhancing fermentation for biohydrogen production. Pre-treatment may be physical, chemical, or biological. Microwave is a physical pre-treatment type achieving lignocellulose substrate delignification within a short time via complete thermal penetration of biomass [3].

Lignocellulose materials are well documented in biofuel generation. Fig (*Ficus carica*) is an edible Mediterranean fruit widely cultivated in Turkiye with yearly export of approximately 200,000 tones [4]. It is a rich source of sugar, organic acids, and protein [5]. Aflatoxin contaminated figs are disposed of by incineration. However, the high sugar content of fig can act as a biohydrogen fermentation substrate.

Carbon and Nitrogen are vital elements needed by all life forms for energy, growth, and genetic build-up. “Carbon to Nitrogen ratio (C/N) translates into nutrient balance availability for microbial utilization in fermentation medium [6]. Anaerobic organisms are highly affected by nitrogen content. Argun et al. (2008) investigated the effects of C/N and C/P ratio on biohydrogen yield and specific production rate from waste wheat powder solution by external addition of N since the wheat powder was nutrient deficient [7]. C/N ratio was varied between 20 and 200, the maximum production yield was obtained at C/N=200 which is defined as a nitrogen-limited condition. Öztekin et al. used acid hydrolyzed waste wheat and the optimal C/N ratio maximizing the yield of formation was determined as C/N=50 [8]. Hydrogen production from microwave hydrolyzed peach pulp showed that nitrogen-limited conditions such as C/N=100-250 are more suitable to enhance hydrogen production. But nitrogen-rich condition as C/N=50 adversely affected hydrogen production [9]. Similarly, Argun et al. reported that C/N=45.7 is optimal for maximum hydrogen production from peach pulp [10].

MATERIALS AND METHODS

Substrate preparation

Waste figs were obtained from the Aegean Exporter Association, Izmir, Turkiye. The figs were cut into small sizes (≤ 5cm) with a handheld knife. This was followed by oven-drying at 72°C for 72 hours. Upon drying, fig wastes were blended using a laboratory-sized blender and sieved with the aid of a mechanized sieving machine to obtain

particle diameter sizes of 150 µm, 212 µm, 250 µm, and 300 µm. Our past microwave study with fig fruit resulted in a total sugar concentration of TS≥ 80 g/L which was achieved with fig pretreatment conditions of substrate concentration 100g/L, particle diameter 370.72 µm, pH 4.96, microwave power 253.67 W, and time 50 mins. These pre-treatment conditions were employed in this study with a total sugar concentration of 82 g/L obtained.

Experimental setup

Mesophilic batch fermentation experiments were conducted in 310 ml capacity serum bottles and capped with an air-tight stopper. The fermentation total working volume was 200 ml, initial TS concentration was kept constant at 40 g/L and nitrogen concentration was varied to obtain C/N= 25, 50, 100, and 150. Urea was used as the nitrogen source, and it was externally added to the fermentation media. A control experiment without nitrogen addition was conducted and named C/N=0. The Total Kjeldahl Nitrogen (TKN) and NH_4-N concentration in the 100 g/L microwave fig hydrolysate were 98 mg/L and 0.24 mg/L.

The fermentation media contained 3.9 g/L KH_2PO_4, 0.05 g/L $FeSO_4.7H_2O$, 0.1 g/L L-cysteine and 0.25 g/L $MgSO_4$ at pH 7.0. Media sterilization was done in an autoclave at 121°C for 15 min. The anaerobic condition in all experimental setups was ensured by passing nitrogen gas from the headspace of the bottles. Serum bottles were placed in a shaker incubator at 37°C.

Organism

C.pasteuranium DSM 525 obtained from DSMZ was used in our study. The organism was inoculated (10% v/v) in an inoculation media containing 40 g L^{-1} glucose, 20 g L^{-1} $CaCO_3$, 10 g L^{-1} yeast extract, and 0.1 g L^{-1} L-cysteine. The contribution of L-cystine to nitrogen content was negligible. Anaerobic conditions were achieved by passing nitrogen gas through the medium before cultivation. The organisms were incubated at 37°C with pH 7.0 for 48 hrs before being used as inoculum.

Analytical Methods

Daily hydrogen production from the five (5) experimental setups was carefully monitored by taking gas samples through the headspace of the bottles and also determining the total gas volume by the water displacement method [11]. Hydrogen concentration was measured using a Gas Chromatograph with TCD. Cumulative hydrogen formation (CHF), hydrogen formation yield, and volumetric hydrogen production rate were calculated [10].

pH range 6.5-7 was ensured throughout the study. Daily samples were carefully centrifuged at 8000 rpm before subjecting clear supernatants to total sugar concentration analysis with a UV-Vis spectrophotometer using the Dubois method [12]. Simple sugars and Total Volatile Fatty Acids (TVFA) concentrations were determined using HPLC [10].

RESULTS AND DISCUSSION

The effect of the C/N ratio (0, 25, 50, 100, and 150) on biohydrogen production was studied via batch fermentation under mesophilic conditions. The cumulative hydrogen production (ml) and hydrogen production yield (mol/mol $TS_{consumed}$) at different C/N ratios are found in Figures 1 and 2, respectively. The cumulative hydrogen volume increased with C/N ratio up to C/N=50 with maximum results CHV=of 861 ml and then decreased for the C/N>50. However, the yield was almost constant at around 1.1 mol H_2/ mol $TS_{consumed}$ for the C/N ratios between 25 and 100. The yield of hydrogen formation in the control experiment without nitrogen source addition was around 0.9 mol H_2/mol $TS_{consumed}$ which is not substantially different than the ones with nitrogen added. The sugar content of the hydrolyzed waste fig was effectively (80%) consumed for all C/N ratios studied. The main organic acids produced were acetic acid (Figure 3) and butyric acid (Figure 4), no lactic acid and propionic acids formed. The nitrogen concentration did not affect the organic acid types and their concentrations. The maximum rate of production was 11.5 ml/h and 57 ml /L h attained at C/N=50. The hydrogen purity in the total gas was 54% at the beginning of fermentation and then decreased to 17% at this ratio.

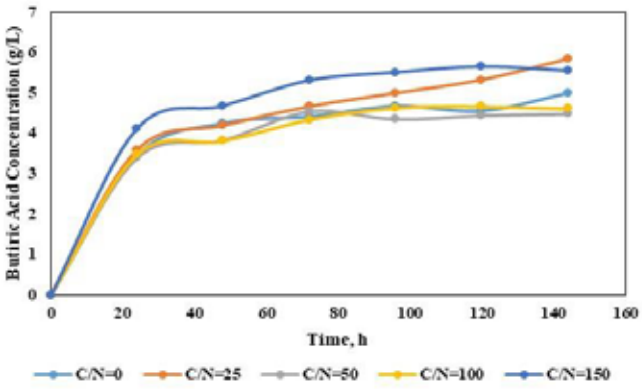

Fig. 4. Variation of butyric acid concentration with time at different C/N ratios.

CONCLUSIONS

The ever-increasing human population translates into an increasing need for energy which is mostly derived from fossil fuels. The environmental effect of fossil fuels shifted attention toward environmentally friendly renewable energy. Biohydrogen, a form of biofuel is renewable energy and capable of contributing its quota to reducing dependency on fossil fuels. Fig (*Ficus carica*) is a Mediterranean fruit rich in sugar. Pretreated waste figs can be subjected to anaerobic fermentation to yield value-added products like biohydrogen. Carbon and nitrogen are macronutrients needed by all life forms for existence. Batch dark fermentation of microwave hydrolyzed waste fig for biohydrogen production showed that waste fig has a high potential for hydrogen generation. Nitrogen content up to C/N=100 in the fermentation media does not substantially affect the yield of hydrogen formation. No external nitrogen addition is required for the yield around 1 mol H_2/mol $TS_{consumed}$. However, the hydrogen formation rate is affected by the nitrogen concentration and the maximum rate was obtained at C/N=50. The lower nitrogen content (C/N=150) limits hydrogen generation. Thus, a C/N ratio of 50 is highly recommended in terms of hydrogen formation rate.

ABSTRACT

The present study uses surface reaction and porous media models to calculate the decomposition performance of bayonet heat exchangers with different catalyst sizes. The results show that the first step of sulfuric acid decomposition reaction is relatively thorough, and the second step of sulfuric acid decomposition reaction is more efficient in the first two-thirds of the catalytic zone. At the same time, the smaller the porosity or particle size of the catalytic zone, the higher the system pressure drop and decomposition rate. The maximum decomposition rate and pressure drop under the current design conditions are 79% and 193Pa, respectively.

Keywords: Sulfuric Acid Decomposition, Surface Reaction, Porosity, Particle Size

INTRODUCTION

As the fourth-generation nuclear power technology, the high-temperature gas-cooled reactor has a higher outlet temperature, which can be used in a variety of process heat utilization methods. Hydrogen production by nuclear energy is one of the important applications. It is usually driven by nuclear heat and adopts a thermochemical iodine-sulfur cycle method to produce hydrogen. In the iodine-sulfur cycle process, it is mainly composed of three chemical reactions, namely Bunsen reaction, decomposition of sulfuric acid and decomposition of hydroiodic acid. The sulfuric acid decomposition reaction requires a high temperature, and the decomposition rate also has a greater impact on the hydrogen production efficiency, so this part is of great significance to the entire process.
Many scholars have carried out research on the decomposition of sulfuric acid through experiments and simulations. Giaconia et al. [1] used siliconised silicon carbide honeycombs coated with iron (III) oxide to conduct a 100-hour sulfur trioxide decomposition experiment, and the catalyst showed good activity and stability. Hong et al. [2] coupled components of multiple materials together, built a sulfuric acid decomposition circuit, and conducted corrosion experiments. Choi et al. [3] designed the unit reactor of the pressurized sulfuric acid decomposition (PSAD) reaction system to evaluate hydrogen production performance. Gao et al. [4] conducted a segmented simulation of the decomposition of sulfuric acid and compared the decomposition performance of the two catalyst forms. Sun et al. [5] developed a model for calculating the phase transition and decomposition of sulfuric acid at the same time and analyzed the influence of flow rate and temperature on decomposition. Shin et al. [6] conducted CFD analysis on the overall structure of the sulfuric acid decomposer and predicted that the decomposition rate of sulfuric acid could reach 60.4%.
At present, there are few simulation studies on the catalysts used for the decomposition of sulfuric acid. This study mainly focuses on the influence of the porosity and particle size of the catalyst bed on the decomposition rate of sulfuric acid and the pressure drop of the system. The catalysts with different particle diameters are arranged in sections to balance the pressure drop and decomposition rate, thereby achieving a higher cost performance.

MODELING AND METHODS

In this study, a two-dimensional axisymmetric model of the sulfuric acid decomposer unit is established for simulation calculation, which mainly includes the helium side and the sulfuric acid side. On the helium side, a heating tube bundle is assumed to provide heat for sulfuric acid. The helium side tube bundle has a radius of 35mm and a length of 1100mm. The radius of the inner tube and the outer tube on the sulfuric acid side are 7mm and 17mm, respectively, and the length is 1350mm. Sulfuric acid exchanges heat with helium in the outer tube, the temperature gradually increases, and then sulfur dioxide is generated in the catalyst area at the bottom of the outer tube, and finally flows out of the decomposer from the inner tube, as shown in Figure 1.

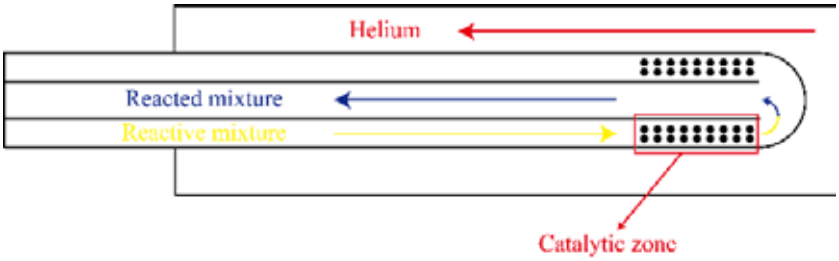

Fig. 1. Schematic diagram of sulfuric acid decomposer unit

The decomposition of sulfuric acid requires regular flow and heat transfer calculations, including continuity equations, momentum equations, and energy equations. In addition, the two-step decomposition reaction of sulfuric acid needs to be calculated using a component transportation model, as follows:

$$\nabla\cdot\left(\rho\mathbf{U}R_i\right)=-\nabla\cdot\vec{M}_i+S_i \quad (1)$$

where where ρ is the density of various fluids, **U** is the fluid velocity, R_i is the mass fraction of substance *i* at a certain local location, M_i is the diffusion flux of substance *i* and S_i is the net rate of reaction to obtain substance *i.*

The chemical reaction rate constant ($k_{f,r}$) has an important influence on the generation or disappearance of a certain substance, as follows:

$$k_{f,r}=A_r e^{-E_r/RT} \quad (2)$$

where A_r is the pre-index factor, T is the temperature, E_r is the reaction activation energy, R is the ideal gas constant. The boundary conditions of this study are shown in Table 1.

Table 1. Calculation condition

Parameter	Value
Mass flow rate of sulfuric acid(kg/s)	0.000175
Inlet velocity of helium(m/s)	0.1
Inlet temperature of sulfuric acid(K)	300
Inlet temperature of helium(K)	1123
Porosity of the catalytic zone	0.3、0.4、0.5
Catalyst particle size(mm)	5、6、7、8、9、10

RESULTS AND DISCUSSION

The particle arrangement of the catalyst bed affects the heat transfer of the flow of sulfuric acid and also affects the pressure drop of the system. This study assumes that the catalyst particles are regular spherical, evenly scattered in the 300mm long catalytic zone. Figure 2 shows the distribution of the proportions of sulfur trioxide and sulfur dioxide with a particle diameter of 5 mm. It can be seen that along the flow direction, sulfuric acid gradually decomposes in the first step to generate sulfur trioxide, and the first step decomposition reaction is basically completed in the middle section of the reactor. After sulfur trioxide enters the catalytic zone, it continues to decompose to produce sulfur dioxide. The first two-thirds of the catalytic zone has a high sulfur dioxide generation efficiency, and sulfur dioxide is mainly generated in this part.

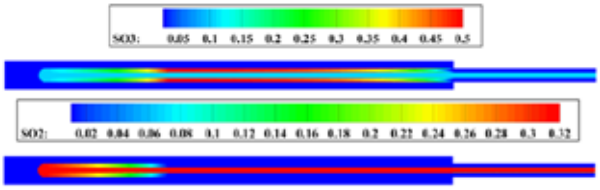

Fig. 2. Distribution of sulfur trioxide and sulfur dioxide

Figure 3 shows the effect of different particle sizes on the decomposition rate and pressure drop. When the porosity is constant, large particles are used to reduce the pressure loss of the system, but also significantly reduce the sulfuric acid decomposition rate. When the particle size is constant, the more compact the catalyst is packed, that is, the smaller the porosity, the greater the pressure loss of the fluid, but the close packing has a larger specific surface area, which also increases the decomposition rate. With the same porosity setting, the particles continue to decrease, the decomposition rate presents a similar linear increase trend, and the pressure drop presents an exponential

increase trend, indicating that the sensitivity between particle size and pressure drop is very high. With the same particle size setting, the porosity decreases by 0.1, the decomposition rate will increase by about 10%, and the pressure drop will increase exponentially. The setting of small particles will increase the pressure drop by about 6 times.The arrangement with porosity of 0.3 and particle size of 5mm has the largest decomposition rate and pressure drop, which are 79% and 193Pa, respectively.

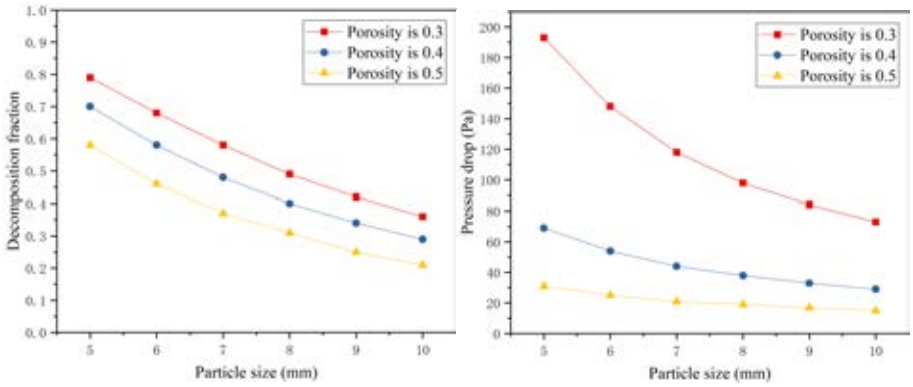

Fig. 3. The effect of catalyst bed layout on decomposition rate and pressure drop

CONCLUSIONS

The decomposition process of sulfuric acid was calculated based on the porous media and the surface reaction model, and the influence of the catalyst layout was studied. The calculation results show that:

- The first step of decomposition is basically completed in the middle of the reactor, and the second step of decomposition is the most efficient in the first two thirds of the catalytic zone. Arranging fine particles in this part is expected to further increase the decomposition rate.
- The particle size continues to decrease, the decomposition rate shows an almost linear increase trend, and the pressure drop shows a geometric increase. The average porosity decreases by 0.1, the decomposition rate increases by about 10%, and the pressure drop can increase by about 6 times at most.
- Under the current layout conditions, the maximum decomposition rate and pressure drop of the sulfuric acid decomposer unit can reach 79% and 193Pa.

ABSTRACT

Efforts to deploy hydrogen widely in the industrial, transportation and electric power sectors will support the creation of a decarbonized future. Nuclear power can provide 24/7 availability of both electricity and heat to support the efficient production of hydrogen through different processes. Hydrogen production from nuclear power can provide a strong opportunity for operating nuclear power plants to avoid curtailment and pair with renewable energy generation to create a decarbonized and flexible energy system. Regional and national nuances will indicate the best use for hydrogen in each country, and a combination of hydrogen applications in each sector will contribute to global decarbonization goals. The option of using currently operating nuclear power plants for hydrogen production, including when and how hydrogen production makes sense economically, is being explored at the International Atomic Energy Agency, by bringing together utilities with various hydrogen production projects. The study includes case studies of existing nuclear hydrogen demonstration projects to gauge project similarities and differences.

Keywords: Hydrogen, Nuclear, Electrolyser

INTRODUCTION

To significantly reduce global greenhouse gas emissions, two major undertakings must take place in tandem: all sectors must be electrified wherever possible, and the electricity sector must be decarbonized. In an increasingly electrified world, power sources will need to shift from fossil fuel to low-carbon generation sources, such as nuclear and renewable energy, to achieve climate goals.

As some heavy-emitting sectors are difficult to electrify, low-carbon hydrogen can be deployed across global industrial, transportation and electric power sectors will support the creation of a decarbonized future. While much of the world's low-carbon hydrogen is expected to come from renewables, nuclear power offers 24/7 availability which can help to lower the cost of hydrogen production. Nuclear hydrogen production has been technically feasible for some time but was previously too expensive in comparison to fossil fuel-produced hydrogen. As climate change mitigation sidelines fossil fuels, new opportunities arise for nuclear power. By 2050, the International Energy Agency (IEA) estimates that more than 60% of global hydrogen production will come from low-carbon sources [1]. In power systems with increasing shares of renewable generation, nuclear hydrogen production could provide a valuable alternative revenue stream for nuclear power plants, allowing for low carbon emitting power sources to remain economic.

Recent hydrogen policy developments

National interest in hydrogen has grown rapidly in recent years. Despite approximately 20 countries adopting or announcing the intention to create national hydrogen development strategies, only five have projects on nuclear hydrogen production with existing nuclear plants: Canada, Sweden, the Russian Federation, United Kingdom and United States. Even these are in nascent stages [2].

Canada [3], the Czech Republic [4], and the United Kingdom [5] mention hydrogen production from existing nuclear reactors in addition to advanced nuclear developments such as Small Modular Reactors, and the more specific, High Temperature Gas-cooled Reactor (HTGR), in their national hydrogen strategies. Both China and Japan are conducting demonstration projects with HTGR, a reactor type that is suitable for hydrogen production with energy efficient processes [6]. Beyond 2030, the Japan Atomic Energy Agency plans to develop hydrogen production facilities using a nuclear heat source [7].

HYDROGEN PRODUCTION METHODS

Unlike natural gas, hydrogen is produced in a chemical process powered by energy in the form of heat and/or electricity. Three main production methods for producing hydrogen are steam reformation, electrolysis, and thermochemical water splitting. The former typically uses energy from fossil fuels and heat; the latter two use water and electricity and/or heat from a variety of sources. Most of the hydrogen today is produced using steam methane reforming, a process which uses natural gas, or by coal gasification. Since both processes produce relatively high carbon emissions, the use of carbon capture and storage technologies may be deployed to reduce emissions before they enter the atmosphere.

Today's main electrolyser technologies can be divided into two types: low temperature electrolysers (LTE) and high temperature electrolysers (HTE). Electrolysers deploy either of these technologies to allow low-carbon hydrogen production using electricity from renewable energy or nuclear power [8,9]. LTE is an established technology and has already been deployed on a commercial scale. LTEs can be further divided into alkaline electrolysers and proton exchange membrane (PEM) electrolysers. Alkaline electrolysers are a mature and commercial-scaled technology that is easier to make in large scale compared to PEM electrolysers. HTEs use heat and electricity to produce hydrogen and are deployed using solid oxide electrolyser cells [10].

Thermochemical water splitting is a method by which water molecules are split into hydrogen and oxygen using heat. Examples include the Copper-Chloride cycle and the Sulfur-Iodine cycle; the latter is incorporated in the Japanese hydrogen project with HTGR [11].

THE BUSINESS CASE FOR NUCLEAR HYDROGEN

For hydrogen to fulfil its potential as an energy source for a decarbonized economy, it needs to be low-carbon, produced in large quantities, and cost-competitive with other hydrogen production methods. Three main parameters are crucial to optimize for the profitability of low-carbon hydrogen production: 1) the capital investment in the electrolyser, 2) the cost of electricity used in the production process, and 3) the capacity factor of the electrolyser.

Capital investments in the electrolyser may be reduced by economies of scale as module size increases, depending on electrolyser technology. The cost of electricity used in electrolysis may be reduced using low marginal cost nuclear or renewable energy compared to fossil fuel generators. Additionally, the relatively high capacity factor of nuclear plants compared to other generation sources allows for the electrolyser to operate over an increased time interval. The longer an electrolyser runs, the greater the impact of the cost of electricity and the lesser the impact of capital expenditures on the levelized cost of hydrogen. Therefore, it is essential to minimize the cost of hydrogen production by achieving an optional annual level of operating hours to balance this trade-off. According to the IEA, hydrogen production costs are minimized when an electrolyser operates with a capacity factor of 34-68% [12].

Demand and market conditions

At present, hydrogen demand is limited to the refining and chemical industrial sectors but is expected to grow significantly by 2050 [13]. "Clusters" are being developed as a tool to simultaneously develop integrated hydrogen production, storage, and transportation with various localized use cases. Cluster-based development can provide hydrogen producers with greater certainty on local hydrogen demand and de-risk their business case by ensuring off-takers. Additionally, clusters can support the development of several different end use applications in tandem, rapidly achieving economies of scale with the added benefit of focusing public support on developments which will benefit various companies and sectors [14].

UTILITY DEMONSTRATION PROJECTS

Four utilities in the US, three in Europe and one in Canada have started or are preparing to start nuclear hydrogen demonstration projects, but little progress has yet been made in Asia. The following are nuclear-powered hydrogen demonstration projects around the world, in order from most advanced to those in early stages of research or conception.

Energy Harbor, an American utility company, is planning a two-year demonstration project at the Davis-Besse nuclear power plant in Ohio, where the company plans to produce hydrogen beginning in 2023. The LTE used in the pilot project is a PEM electrolyser, which consumes 2 MW of electricity from the nuclear power plant and produces 800 to 1,000 kg of hydrogen per day. Energy Harbor's objective is to explore the economic viability of hydrogen production in nuclear power plants and to demonstrate the compatibility and synergy of the two technologies [15].

Xcel Energy plans to complete a hydrogen production demonstration project using high temperature steam electrolysis at the Prairie Island nuclear power plant in Minnesota, USA. Xcel intends to constantly produce hydrogen in the small-scale demonstration project but in the future will produce hydrogen when electricity prices are low due to high wind power output. The electrolyser is planned to produce about 90 kg of hydrogen per day [16].

Arizona Public Service Company in the US conducted a techno-economic assessment of using hydrogen produced from its Palo Verde nuclear generating station to co-fire in Unit 3 of the Saguaro natural gas fired turbine. The assessment concluded that the cost of capacity from co-firing hydrogen was competitive with battery storage for durations longer than four hours. A 17 MW electrolyser with a hydrogen compression and storage system project will start from 2022 [17].

Exelon plans to install a 1.25 MW PEM electrolyser at the Nine Mile Point nuclear plant in the US State of New York. The company also plans to explore dynamic operation of the electrolyser [18].

EDF UK completed a feasibility study for hydrogen production at the Heysham nuclear power station [19]. EDF identified potential off takers, but none were interested at the price point anticipated by EDF. The company is now exploring hydrogen production at the site of the Sizewell B nuclear power plant, where it plans to begin installation of a 2 MW electrolyser in 2022 and production of up to 800 kg of hydrogen per day. The planned nuclear plant Sizewell C is expected to eventually produce hydrogen as part of an energy hub to support global trade [20]. The plan is for Sizewell C to include a 1 GW electrolyser by 2030 to produce 145,000 tons of hydrogen annually [21].

Rosatom plans to build a hydrogen production and conversion test facility at the Kola nuclear power plant in Russia. The hydrogen complex is expected to be operational in 2024 and will be equipped with a 1 MW alkaline electrolyser which could be expanded to 10 MW later [22].

Vattenfall, a Swedish energy utility, has been producing hydrogen using the Ringhals nuclear power plant since 1997. The 0.8 MW electrolyser produces between 60 and 110 m^3 of hydrogen per hour. The hydrogen produced is used to cool the nuclear generators and is injected into the feed water to prevent corrosion. Vattenfall, having several non-nuclear hydrogen projects, does not currently plan to expand or develop hydrogen production at its nuclear power plants [23].

In 2021, Bruce Power of Ontario, Canada, examined the technical feasibility and business case for a pilot project to produce hydrogen using electricity from the Bruce nuclear power plant. The project will study the benefits of hydrogen production, including export opportunities, local interest, and jobs created [24].

For each of these utilities, the anticipated use of hydrogen differs by region and demonstration project (Table 1).

Table 1. Comparison of Intended Nuclear Hydrogen Applications Among Utilities with Demonstration Projects

	Utility name						
	Energy Harbor	**Xcel Energy**	**Arizona Public Service**	**Exelon Corporation**	**EDF UK**	**Rosatom**	**Bruce Power**
Technology and size of demonstration project	LTE PEM, 2 MW	HTE, 150 kW	LTE, 17 MW	LTE PEM, 1.25 MW	Sizewell B (LTE, 2 MW) Sizewell C (HTE)	LTE, 1 MW	LTE, 5 MW
Use for demonstration project's nuclear hydrogen	Manufacturing and transportation	Company's NPP	Company's natural gas-fired power plant	Company's NPP	Transportation and equipment for new NPP construction	Energy storage in remote and isolated areas	To be determined
Potential uses for nuclear hydrogen in the future	Manufacturing (oil refining and steel production), transportation	Oil, gas, and ammonia production, transportation , power generation	As an energy storage tool to balance the output of variable solar power	Injection into gas pipelines, co-firing of gas plants, ethanol production, petroleum refining	Cargo, public transportation, ships, aviation, industrial processes, district heating	Energy storage in remote and isolated areas	Fertilizer production, power and heat for heavy industry, transportation

CONCLUSIONS

To further deploy hydrogen production from nuclear power, it is important to understand demonstration projects based on their similarities and differences. Shared attributes of each of the projects are likely to be continued in the deployment of new projects. Conversely, unique aspects from each project should be carefully considered to determine whether they are due to the project's unique goals and regional considerations or matters for which a consensus must still be found. Additionally, technology improvements compared to what is available today such as advanced nuclear reactors with more efficient thermo-chemical splitting methods have the potential to redefine the future of hydrogen production.

Almost all nuclear hydrogen projects are still in an early demonstration stage, and most projects are expected to be completed in two to three years. It will be necessary to continue to follow these projects to identify successes and challenges in the deployment of hydrogen production from nuclear energy. As nuclear hydrogen production is scaled to commercial size, it is important to identify how to resolve challenges from scaling-up the electrolyser, meeting regulatory requirements, transporting and storing hydrogen, and further development of hydrogen demand.

ABSTRACT

A unique, solar, and nuclear based hybrid system is developed to generate hydrogen, ammonia, heat, food, power and fresh water in an integrated and sustainable fashion. The integrated system is analyzed according to the first and second laws of thermodynamics, extensively, for five different cities in a time-dependent manner. The floating and bifacial PV options are considered and analyzed as two different options for the cities. In the average year in Istanbul, 2 × 250 MW_{th} high temperature gas cooled reactors with 120 MW_p PV plants in the integrated system met 738.7 GWh annual electrical load, generated 20828 tons of hydrogen in the floating PV option and 22360 tons of hydrogen in the bifacial PV option. The overall energy and exergy efficiencies are found to be 52.34% and 57.61% for the floating PV option 54.13% and 59.54% for the bifacial PV option in Istanbul.

Keywords: Floating Photovoltaic, Bifacial, Hydrogen Energy, Ammonia, Exergy

1. INTRODUCTION

In order to combat climate change, governments around the world take measures and target to reduce CO_2 emissions. Phasing out from fossil-based fuels as well as conflicts between countries lead to fuel shortages as well as indirect shortages such as fertilizer, food, water. In order to secure the emission targets to reach net zero emission by 2050 and 2060, renewable and sustainable energy systems needs to be developed in a smart fashion [1].

Renewable-nuclear hybrid energy systems has synergetic advantages to overcome challenges that can be faced if renewable or nuclear systems used alone. The intermittency is one of the major challenges of renewables that can be mitigated with the nuclear option. On the other hand, the high levelized cost of electricity of nuclear power can be reduced with low levelized costs of electricity from renewables [2,3].

The proposed system uses a hybridized nuclear solar system to generate ammonia, hydrogen, heat, electrical power, fresh water and food in a novel integration.

2. SYSTEM DESCRIPTION AND ANALYSIS

A high-temperature gas cooled small modular nuclear reactor design is used as Chinese high-temperature gas-cooled pebble bed module (HTR-PM), where each module has 250 MW_{th} capacity. Two reactors are used in the proposed system, which can generate up to 200 MW_e. On the other hand, two different photovoltaic (PV) plant options are used in the system. The first PV option is a bifacial PV plant where a land-based tracker system is used with bifacial PV modules. The other one is a floating PV plant where monofacial PV modules are used on floating platforms. Solid oxide electrolyzer, pressure swing adsorption air separator, ammonia reactor are among the other components of the integrated system. Fig. 1 shows the proposed system layout.

The proposed system is analyzed for five different cities around the globe, namely, Barcelona, Spain; Istanbul, Turkey; Los Angeles, United States; Toronto, Canada; Tokyo, Japan for both bifacial PV and floating PV options. Floating PV plants are considered especially for the cities with land shortages, such as Tokyo and Istanbul.

The nuclear plant and multi-effect distillation desalination system are simulated by using the DE-TOP software package. Both of the PV options are simulated by using PVSyst software package. The results are imported to analyze these systems with first and second laws of thermodynamics by using the mass, energy, entropy and exergy balance equations.

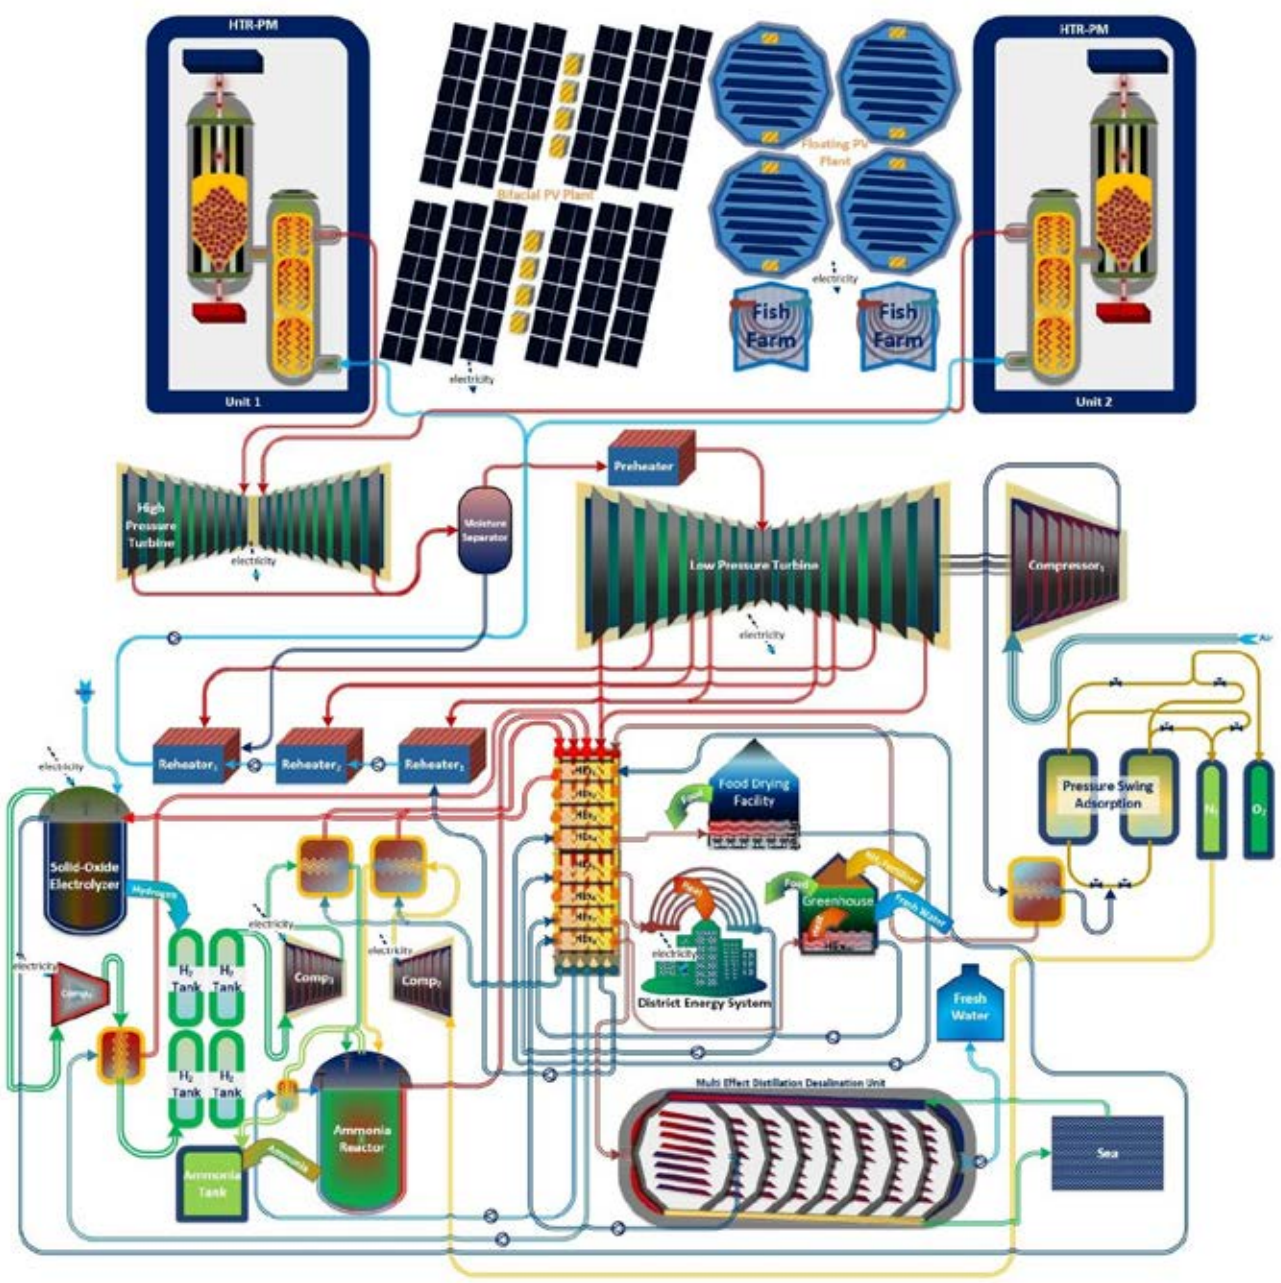

Fig. 1. A layout of the developed system

3. RESULTS AND DISCUSSION

The proposed system is simulated and analyzed with a thermodynamic based approach. The proposed system is considered to be connected with a virtual grid. The excess electricity is used to generate hydrogen and ammonia; the excess heat is used to generate hydrogen in the solid-oxide electrolyzer, fresh water with the desalination unit as well as to heat district energy system and agricultural facilities. The produced ammonia can be used in agricultural activities as a fertilizer, as well as it can be used as a fuel or feedstock in related sectors. In the average year in Istanbul, the proposed system met 738.7 GWh annual electrical load, generated 20828 tons of hydrogen in the floating PV option and 22360 tons of hydrogen in the bifacial PV option. The overall energy and exergy efficiencies are found to be 52.34% and 57.61% for the floating PV option 54.13% and 59.54% for the bifacial PV option in Istanbul. Fig. 2 shows the obtained results of the proposed systems' analysis for five different cities around the globe.

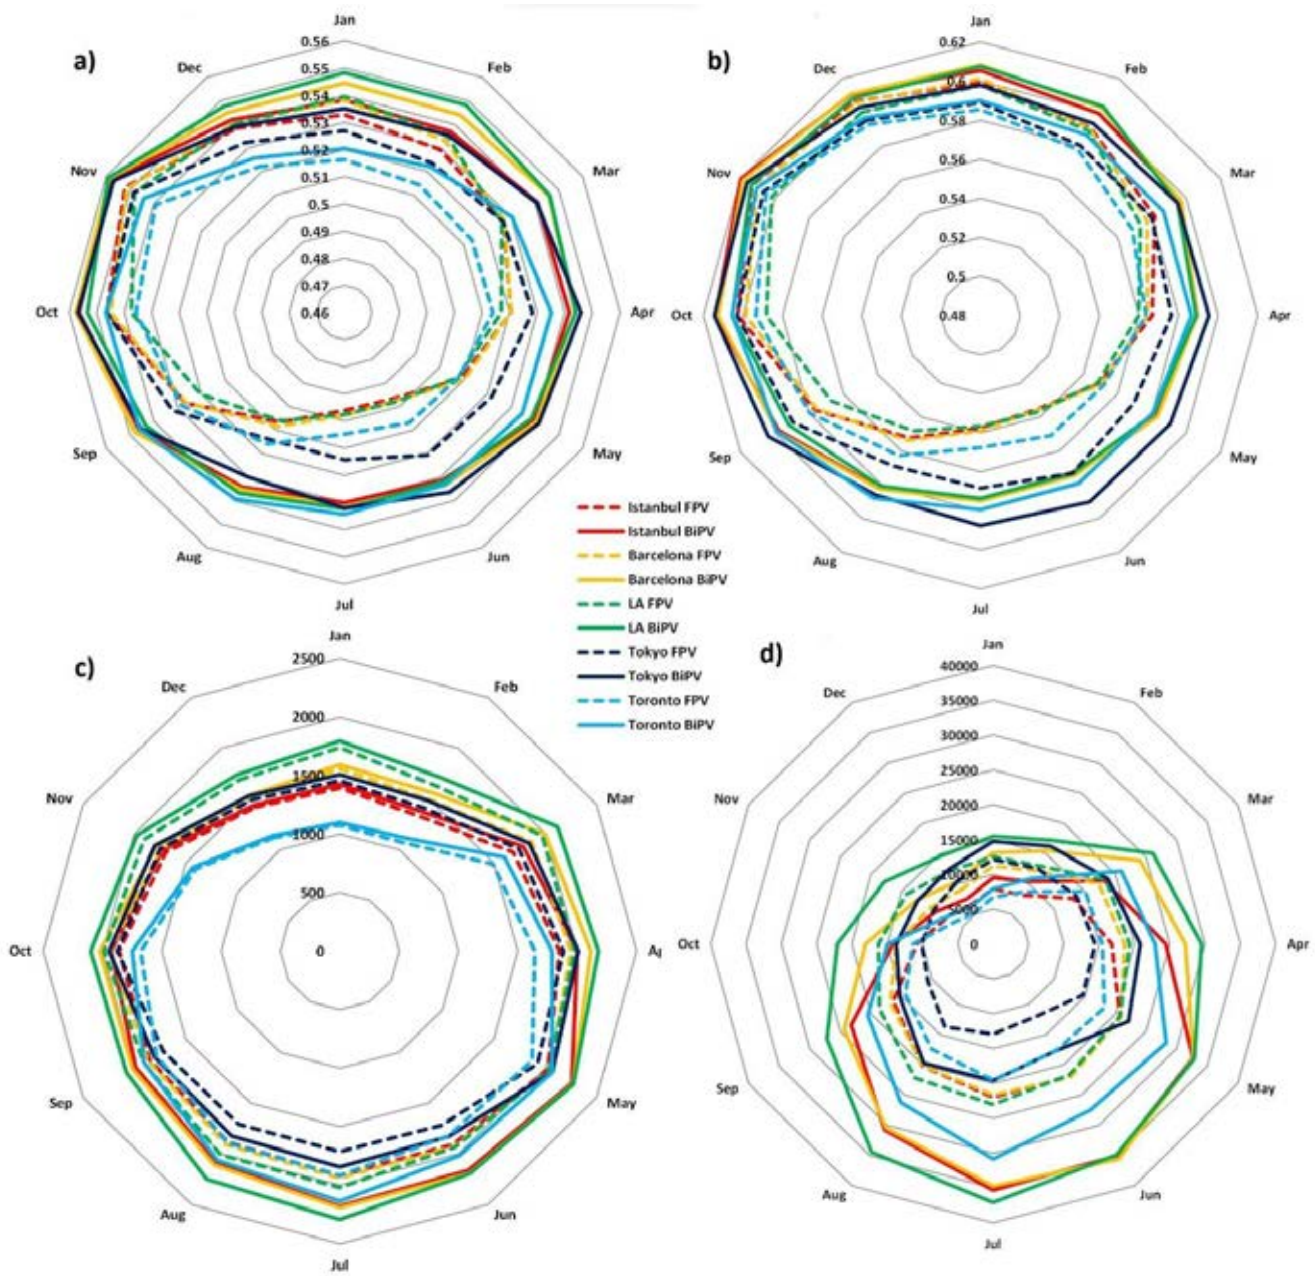

Fig. 2. For the overall systems: a) energy efficiency, b) exergy efficiency, c) hydrogen generation (tons/month), d) PV electricity generation (MWh/month)

4. CONCLUSIONS

The hybridization of nuclear and solar systems has achieved unique advantages by (i) preventing intermittencies in compared to the renewable-alone systems, (ii) reducing carbon emissions in compared to fossil-based systems, (iii) lowering the levelized cost of energy compared to the nuclear-alone systems. The bifacial option has increased both energy and exergy efficiencies and significantly increased the PV electricity production.

ABSTRACT

In this paper, the multiobjective optimization of a nuclear cogeneration plant for hydrogen production is carried out. The analysis focuses on the secondary cycle of a pressurized water reactor nuclear cogeneration plant providing process heat and electrical energy to a high-temperature steam electrolysis facility. The utopia point method is used to determine the values of heat/electricity energy ratio, hydrogen production capacity, live steam temperature and steam extraction node that yield a compromise optimum solution between thermal efficiency, thermal-to-hydrogen production efficiency, exergy efficiency and utilization factor. For a hydrogen production capacity of 7 kg/s, an energy ratio of 0.0561 results with the best overall performance, while an energy ratio of 0.10 gives the best performance for a capacity of 0.1 kg/s.

Keywords: Hydrogen Production, Nuclear, Multiobjective Optimization, PWR, High-Temperature Steam Electrolysis

INTRODUCTION

The rapid increase in global warming necessitates a fast transformation in energy infrastructure and transportation sector. Hydrogen is a promising candidate for the mitigation of greenhouse gas emissions. However, steam methane reforming is the most widely utilized process for hydrogen production, which caused an emission of 900 Mt of CO_2 in 2021 [1] corresponding to approximately 2.8% of the global annual emissions. Therefore, alternative production methods should be utilized in order to fully reveal the potential positive effect of hydrogen use on climate change. In this respect, nuclear energy is an advantageous option to produce hydrogen in an environmentally friendly manner.

Among the alternative hydrogen production methods, the high-temperature steam electrolysis (HTSE), which requires energy in both electrical and heat forms, is energetically more efficient than its counterparts [2]. Moreover, HTSE is also preferable to other alternatives in terms of its cradle-to-grave environmental impact [3,4]. Although, studies [5,6] focus on coupling the HTSE facility to high-temperature reactors, utilization of existing light water reactors (LWR) will accelerate the transformation of infrastructure intended for sustainable hydrogen production. In fact, techno-economic analysis of an HTSE facility coupled to an LWR showed that the nuclear facility would benefit from hydrogen production [7].

In this study, a multiobjective optimization (MOO) of a pressurized water reactor (PWR) based nuclear cogeneration plant for hydrogen production through HTSE process is carried out. A comprehensive thermodynamic parametric cycle analysis for the secondary cycle of the PWR plant is performed in order to investigate the impacts of the decision variables of heat/electricity energy ratio, hydrogen production capacity, live steam temperature and steam extraction node on the objective functions of thermal efficiency, thermal-to-hydrogen efficiency, utilization factor and exergy efficiency. Then, MOO of the plant is done with the utopia point method to determine the optimum compromise solutions for the decision variables.

THERMODYNAMIC ANALYSIS AND MOO OF THE NUCLEAR COGENERATION PLANT

The secondary cycle of the PWR nuclear cogeneration plant is illustrated in Fig 1. Thermal energy extracted from the reactor core via the primary cycle is transferred to the secondary cycle via the steam generator. The high- and low-pressure turbines produce electrical energy through the generator while the condenser cools the working fluid through a tertiary loop. Feedwater heaters (FWH) increase the thermal efficiency of the plant and provide operational flexibility for cogeneration. Green and yellow lines in Fig 1 represent the steam extraction and condensate return routes, respectively.

The thermodynamic model is constructed by applying the steady-state mass and energy conservation and entropy balance equations to all components of the cycle to determine the mass flow rate and thermodynamic properties of all states. Then, the thermal, thermal-to-hydrogen, exergy efficiencies and utilization factor of the cogeneration plant are calculated by

$$\eta_{th}=\frac{\dot{W}_{net}}{\dot{Q}_{SG}},\ \eta_{H_2}=\frac{\dot{m}_{H_2}\Delta H_{H_2}}{\dot{Q}_{process}+\dot{W}_{H_2}/\eta_{th}},\ \eta_{ex}=\frac{\dot{X}_{out,\dot{W}_{net}}+\dot{X}_{out,\dot{Q}_{process}}}{\dot{X}_{in,\dot{Q}_{SG}}},\ \varepsilon_u=\frac{\dot{W}_{net}+\dot{Q}_{process}}{\dot{Q}_{SG}} \quad (1)$$

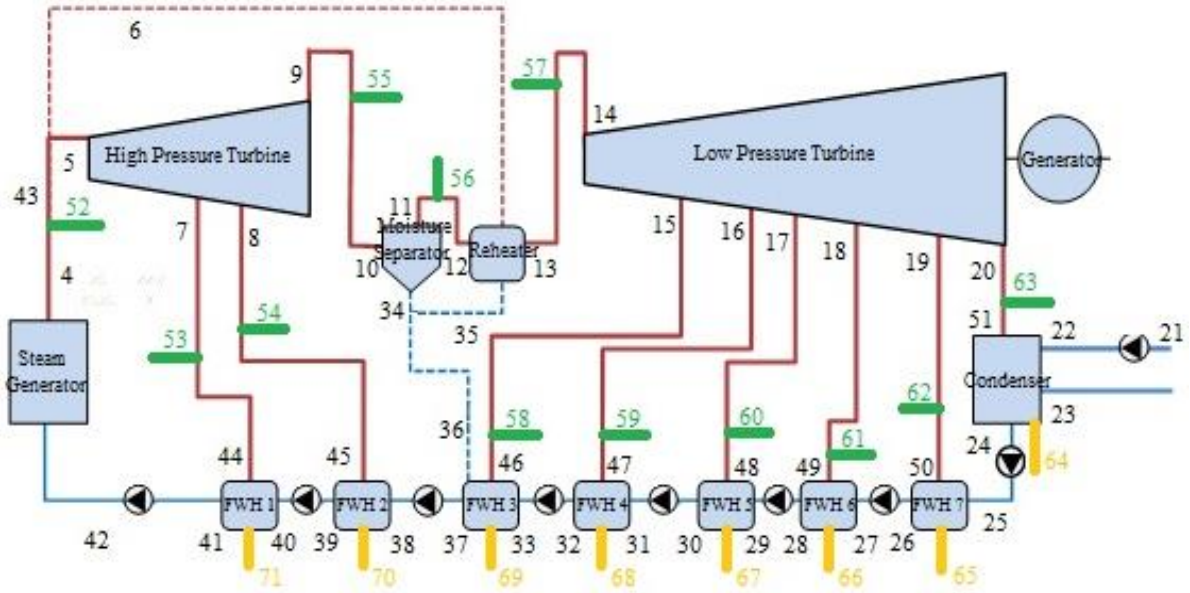

Fig. 1. Secondary cycle of the pressurized water reactor cogeneration plant.

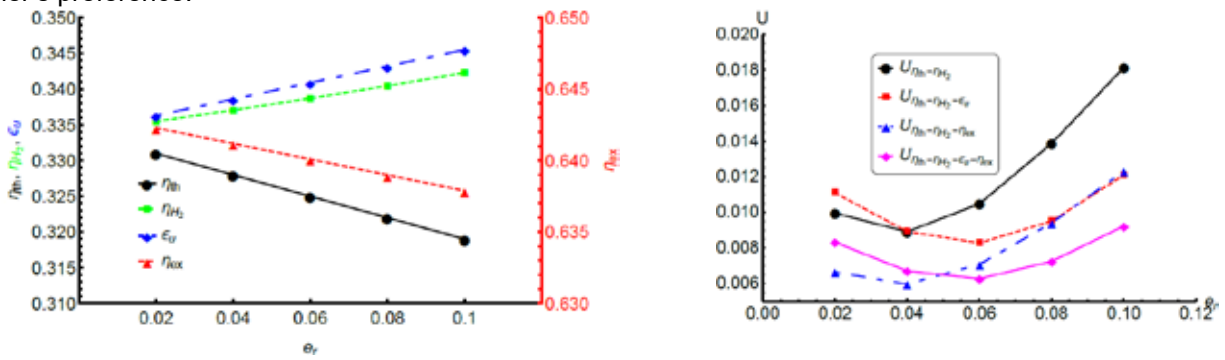
respectively. In Eq. (1), $\dot{W}_{net}$ is the net electrical power, $\dot{Q}_{SG}$ is the heat transfer rate through the steam generator, $\dot{m}_{H_2}$ is the hydrogen production rate, ΔH_{H_2} is the formation enthalpy of hydrogen, $\dot{Q}_{process}$ is the rate of heat transferred from the secondary cycle to the HTSE facility, $\dot{W}_{H_2}$ is the rate of energy transfer to the HTSE facility in the form of electricity, $\dot{X}_{out,\dot{W}_{net}}$ and $\dot{X}_{out,\dot{Q}_{process}}$ are the rates of exergy output of the secondary cycle in form of electricity and heat, respectively, and $\dot{X}_{in,\dot{Q}_{SG}}$ is the exergy expended in the cycle. MOO of nuclear cogeneration plant's secondary cycle with the utopia point is carried out by minimizing a composite function that is formed through the objective functions:

$$\text{Minimize}\left\{\sum_{i=1}^{k}w_i^p\left[\frac{f_i(\boldsymbol{x})-f_i^u}{f_i^{max}}\right]^p\right\}^{1/p}\quad \text{subject to } a_j\le x_j\le b_j,\ j=1,2,...,m \quad (2)$$



In Eq. (2), f_i and w_i are the objective functions and the corresponding weights, respectively, x is the set of decision variables, f_i^u and f_i^{max} are the utopia and maximum values of the objective functions, respectively, and a_j and b_j are the constraints of the decision variables.

RESULTS AND DISCUSSION

This work deals with the multiobjective optimization of a nuclear cogeneration plant for hydrogen production. Energy is transferred from the secondary cycle of the cogeneration plant to a HTSE facility in the form of process heat and electrical energy. Thermal, thermal-to-hydrogen, exergy efficiencies and utilization factor of the cogeneration plant are considered as the objective functions while energy ratio ($e_r=\dot{Q}_{process}/\dot{m}_{H_2}\Delta H_{H_2}$), hydrogen production capacity, live steam temperature and steam extraction nodes are the decision variables.

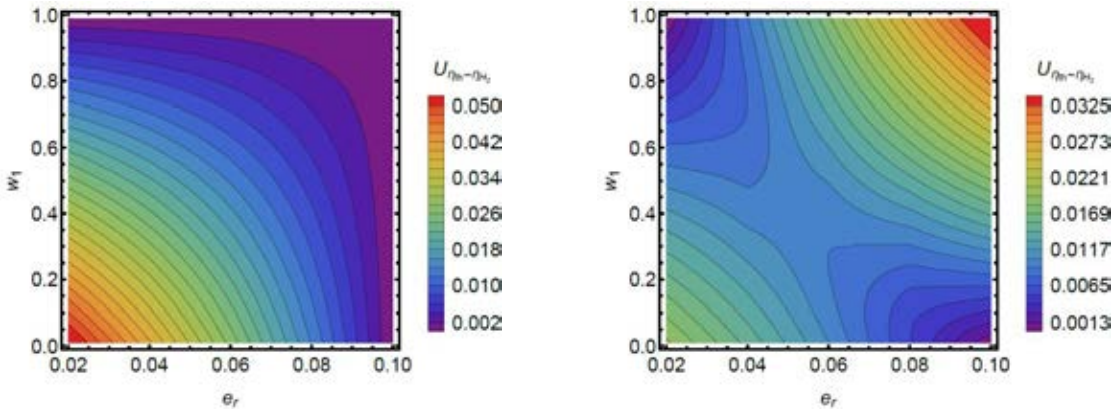


Fig. 2a illustrates the variation of the objective functions with the energy ratio for a hydrogen production rate of 7 kg/s where steam is extracted from node 52, the condensate returns at node 64 and steam temperature at the outlet of the steam generator is 277°C. It is observed that the thermal and exergy efficiencies decrease with an increase in energy ratio, while the thermal-to-hydrogen efficiency and utilization factor have an opposite behavior. These results propound the need for MOO, and Fig. 2b represents the impact of energy ratio on different composite functions where equal weights are used for all cases. The optimum value of energy ratio depends on designers preferences. $U_{\eta_{th}-\eta_{H_2}}$, $U_{\eta_{th}-\eta_{H_2}-\eta_{ex}}$, $U_{\eta_{th}-\eta_{H_2}-\varepsilon_u}$, $U_{\eta_{th}-\eta_{H_2}-\eta_{ex}-\varepsilon_u}$ are minimized at e_r values of 0.0380, 0.0375, 0.0569 and 0.0561, respectively.

The hydrogen production capacity has a significant impact on the MOO of the nuclear cogeneration plant. The contour plots in Figs. 3a and 3b show the Pareto set of $U_{\eta_{th}-\eta_{H_2}}$ with respect to energy ratio for hydrogen production capacities of 0.1 kg/s and 7 kg/s, respectively. When the hydrogen production rate is 0.1 kg/s, the optimum value of the energy ratio is 0.10 for all choices of weight functions, whereas for the production rate of 7 kg/s, it depends on designer's preference.

(a) (b)

Fig. 2. Variation of (a) objective functions and (b) MOO composite functions with the energy ratio.

(a) (b)

Fig. 3. Pareto set of $U_{\eta_{th}-\eta_{H_2}}$ for hydrogen production rates of (a) $0.1 kg/s$ and (b) $7 kg/s$.

CONCLUSIONS

The multiobjective optimization of a nuclear cogeneration plant aimed to produce hydrogen with high-temperature steam electrolysis is performed with the utopia point method. Thermal, thermal-to-hydrogen, exergy efficiencies and utilization factor of the cogeneration plant are chosen as the objective function, and energy ratio, hydrogen production capacity, live steam temperature, steam extraction nodes and ambient conditions are considered as the decision variables. The effects of energy ratio and hydrogen production rate are presented. Results show that, depending on the choice of composite function the optimum value of energy ratio lies in the range of 0.037-0.057 for a hydrogen production rate of 7 kg/s, and it is 0.10 for a production rate of 0.1 kg/s.

NUCLEAR HYDROGEN PERSPECTIVES IN ROMANIA

[1] Ioan Iordache, [2] Mihai Varlam, [2] Elena Carcadea, [2] Mihaela Iordache*
[1] National Institute for Research, Development and Testing in Electrical Engineering – ICMET, Decebal Str., Craiova, Romania
[2] National Research and Development Institute for Cryogenics and Isotopic Technologies -ICSI, Uzinei Str., Rm. Vâlcea, Romania

*Corresponding author e-mail: iordache.ioan@icsi.ro

ABSTRACT

This work presents the latest advances of nuclear hydrogen perspectives in Romania. The topic is really new and nuclear hydrogen is considered a new perspective through its low carbon or zero carbon production. The role of nuclear hydrogen production in a low-carbon economy is analysed now by many scientist and many stakeholders, especially national or local authorities, consider that as a new perspective for nuclear energy sector.

Keywords: Romania, Nuclear Hydrogen

INTRODUCTION

Romania is a country that traditionally produces hydrogen [1]. Romania's energy security must take in consideration all global perspective and the newest trends in nuclear energy. In this work authors show an accurate picture about national specific situations in the field of the nuclear hydrogen perspectives in Romania.

Romania recognise the opportunity to use the nuclear energy sector in order to produce hydrogen, of course others also understood this: Argentina, Canada, Germany, Hungary, Indonesia, Italy, Libya, Pakistan, Russia, the UK or the USA. Many form above list have very active progressing research and development initiatives.

The authors consider that nuclear hydrogen is an opportunity to decarbonise significant sectors not only the ability to produce clean hydrogen economically and sustainably in large scale; and are agree that the uncertainties related to nuclear hydrogen technologies and economics can be a barrier to their development. The potential for nuclear power plants can be valorised mere because there can be produced hydrogen using both, power and heat. Referring to the higher temperatures, today's commercial plants output is less 350°C. The nuclear community must focus his attention to the advanced high-temperature reactors for hydrogen production. The high temperature reactors will be the leading technology for future nuclear hydrogen production and nuclear-renewable hybrid energy systems must be considered [2-4].

The hydrogen market need to be developed concomitantly in all directions: the full supply/value chain, including supply, storage, transport, distribution and end use applications.

The most thermochemical cycles require temperatures that exceed 800 °C. The "coldest" cycle is copper-chlorine where the required maximum temperature does not exceed 550 °C. This advantage makes the connection between the Cu-Cl cycle and CANDU nuclear reactors. University of Ontario Institute of Technology (UOIT) and Atomic Energy of Canada Limited (AECL), both of Canada, together with other collaborators, have made a partnership to study, research and develop of this thermochemical cycle. The most studied cycle is the sulphur-iodine S-I or SI, with the next institutes or agencies conducting tests on pilot installations: Japan Atomic Energy Agency (JAEA), General Atomics (GA), Commissariat of Energy Atomic (CEA, France), etc.

NUCLEAR HYDROGEN ASPECTS IN ROMANIA

Romania, the National Hydrogen and Fuel Cell Centre (Fig. 1), is collaborating with Canada on nuclear hydrogen production with the thermochemical Cu-Cl cycle. The group of authors currently performs theoretical and experimental research in integrating renewable energy and low-carbon hydrogen production, catalytic membrane reformer design, thermo-chemical water splitting. The potential of low temperature thermo-chemical cycle as Copper-Chlorine (Cu-Cl) for large-scale hydrogen production using nuclear energy is under investigation to perform integrated lab-scale experiments. The Center was a part of an international project named "Clean Hydrogen Production with Water Splitting Technologies", with Ontario Tech University as the leader of the project. The Center has participated in projects involving the assessment of the potential and relevant business cases for large scale and seasonal storage of renewable electricity by hydrogen underground storage in Europe, HyUnder consortium. The scope of Romanian participation was to identify the most promising site for hydrogen underground storage. For large scale underground storage, hydrogen can be produced by both, renewable and nuclear. Above research and development projects have the mission to

implement, develop and disseminate nuclear hydrogen in Romania, as well as to support national priority policies in the field of energy.

The Romanian authorities need to understand that concerns about nuclear hydrogen are important to the international community and that it is time to take concrete action. Even if the scientific community has a limited number of initiatives, it can support national needs to integrate and participate in international initiatives in this field.

Fig. 1. National Center for Hydrogen and Fuel Cell

CONCLUSIONS

The hydrogen scientific community from Romania is conscious by the perspective and the role of nuclear hydrogen production as part of the whole hydrogen supply chain/lifecycle developed, including demand, production, storage and distribution. The decision to support it by national authorities must be in line with the projects' participation of scientific community. There are several ongoing initiatives in many countries which indicates to the Romanian authorities that the concerns are important at the level of the international community and that it is time to take concrete actions.

NUCLEAR HYDROGEN PROJECTS TO SUPPORT CLEAN ENERGY TRANSITION

[1*]*Alina Constantin*
[1]International Atomic Energy Agency, Vienna, Austria

*Corresponding author e-mail: a.constantin@iaea.org

ABSTRACT

Hydrogen is expected to be a game changer in the fight against climate change, being able to support the clean energy transition through a variety of roles: decarbonizing different hard-to-abate industrial sectors (such as steel, cement production) and transport (in long haul vehicles, ships and aviation), direct use as a fuel, chemical feedstock or in the form of synthetic fuels, and providing the ability to integrate with hybrid energy systems and renewables, enhancing energy storage and tapping full potential of renewable energy sources. As a consequence, significant increase in hydrogen production is foreseen by 2050, with all the generation coming from zero-carbon processes (electrolysis/thermochemical cycles using clean electricity and heat) or from a low carbon process using steam methane reforming with carbon capture and storage. Nuclear energy can be capitalized on both electricity and heat to provide a clean and reliable source of hydrogen through various processes. There are currently various demonstration projects undergoing in several countries to showcase use of nuclear energy to produce clean hydrogen, considering both the current reactor fleet and advanced reactors. This paper provides an overview of these projects.

Keywords: Nuclear Power; Hydrogen; Decarbonization; Clean Energy

INTRODUCTION

Hydrogen is a commodity chemical species playing a vital role in many industries. As of today, industries such as petrochemical refining, ammonia and methanol production, as well as steel manufacturing, require the largest hydrogen amounts totalling around 70 Mt annually [1]. The hydrogen is produced almost entirely from fossil fuels (natural gas: 48%; off-gases: 30%; coal: 18%; water electrolysis: 4% [2]), leading to CO2 emission of around 830 million tonnes per year [1, 3]. About 6% of global natural gas and 2% of global coal feed the production of the necessary hydrogen [1]. As a fuel, hydrogen has the highest energy content by weight (3 times higher than gasoline) and its use does not release any carbon dioxide on combustion. However, it can have high upstream carbon intensity depending on the energy source and feedstock used to generate it. Hydrogen is a critical feedstock for the entire chemicals industry, including liquid fuels. The Energy Transitions Commission estimates a 5-7-fold increase of hydrogen utilization from today's level by 2050 [4]. The challenge the policy makers need to address consists in finding effective mechanisms to stimulate the production of "clean" hydrogen without generating greenhouse gas emissions as most of the hydrogen comes today from fossil fuel. Fossil fuels have still the biggest share in hydrogen production as the energy consumption in the process is lower than required by electrolysis of water [5] and the production cost is also lower. The most widespread technology to generate hydrogen (accounting for ~76% of the produced hydrogen [3]) is steam methane reforming (SMR). Hydrogen can be also produced by coal gasification method and this option is well represented in China where more than 80% of the world's coal gasification plants are located. This method has the lowest cost for hydrogen production [3]. The SMR technology results in emission of 10 tonnes of CO2/ 1 tonne of H2 while coal gasification produces 19 tonnes of dioxide CO2/ 1 tonne of H2

HYDROGEN PRODUCTION USING CURRENT NUCLEAR FLEET

The existing initiatives for demonstration nuclear hydrogen projects using the operating fleet of reactors focus first on considering electrolysis and introducing that as an additional means to capitalize the clean electricity produced by the nuclear plant. These projects imply a close coordination among industry partners and various stakeholders to evaluate the technical and the economic feasibility and to facilitate implementation. The successful deployment of the demonstration projects is expected to pave the way for large scale projects as they prove the technology and viability of such endeavours, while also supporting the creation of a market for these technologies and attracting more investment into the sector.

Canada. The Nuclear Innovation Institute (NII) has been conducting a study to evaluate the technical feasibility and business case for hydrogen production from nuclear power, also investigating the opportunity for a pilot project at the Bruce Nuclear Generating Station. The Hydrogen Strategy for Canada [6] outlines a role for nuclear electricity to produce hydrogen at off-peak times using nuclear reactors in Ontario, where three of the four nuclear generation stations are located, and in New Brunswick [6].

Europe. In July 2020, the European Commission published the Hydrogen Strategy for a Climate-Neutral Europe [7] to guide the steps towards achieving a hydrogen economy, containing targets, investment goals and regulatory mechanisms to support. Several EU countries (France, Germany, Netherlands, Portugal and Norway, as of September 2020) have already established national hydrogen strategies [3] with different approaches (e.g. France is supportive of nuclear-produced hydrogen while Germany relies on hydrogen imports). However, the European Hydrogen Strategy excludes nuclear power from making a contribution to hydrogen economy over a long-term, envisioning it entirely based on hydrogen produced using renewables sources [3], diminishing the commercial incentive for low carbon energy producers (nuclear, hydropower) to invest in hydrogen generating technologies and hydrogen network infrastructure [3].

United Kingdom. EDF is currently assessing hydrogen production using its fleet of UK nuclear reactors (including Hinkley Point C (under construction) and Sizewell C (proposed to be constructed)). A feasibility study on hydrogen production using electrolysis at Heysham Nuclear Power Station was conducted in 2019 [8], under the Hydrogen to Heysham (H2H) project, to investigate the possibility of replication and scaling up at other nuclear sites across the UK. The study included an assessment of the hydrogen market, engineering design at the Heysham Nuclear Power Station, process risk assessment and implementation steps, and confirmed that the H2H project is technically feasible and further development of this hydrogen supply solution could contribute to the UK's commitment to net zero carbon emissions by 2050. The H2H project was assessed to have a carbon footprint of 24 gCO2/kWh H2 compared to 509 gCO2/kWh H2 for an equivalent grid-connected project [8] and produce at maximum capacity 800 kg hydrogen per day, considering a 2MW electrolyser system (1 x 1MW Alkaline and 1 x 1MW PEM electrolysers). Assuming a wholesale electricity price of £63/MWh, over a 20-year lifetime of the H2H project, the levelized cost of hydrogen (LCOH) calculated was £6.73 – £8.60/kg [8]. The study also estimates that a future electrolyser capacity of about 550MW across UK's nuclear fleet could produce about 220000 kg of hydrogen per day by 2035, with a levelised cost of hydrogen as low as £ 1.89/kg ($ 2.44/kg) [4]. Due to the challenges in developing a successful business model arisen from the lack of support or incentives for end users to consume the hydrogen produced, the project was not able to progress to the demonstration phase [9]. The Nuclear Industry Association's (NIA) Hydrogen Roadmap, endorsed by the Nuclear Industry Council, and the cross-sector Action Plan prepared by the National Nuclear Laboratory (NNL) outline how nuclear power could contribute in producing massive quantities of zero carbon hydrogen to the emerging hydrogen economy [10]. In November 2020, Sizewell C announced its interest to develop a hydrogen demonstrator project. Current steps also include an Innovate UK funded study on transitioning from a diesel to a hydrogen fleet of vehicles at Sizewell [9]. A new nuclear project in Suffolk is looking to develop a demonstration electrolyser at around 2MW to produce up to 800 kg of hydrogen per day that can be used in bus transport for construction workers to and from Sizewell C site [9].

United States: U.S. Department of Energy (DOE) established the H2@Scale initiative bringing together various stakeholders to advanced clean and affordable hydrogen production, transport, storage and utilization. The DOE's H2@Scale Consortium facilitates R&D projects that leverage the world-class capabilities of the national laboratories in partnership with industry and academia. One of the free-to-access resources to inform hydrogen technology development that was prepared under H2@Scale initiative is a techno-economic analysis on the viability of retrofitting existing pressurized water reactors (PWRs) to produce hydrogen via high temperature steam electrolysis [11]. Partly funded by the H2@Scale, Exelon started developing a multi-year nuclear hydrogen demonstration project in August 2019 to install a 1 MW PEM electrolyser at one of its boiling water reactors (BWR) [12]. DOE is funding also 3 additional projects to demonstrate hydrogen production at 3 nuclear power plants: the Energy Harbor's Davis-Besse NPP in Ohio (using a 2 MW PEM electrolyser), the Arizona Public Service (APS) Palo Verde NPP in Arizona (to study the potential of a reversible PEM electrolyser, with the reactor producing electricity at peak demand and hydrogen during low peak demand) and an Xcel Energy NPP in Minnesota (using HTSE technology for hydrogen generation [13]), expecting to showcase significant advances for improving the long term economic competitiveness of LWRs. Hydrogen produced through these projects will have various applications: for example, the hydrogen from Davis-Besse may initially be used to supply public transportation fleets in Ohio or in new direct iron reduction plants being constructed to produce steel [13].

SUMMARY AND CONCLUSION

Nuclear hydrogen production has the potential to enable nations to achieve their Net Zero targets by supporting energy system and industrial decarbonization. There are still barriers and challenges that remain to be addressed for an accelerated deployment of nuclear hydrogen but also opportunities that comes from the benefits that nuclear energy can provide to support massive production of hydrogen, using various reactor technologies: either the current fleet, operating in cogeneration mode and producing hydrogen through electrolysis process, the advanced high temperature reactors coupled with thermochemical cycles, or the innovative small modular reactors that comes with an enhanced operational flexibility and can be at the heart of the growing hydrogen market. The nuclear industry's

entry into the hydrogen sector enables diversification of its role beyond supply of clean electricity and allows it to contribute to sustainable decarbonization of several other sectors, particularly the difficult to decarbonize industries. This strengthens its role and ensures its long term relevance in the national energy systems and economies.

Through its main pillars of work – nuclear safeguards, nuclear safety and security and the peaceful uses of nuclear technology, the International Atomic Energy Agency supports various activities on nuclear hydrogen production, aiming to provide technical expertise, dedicated mechanisms and tools for Member States considering nuclear hydrogen production in their national strategies for decarbonization of energy.

ABSTRACT

The isotopic exchange between hydrogen and liquid water (LPCE) is one of the most efficient process for hydrogen isotopes separation in order to remove tritium from nuclear effluents, produced in fission and fusion reactors. In order to increase the efficiency of isotopic exchange process, the chemical exchange (promoted by hydrophobic catalyst) is usually associated with conventional distillation process (promoted by hydrophilic packing), the both processes being promoted by using so called “mixed catalytic packing”. A new catalytic support (modified organic copolymer) and two new procedures (A and B), based on chemical and thermal treatments of hydrophilic packing has been proposed and tested. The main characteristics of the catalyst and hydrophilic packing have been evaluated and discussed in deep correlation with hydrogen isotopes separation performances. The experimental results showed as the new catalytic support and the treatment based on solution B, at increased temperature are a promising idea and can be applied to manufacture a new improved mixed catalytic packing. This type of mixed catalytic packing is under testing to be proposed to equip the isotopic exchange columns of the future Tritium Removal Facility for heavy water detritiation.

Keywords: Hydrogen isotopes, Hydrophobic catalysts, Hydrogen -water isotopic exchange, Mixed catalytic packing

INTRODUCTION

The separation of hydrogen isotopes (deuterium and tritium) is very important, especially in nuclear energy field but and others domains, too. During operation of CANDU fusion reactors, the tritium content in the heavy water increases and it has to be removed to protect the staff and to reduce potential contamination of the environment. On the same time, recovered tritium is a valuable material for various applications but especially as fuel for future fusion reactors-International Thermonuclear Experimental Reactor-ITER project [1]. ITER reactor is planned to begin its operation in 2027 and requires a total of 18 kg of tritium over its planned 20-years and will depend entirely on an external tritium source. The cryogenic distillation (CD) combined with catalysed isotopic exchange between hydrogen and liquid tritiated water (LPCE), it’s one of the most suitable technologies (CD-CE) for hydrogen isotopes separation. In LPCE process, the tritium from tritiated water is transferred to the hydrogen gas through the following consecutive steps [2]:

$$HTO_{(V)} + H_{2(G)} \leftrightarrow HT_{(G)} + H_2O_{(V)} \quad (1)$$

$$HTO_{(L)} + H_2O_{(V)} \leftrightarrow HTO_{(V)} + H_2O_{(L)} \quad (2)$$

$$HTO_{(L)} + H_{2(G)} \leftrightarrow HT_{(G)} + H_2O_{(L)} \quad (3)$$

Reaction (1) becomes effective only in presence of a *hydrophobic catalyst* which has to repel the liquid water but to allow to water vapour and hydrogen gas to reach the active catalytic centres and to accelerate the isotopic transfer process. On the other hand, the process (2) it’s a conventional water distillation process and need an efficient contact element (hydrophilic packing) in order to increase the contact area between water vapour and liquid water. The mixture consisting of hydrophobic catalyst and hydrophilic packing in various ratio it is called “mixed catalytic packing”.

This work presents the last proposals of the authors concerning the improvement of separation performances and stability of the mixed catalytic packing by increasing of wettability of hydrophilic component and a new catalytic support.

EXPERIMENTAL

The Hydrophobic Catalyst

The key element in increasing the hydrogen isotopes separation performances and in minimizing the LPCE column sizes is *the hydrophobic catalyst* which promotes tritium transfer from tritiated water vapor to deuterium, as in reaction (2). Over 100 metal/support catalyst types were prepared and tested at laboratory scale [3]. The main differences between them consists of support nature, active metal deposition method and wet-proofing method.

By authors work in Romania, a few catalyst types, based on platinum on carbon and polytetrafluoroethylene styrenedivinyl-benzene and have been prepared, characterized and tested in LPCE process. Though the both type of catalyst proved similar tritium separation performances, the stability of Pt/SDBC, quickly decreased and finally the Pt/C/PTFE has been selected for LPCE process [1, 4]. Therefore in this work, a new catalytic support based on modified organic copolymer is proposed and tested. The research efforts have been focused to optimize, preparation conditions, increasing of hydrophobicity and to get compatible characteristics for using in mixed catalytic packing.

Table 1. Composition and main caractheristics of St-DVB catalytic suport

Code	DVB, wt.%	ESt,[a] wt.%	St, wt%	Dilution Ration (mL/mL)	Q_T, g/g	Q_w, g/g	Surface Area m^2/g	Volum Pores cm3/g	Radius pores Å
St-DVB	50	25	25	0.5	1.128	0.082	328.8	0.523	45.02

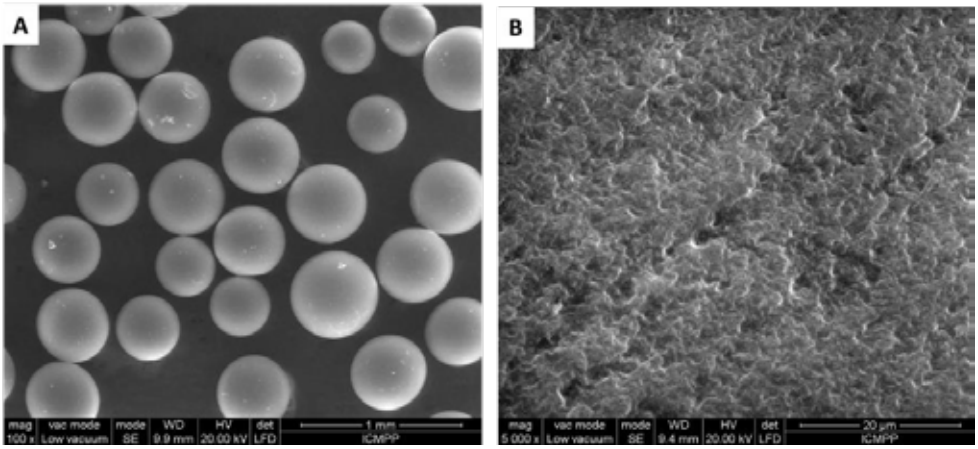

Fig. 1. SEM image (A) and in section (B) of SDB catalytic support

In order to increase the hydrophobicity of SDB, various amounts of silicone agent (CTMV-1) has been added in various ratios and simultaneously impregnated with a salt of metal active precursor by a new method, subject to be patented.

Hydrophilic packing and mixed catalytic packing

Usually in LPCE process are used structured Sulzer packing (made of metallic net) and their efficiency in water distillation process strongly depends on its wettability, therefore our research efforts have been focused on increasing the wettability packing by two new specific treatments:

a) chemical treatment to increase the roughness of metallic wire and specific area;

b) thermal treatment in controlled atmosphere to produce a thin layer of hydrophilic metallic oxides at wire surface

To increase the external surface (roughness) of metallic wire of metallic gauze , three solutions (A , B and C) of various composition at different duration and temperatures have been applied;

The increasing of the roughness of metallic wire after chemical treatment has been proved by SEM analyse and in is shown Fig. 2 [5]. The chemical treatment with B solution has increased the wettability with 20%, average.

Thermal treatment consists of in heating of hydrophilic packing in controlled atmosphere at various temperatures and contributes at creation of thin layer (3-7 μm) of metal oxides and to an average increasing of wettability with 15%;

By applying of the both treatments, firstly chemical and then thermal, the increasing of wettability has been around 28%, like as in Table 2 is shown.

Future investigations are still necessary concerning composition, the adherence of metal oxides layer and packing behavior under LPCE process conditions.

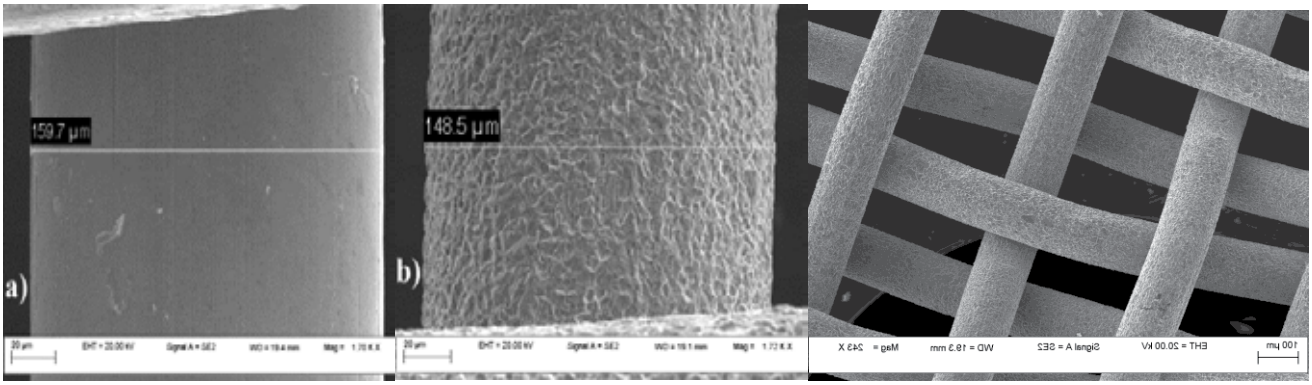

Fig. 2. SEM image of stainless-steel wire for untreated (a) and treated packing (b)

Table 2. The increasing of hydrophilic packing wettability after chemical and thermal treatments at various temperatures

Type of material	(T_1)ºC	(T_1 + 50)ºC	(T_1 + 150)ºC	(T_1 + 200)ºC	(T_1 + 300)ºC	(T_1 + 350)ºC
Bronze Phosphorous	9 %	12 %	17.5 %	19 %	26 %	29 %
Stainless steel	6 %	10.5 %	15.5 %	20.5 %	25.5 %	27 %

CONCLUSIONS

To increase the hydrogen isotopes separation performances by hydrogen-water isotopic exchange, a new catalytic support based on modified organic copolymer and two new procedures for improvement of hydrophilic packing wettability has been proposed and investigated, the new catalytic support shown physico-chemical characteristics and high hidrophobicity and could be a potential candidate for the future improved catalyst.

The both new treatments of hydrophilic packing for increasing of roughness and for covering the external surface with thin layer of hydrophilic metallic oxides have contributed to the significant increasing of the wettability of mixed catalytic packing.

Future investigations are still necessary concerning composition, the adherence of metal oxides layer and packing behavior under LPCE process conditions.

ABSTRACT

Further advances in the hydrogen separation membranes field require investigating materials with high H_2 permeation and selectivity by predicting the performance from simulation modeling. In this study, a two-dimensional CFD simulation model is developed for investigating the hydrogen separation process across the pure palladium membrane type. The influences of feeding pressure, H_2 feeding flow rate, and membrane thickness on the hydrogen permeation process were investigated. Two Pd-membrane thicknesses of 15μm and 20μm were investigated to understand the hydrogen embrittlement and diffusion through pure Pd-membrane. The velocity, concentration, and diffusion mass transfer flux distribution were numerically achieved by the model. The results showed that the higher feeding pressure can promote the concentration and hydrogen flux distributions that lead to more separated hydrogen. The feeding pressure plays an important factor in membrane separation processes. The simulation analysis showed that the hydrogen velocity distribution increased with the feeding gas flow rate. Furthermore, the diffusion flux was enhanced with the permeation time and the feeding flow rate increased. It can be concluded that the hydrogen concentration and diffusion mass transfer flux through thick membranes was low compared with lower membrane thickness. However, high membrane cost has limited development that requires thin membranes because the best membrane separation materials are precious metals. It can be expected that the CFD simulation model will aid in the membrane separation design, selection, and development.

Keywords: Numerical simulation, Palladium membrane (Pd), Hydrogen separation, Hydrogen flux.

INTRODUCTION

Hydrogen production from different feed stocks is expected to enhance in the future and moves toward using hydrogen as a new energy carrier. Hydrogen can be generated by various industrial processes such as water electrolysis, steam reforming, and coal gasification, which it can be used for the hydrogen production from traditional energy sources [1, 2]. Hydrogen production from fossil fuels acts over 90% of total generated hydrogen (mainly natural gas steam reforming). Most of the produced hydrogen is utilized in a large-scale industrial application processes such as textile industries, chemical, petrochemical, metallurgical, and raw materials like ammonia, hydrogen peroxide, and methane [3]. The hydrogen permeation modeling becomes an important method for describing and identifying the permeation process through Pd-based membranes. Many efforts for H_2 permeation modeling have been investigated to predict the hydrogen diffusion and selectivity [4]. The hydrogen permeation through Pd-Cu40% membrane has been experimentally investigated under gas driven permeation and plasma driven permeation [5]. It has been investigated that the abatement of concentration polarization in the membrane separation process is a considerable issue because of its impact on decreasing efficiency of hydrogen separation and the operation cost increased [6]. Also, the literature survey elucidated the membrane design configuration importance in enhancing the membrane performance and mass transfer process across the membrane surface.

In this study, two-dimensional CFD simulation modeling is developed to investigate the hydrogen permeation process through Pd-membrane. The effects of hydrogen feeding flow rate, feeding pressure, and Pd-membrane layer thickness on the hydrogen permeation process through pure Pd-membrane are investigated. The velocity profile, concentration, and hydrogen diffusion flux distributions are evaluated at different permeation axial positions. The hydrogen separation through two different Pd-membrane thicknesses is evaluated to understand the hydrogen dissociation process across the pure palladium membrane.

NUMERICAL MODEL GOVERNING EQUATIONS AND BOUNDARY CONDITIONS

The numerical simulation and modeling give the ability to investigate the effect of different parameters on the membrane reactor performances. The numerical modeling governing equations include the transport species, continuity, and momentum equations. In this simulation, two-dimensional mathematical model, 2D-axisymmetric, isothermal, and laminar flow are considered as the model assumption. Figure (1) shows the designed reactor 2D geometry and the applied meshing to the membrane reactor domain.

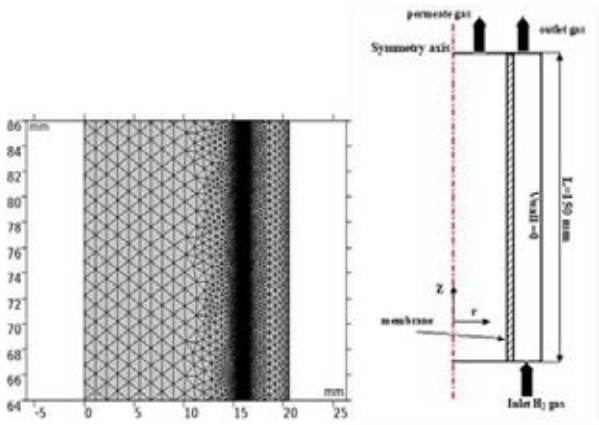

Fig. 1. Schematic diagram of 2D geometry and meshing domain.

The numerical model governing equations will be given in this section. The continuity governing equation of hydrogen species transport in general form of the Pd-membrane separation system is given as follows [7]:

$$\frac{\partial C_i}{\partial t} = -(\nabla . C_i V) - (\nabla . J_i) + R_i \quad (1)$$

Where V and t are velocity and time, respectively. The hydrogen separation process occurs in the cylindrical vertical z-direction coordinates and radius r. Navier-Stokes equation in cylindrical coordinates is used to determine fluid flow properties according to the following equation [8],

$$-\nabla . \mu(\nabla u + (\nabla u)^T) + \nabla P + \rho \frac{\partial u}{\partial t} + \rho(u . \nabla)u = F, \nabla . u = 0 \quad (2)$$

Where the fluid dynamic viscosity is μ (kg/m.s), u (m/s) denotes velocity, density of the fluid is ρ (kg/m^3), pressure is P (atm), and the body force is F (N/m^3).

The numerical model boundary conditions can be defined as follows, Initial concentration value is zero, no slip velocity, symmetry boundary, inlet velocity is V_0 at z=0, and the feed side inlet and outlet pressure is atmospheric pressure.

RESULTS AND DISCUSSION

Influence of feeding pressure on the permeation process

The hydrogen concentration at different feeding pressures is demonstrated in Figure (2). The hydrogen concentration results of all feeding pressures are increased with the reaction time. Moreover, it is noted that the hydrogen concentration of feeding pressure of 200 kPa is slight lower than other tested feeding pressures. However, the highest H_2 concentration is almost obtained at feeding pressure of 400 kPa. The H_2 concentration is varied at the beginning of permeation process then increased with time. The concentrations of hydrogen is slightly enhanced with the increase of feeding pressure, because of the main driving force of the permeation process is the partial pressure difference between retentate and permeate side.

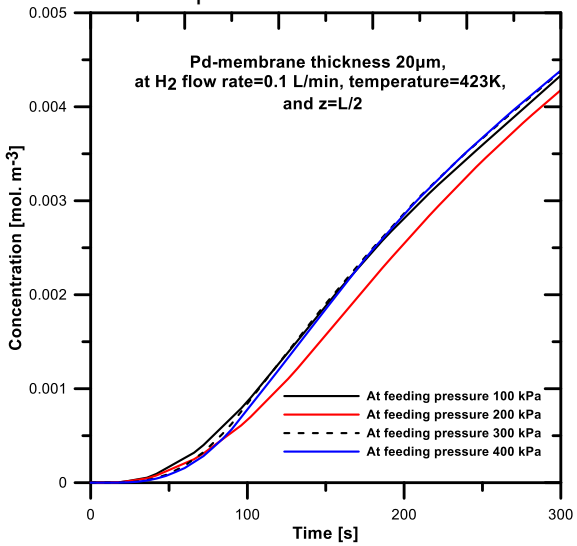

Fig. 6. Hydrogen concentration at different feeding pressures.

Influence of hydrogen feeding flow rate on hydrogen separation

The hydrogen concentration was evaluated at different permeation side positions. Figure (3) represents the hydrogen concentration results of H_2 flow rates of 0.5, 1 L/min at different z-direction positions. It was observed that the hydrogen concentration at zero position is greater than that obtained at the center and outlet of permeation side.

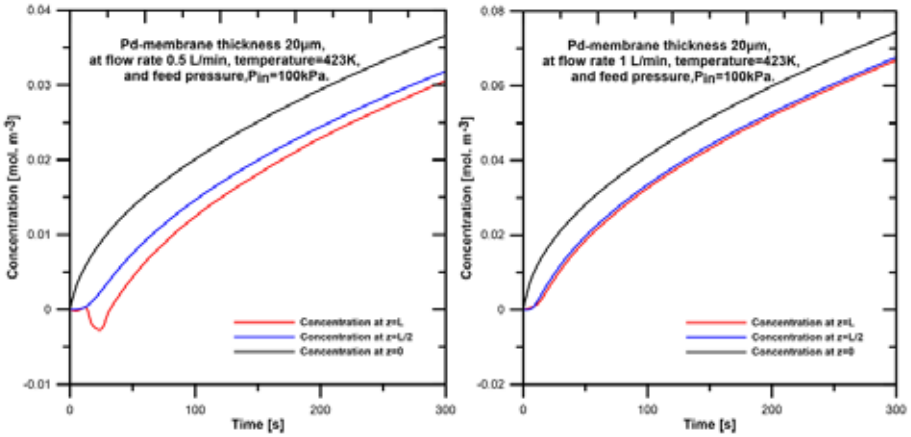

Fig. 3. Comparisons of H_2 concentrations at different positions.

CONCLUSIONS

The current study presented the two-dimensional CFD simulation model for two parameters influencing the hydrogen separation process across the Pd-membrane type. The effect of feeding pressure, reactor gap distance, hydrogen concentration, and heating temperature on the permeation process are investigated for both membrane types. Moreover, the simulation analysis results of pure Pd-membrane are investigated at different operating conditions. The results showed that the higher feeding pressure can promote the hydrogen flux and leads to more separated hydrogen. Also, the feeding pressure plays an important factor in membrane separation processes. The effect of H_2 feeding flow rate and membrane thickness on the hydrogen permeation process was investigated. The simulation analysis was carried out at a reactor temperature of 150ºC and feed pressure of 100 kPa. Pure hydrogen with a concentration of 100% was considered in this simulation analysis. The velocity, concentration, and diffusion mass transfer flux distribution were numerically reported by the model. The simulation results showed that the hydrogen velocity distribution increased with the feeding gas, while the velocity decreased and reach zero at the membrane wall. Furthermore, the diffusion flux increased with permeation time and the feeding flow rate increased. Also, the hydrogen concentration was influenced by the feeding hydrogen flow rate. It was clear that the hydrogen concentration gradient of feeding flow rate 1 L/min was greater than 0.1 and 0.5 L/min because of larger H_2 flow rate will lead to more H-atoms adsorbed by the Pd-membrane surface. Two Pd-membrane thicknesses were investigated by the current model. It can be concluded that the hydrogen concentration and diffusion mass transfer flux through thick membranes was low compared with small membrane thickness values. It can be expected that the CFD simulation model will be helpful in the membrane separation design and development.

ABSTRACT

Hydrogen is considered the energy of the future. In order to achieve this goal several technological obstacles and gaps related to the ultra-purification of hydrogen must be solved and improved. One of the adopted means used to purify Hydrogen is related to the usage of dense membranes made of Pd based alloys (i.e. Pd/Cu) due to its perfect permeability and selectivity towards hydrogen. Therefore, the current work was focused on showing the negative impact generated due to corrosion of Pd, Cu and Pd/Cu in accelerated corrosive acidic media (0.25 M HCl) at various operating conditions [temperatures (30 and 50ºC) and speeds of agitation (0, 300, 600, and 900 RPM)] to simulate the actual corrosion reaction resulted from hydrogen gas in real applications. The results reveled that copper will dissolute in a greater way if combined with palladium in an alloy to fabricate dense membranes to purify hydrogen.

Keywords: Corrosion, Hydrogen purifiers, Pd, Cu

INTRODUCTION

The fossil fuel-based economy caused several global crises during the elapsed 30 years such as greenhouse gases (GHG). Therefore, huge efforts were focused on developing renewable, sustainable and environmentally friendly technologies to utilize hydrogen in order to reduce the dependence on fossil fuels. One of these technologies are dense membranes made of Pd alloys used to produce ultra-pure hydrogen using single purification step based on solution-diffusion mechanism. Copper is used as an alloying element with palladium to form Pd/Cu to be used in these membranes due to the low price of copper as well as its great resistance to sulfur poisoning. In these kind of membranes, high-pressure feed gas mixture is applied to one end of the membrane whilst maintaining a relatively low pressure on the opposite side. Large hydrogen partial pressures will initiate a mechanism known as mass transport. Hydrogen will migrate across the membrane to form the permeate leaving behind the impurity gases as retentate [1,2,3]. Membrane performance is generally described by its permeability, selectivity and thermal stability. Permeability measures the capacity of a membrane to process the permeate gases and denotes the flux through a membrane per unit of area and time at a given pressure gradient. Selectivity measures the ability of separating the desired component from the other components of the gas mixture and is usually determined by the permeation rate of pure hydrogen and other pure gases such as nitrogen and helium [4]. Any change in the material of the dense membrane will be reflected on its permeability and selectivity to hydrogen, therefore the current work was focused on investigating the corrosion behavior of Pd and Cu using acidic medium (0.25 N HCl) at various operating temperatures (30 and 50ºC) and speeds of agitation (0, 300, 600, and 900 RPM) in order to accelerate and simulate the actual corrosion reaction occurred in dense membranes made of Pd/Cu.

EXPERIMENTAL WORK

Potentiodynamic corrosion tests were performed for single metallic specimens made of Pd or Cu in corrosive acidic media (0.25 M HCl) at various operating conditions [temperatures (30 and 50ºC) and speeds of agitation (0, 300, 600, and 900 RPM)]. Galvanic corrosion currents and coupling potential were measured for Pd/Cu at the given operating conditions using Zero Resistance Ammeter (ZRA). Taking into considerations that Open Circuit Potential (OCP) of copper and palladium were also measured before each run.

RESULTS AND DISCUSSION

Corrosion of Copper

The results revealed that increasing the speed of agitation from (0 to 900 RPM) at the given temperatures resulted an increase in the corrosion rate of copper, except at 50ºC and 600 RPM, where the rate was shifted to lower value (i.e. 0.288 mm/y) . The reason behind the decrease in the corrosion rate is due to the formation of a protective film made of the corrosion products on the copper surface, which slowed down the rate of mass transfer of hydrogen and oxygen ions to the copper surface, while increasing the speed from (0 – 900 RPM) caused a removal of the mentioned

protective film and as a result it increased the diffusion or migration of hydrogen and oxygen ions to copper surface. This trend is in agreement with Stupnis˘ek-Lisac et al. [5], Saeed et al. [6], Modestov et al. [7], Smyrl et al. [8], Habbache et al. [9], and Nielsen et al. [10].

Corrosion of Palladium

The results showed that corrosion rates of palladium were decreased with increasing temperature due its passive behavior, except at 600 RPM, where it was increased with increasing temperature. Basically, the corrosion rate of palladium at 30ºC was increasing with increasing speed of agitation from (0 – 300) RPM, then decreasing at (300 – 600 RPM), followed by an increase at (600 – 900 RPM). Whereas, at 50ºC corrosion rate of palladium was continuously increasing at (0 – 600 RPM) followed by a decrease at (600 -900 RPM). In other words, this condition caused palladium to lose its passivity as a result of the interactions among the operating conditions (i.e., temperature and speed of agitation) which is in agreement with the opinion given by Craig et al. [11] where they have mentioned that palladium corrodes anodically in hydrochloric acid at certain operating conditions. Maximum corrosion rate was observed at 30ºC and 300 RPM with 0.107 mm/y, while the minimum rate was observed at 50 ºC and 0 RPM with 0.018 mm/y. It is important to report that corrosion rates of palladium were significantly lower than that of copper under all studied operating conditions.

Galvanic Corrosion of Palladium/Copper Alloy

The results indicated that Cu was aggressively corroded in order to protect Pd in the galvanic couple of Pd/Cu because the location of coupling potentials were below the polarization curves of Pd at the mentioned operating conditions as well as the polarization curve of Cu indicated higher corrosion current densities than Pd based on the intersection value of the cathodic portion with the anodic portion of Tafel region within each polarization curve without forgetting the effect of increasing the speed of agitation (0, 300, 600 and 900 RPM) which played a vital role in changing the corrosion rates in both Cu and Pd. On the other hand, the results of the average galvanic currents (Ig, av) of Cu which represents the rate of galvanic corrosion of the active part in the Pd/Cu couple obtained by calculating the area under the curve using trapezoidal rule revealed that the average galvanic currents (Ig, av) of Cu were increasing with the increase in the speed of agitation from 0 to 900 RPM at both temperatures (30 and 50ºC). The extracted results were in agreement with Schweitzer [12], Revie et al. [13], and Katarzyna et.al [14].

CONCLUSIONS

The results revealed that increasing temperature and/or speed of agitation will affect the corrosion rate of Pd, Cu and Pd/Cu couple. In fact, copper showed a special behavior at 50ºC and 600 RPM, where the rate was shifted to lower value (i.e., 0.288 mm/y). The reason behind the decrease in the corrosion rate is due to the formation of a protective film made of the corrosion products on the copper surface, which slowed down the rate of mass transfer of hydrogen and oxygen ions to the copper surface. While, increasing the speed from (0 – 900 RPM) caused a removal of the mentioned protective film and as a result it increased the diffusion or migration of hydrogen and oxygen ions to copper surface. On the other hand, the results showed that corrosion rates of palladium were significantly lower than that of copper under all studied operating conditions. It is worth to mention that the results indicated that Cu was aggressively corroded in order to protect Pd in the Pd/Cu couple. As a result, it is obvious that coupling of Pd and Cu to form Pd/Cu alloy will have a negative impact on the performance when used as a dense membrane for hydrogen purification.

ABSTRACT

In this work, we report the synthesis and application of novel polymeric membranes, based on polymerized ionic liquids (PILs), to be used for the separation of hydrogen from gas mixtures with CO_2.
Dense membranes have been developed by using phosphonium-based PILs copolymerised within an original acrylate formulation that allowed to overcome some of the main limitations related to ionic liquid membranes. The membranes showed remarkable separation properties exceeding the Robeson upper bound for the CO_2/H_2 gas pair.

Keywords: Polymerizable ionic liquids, Ionic liquid membranes, CO_2 separation, Hydrogen

INTRODUCTION

The production of hydrogen from fossil but also renewable fuels in most of cases relies on reforming reactions which lead also to the formation of CO_2 as product. Therefore, the possibility to separate H_2 and capture CO_2 from these gas mixtures is of tremendous interest. Membrane technology is highly appreciated in this field thank to its simplicity in concept and operation, easy scalability, high selectivity and relatively low energy consumption [1]. In recent years, Ionic liquids (ILs) have gained a high interest from the scientific community owing to their low toxicity, high thermal stability, low volatility, and high tunability, which makes the ILs very versatile and useful for different applications. The combination of ILs with membrane technology is an approach that has been implemented during the last 20 years, particularly exploiting the higher solubility of CO_2 (with respect to CH_4 and N_2) in many available ILs.

In this work, we have developed a novel PIL-based membrane by copolymerization of a polymerizable phosphonium IL with acrylic monomers, which has shown interesting performances in CO_2/H_2 separation by membrane technology.

MATERIALS AND METHODS

Dense transparent membranes were prepared by mixing HEMA (52 wt%), water (8 wt%), DTAB (13 wt%) and the polymerizable IL (27 wt%). EGDMA (3 wt% on the weight of HEMA+PIL) and DMPA (0.6 wt%) were then added to the mixture to obtain a homogenous solution. Then, the mixture was cast between two glass plates and photo-polymerized for 3 minutes under UV light (lamp emission from 180 nm to visible light, 500 W, Purchased from Helios Italquarz s.r.l.). Polymerized membranes were then removed from the glass plates in water, then washed and stored in water until their use. Various membranes were prepared varying the length of the alkyl chain and the anion of the ionic liquid. All details on preparation and characterization can be found in [2, 3].
The separation properties of the membranes were investigated at 25 and 50 °C, with single gases (CO_2, N_2, CH_4, H_2) in saturated conditions under a feed pressure up to 10 bar, to measure the permeating flux and evaluate permeance and ideal selectivity. The flat sheet membranes were placed in a stainless-steel module located inside a furnace and the gases were fed by means of mass flow controllers opportunely calibrated. A back-pressure regulator on the retentate line controlled the pressure on feed/retentate and the streams flow rate were measured by means of two bubble soap flow meters. The pressure on permeate side was maintained atmospheric. The gas saturation was made by means of a humidifier allocated inside the furnace before the module inlet, so to have the same temperature and pressure and the level of humidity was measured by means of two sensors placed on feed and permeate lines.

RESULTS AND DISCUSSION

The mass transport properties of the various prepared membranes were assessed by feeding single gases, to determine the suitability of these materials for separating H_2 from other gases such as CO_2, CH_4, N_2. Both the length of n-alkyl chain and the different type of anion influenced the separation ability of the membranes (Fig. 1).

All membranes resulted selective toward CO_2 permeation, and this can be mainly attributed to the presence of PILs, which promote the solubility of CO_2, preferentially favoring its permeability, with respect to the other gases for which the transport is mainly influenced by diffusion. The permeability of all the investigated gases decreased with the length of the PIL alkyl chain. Therefore, membrane selectivity toward CO_2 permeation increased as the PIL chain length became longer, and the poly[P_{888}VB][BF_4]+acrylates showed the highest selectivity with respect to the other membranes prepared with a shorter n-alkyl chain length.

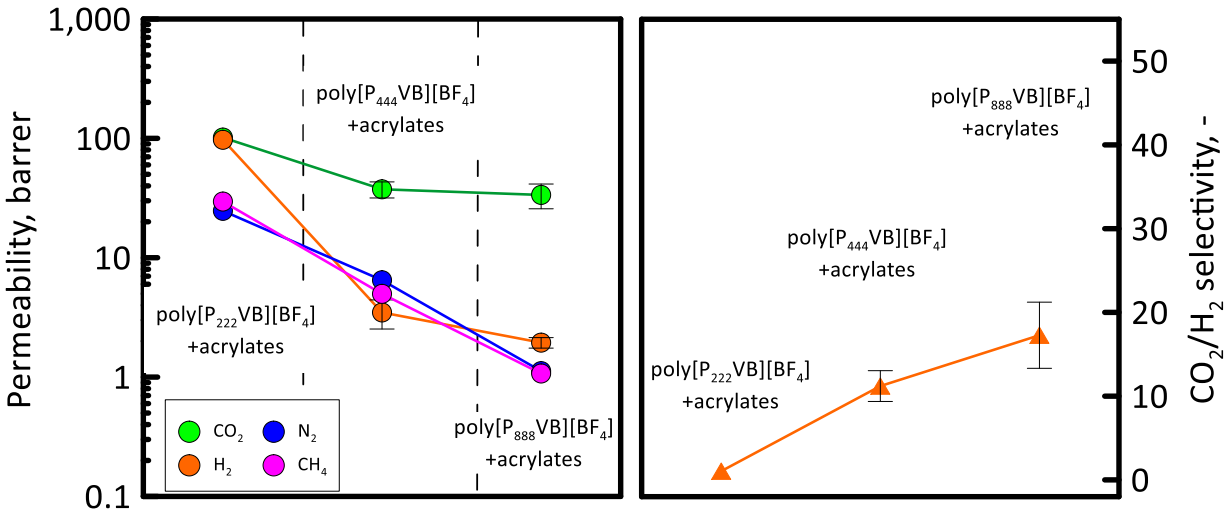

Fig.1 Single gases permeability and CO_2/H_2 selectivity as a function of PIL alkyl chain length. Temperature=25°C

The nature of the counteranion can also influence the mass transport properties. The poly[P_{888}VB][TF_2N]+acrylates membrane showed a higher permeability of all gases with respect to the one prepared using $BF4^-$ and also to both blank membranes. This is reflected in overall lower CO_2/H_2 selectivity, which was 4.6 against 17.3 of the poly[P_{888}VB][BF_4]+acrylates.

When reported in the Robeson trade-off diagram, poly[P_{444}VB][BF_4]+acrylates and poly[P_{888}VB][BF_4]+acrylates membranes exceeded the upper bound for CO_2/H_2 gas pair. Overall, it can be clearly seen the advantage, particularly in terms of selectivity offered by the addition of PILs with respect to the performance of the blank membrane (Fig. 2).

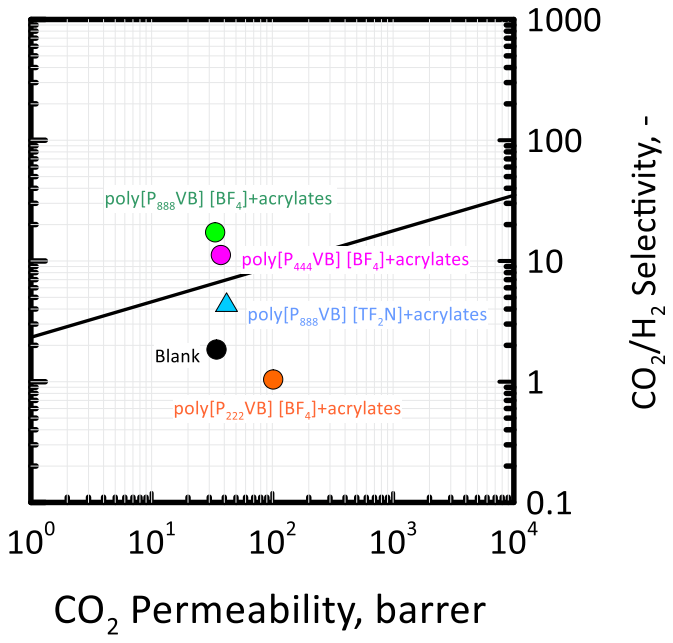

Fig. 2 Robeson plots for CO_2/H_2 gas pairs at 25°C, for different membranes

CONCLUSIONS

In this work, we developed a new copolymer-membranes containing polymerized ILs for hydrogen separation from carbon dioxide by employing a completely new formulation based on different acrylate compounds, including a polymerizable IL. The membranes with BF_4^- as the anion showed the best permeation properties and, among them, the poly[P_{888}VB][BF_4]+acrylates exceeded the Robeson upper bound for CO_2/H_2 gas pair, thanks to the favorable combination between a low water uptake and suitable dimensions of the free volumes in the polymeric network, as confirmed by advanced NMR investigations. The new developed membranes showed good potentialities to efficiently separate hydrogen from other gases in wet state, which simulates the conditions typically found in many H_2-CO_2-containing streams, where the high moisture content tends to negatively affect gas treatment.

ABSTRACT

Hydrogen is a potential alternative for fossil fuels. Membrane technology has been a prominent separation approach for H2 purification. The recently discovered new membranes based on GO and rGO show superior properties such as high hydrophilicity, good dispersion in water, nanopores and good mechanical behavior. The main objective of this project is to develop mixed matrix membrane with different polymeric bases of PEBA and PI with graphene oxide (GO) incorporation as inorganic filler. Gas permeability and selectivity of polymer membranes prepared by solution casting method were tested. Gas separation tests of the membranes were carried out at 35°C and 3 bar feed pressure. Gas permeability and selectivity results indicated that PEBA/rGO membrane with 0.3 wt% of GO has the highest H_2 and CO_2 permeability at 10.3247 and 54.8786, respectively, H_2/N_2 selectivity of 7.9828 and CO_2/CH_4 selectivity of 21.0590. PI/rGO membrane with 0.3 wt% of GO has the highest H_2 and CO_2 permeability at 7.3533 and 0.9026 barrer at 3 bar, respectively, H_2/N_2 selectivity of 50.2650 Barrer and H_2/CH_4 selectivity of 287.6653. Work continues with the addition of copper-based MOF structures.

INTRODUCTION

Membrane technology is a separation process which allows certain species to pass through the membrane while restricting the others depending on the properties of the membrane material [1]. Membrane technology is widely used in industrial applications such as air separation, ammonia production, carbon dioxide separation, nitrogen production and hydrogen recovery. The advantages of this technology over traditional separation processes include lower capital and operating costs, better efficiency, and lower risk. Hydrogen is seen as the energy carrier of the future with its high energy density and environmentally friendly features. Hydrogen, which is not found in pure form in nature, is separated from the gas mixture by various techniques. Gas mixtures are separated in industrial systems using cryogenic distillation, adsorption and polymeric membranes. While examining the efficiency of membrane systems, the most important parameters emphasized are selectivity and permeability. Permeability reflects the rates at which components (penetrants) are transported across a membrane, and selectivity is the ratio of the permeability of the more permeable component to the less permeable one. Permeability and selectivity are the two most important parameters for evaluating the separation performance of a membrane. High selectivity and high permeability are expected for an effective gas separation system [2].In recent years, research directions have been focused on both inorganic and organic materials to develop membranes with desirable hydrogen separation properties. Today the application of polymeric membranes for the H_2 recovery is limited due to the well-known trade off relationship between the permeability and the selectivity and therefore alternatives such as inorganic and mixed matrix membranes (MMMs) are proposed in many studies [3]. A new approach, mixed matrix membranes (MMMs), are mixed matrix materials consisting of homogeneously intertwined polymeric and inorganic particle matrices. Various types of Metal-organic frameworks (MOFs) can be synthesized by varying the combination of different organic binders and metal ions. This adaptability makes MOFs promising candidates for separation applications compared to zeolites and other inorganic fillers. The selection of suitable MOF/polymer pairs is crucial for experimental efforts to improve the performance of MMMs. GO nanosheets can assemble a graphene laminate membrane and GO can be used as the filler embedded in a polymer matrix to obtain MMMs. GO-based membranes are predicted to be highly selective owing to their inherent 2D channels[4]. In addition, the rGO would partially aggregate with in the polymer matrix, forming a stacked laminated structure with high efficient molecular sieving galleries between neighbouring nanosheets, while the planar pores on the graphene oxide ensured much shorter gas permeation pathways through the laminated rGO structure compared with nonporous GO[5]. Matrimid 5218®, was chosen for the manufacturing of the membranes. Matrimid® 5218 is a commercially available thermoplastic polyimide (PI). We decided to choose this glassy polymer because it presents a good trade off between H_2 permeability and both H_2/N_2 and H_2/CO_2 selectivities. Also, this polyimide is frequently used in the manufacture of MMMs and has attracted a lot of attention for gas separation membranes due to the combination of relatively high gas permeability coefficients and separation factors coupled with excellent mechanical properties, solubility in non-hazard organic solvents and commercial availability

[6]. And Pebax®1657 is a good candidate for separation of CO_2 from other gases. Pebax shows great flexibility and process ability; however, its separation performance has been constrained due to the trade-offbetween permeability and selectivity. Therefore, numerous studies have been performed to achieve the better permeability and selectivity for Pebax membranes. Among the available techniques, blending is aunique alternative and it is preferred due to its simplicity, commercial character, reproducibility and cost-effectiveness for tuning membranes properties[7]. In the current study, membranes are being developed for hydrogen separation with two different polymers, PEBA and PI, based on GO-rGO. In this way, it was possible to compare both fillers in both membranes. Cu-MOF, Cu-MOF@GO and Cu-MOF@rGO were prepared for the continuation of the study. In this way, the overall aim of the present work was extended to examine the effect of functionalization of MOFs on the performance of MMMs and to compare membranes obtained with MMMs made with the same polyimide matrix.

MATERIALS AND METHODS

Materials

Matrimid® 5218 (PI, polyimide of 3,3',4,4'-benzophenone tetracarboxylic dianhydride and diaminophenylidane)) polymer was kindly provided by Huntsman Advanced Polymers in powder form. The solvent for polyimide was N-methyl-2-pyrrolidone (NMP, 99% VWR Chemicals). Graphene oxide (GO) was supplied by AEROFEN (TR). Poly(ether-b-amide); PEBAX® 1657, Ethanol (C_2H_5OH), Copper (II) acetate monohydrate $Cu(AC)_2.H_2O$ was purchased from Acros Organics. Dimethylformamide (DMF), ($(CH_3)_2NCOH$) and 1,3,5-benzenetricarboxylic acid (BTC). All gases were purchased from Habas Co. (Turkey) with a purity of at least 99.95%.

Preparation of Membranes

The PEBA/GO MMMs were fabricated by a solution casting method. PEBA were dispersed in a solvent mixture of 70 wt % ethanol and 30 wt % water and GO powders were dispersed in a solvent mixture of 70 wt % ethanol and 30 wt % water and then treated by ultrasonication for 1 h. After that a homogeneous solution was obtained by mixing these two solutions. The suspension was poured into a clean Petri dish with a diameter of 11 cm and covered a glass plate to control the evaporation rate. After solvent evaporation at room temperature, the petri dish was placed in a vacuum 200 mbar. PEBA/rGO membranes were prepared by the same method. After drying of PI polymer powder at 120ºC for 12 h, polymeric solutions (7 wt.%) were prepared by using NMP as solvent. Thin films with a thickness ranging from 80 to 100 µm were prepared by solution casting on a glass petri dishes. For the preparation of the dope solution (7 wt% of solid), first of all, the desired amount of GO (to obtain 0.1, 0.2 and 0.3 wt% of GO in MMM) was dispersed into NMP and the mixture was stirred at room temperature and sonicated. Then, the polymer was added into the GO solution. A petri dish with a diameter of 11 cm was used for solution casting. After solvent evaporation at room temperature, the petri dish was placed in a vacuum. PI/rGO membranes were prepared by the same method. The PI MMMs were dried at room temperature for 24 h and were further dried in a vacuum oven (Binder ED23) at 120ºC for 24 h and 200 mbar.The membrane thickness was measured using a digital micrometer Mitutoyo Digmatic Series 369 (accuracy ± 0.001 mm). This micrometer is equipped with two plates of 2 mm diameter specially designed to measure thin films. The resulted values of thickness represent an average of five measurements, one in the center of the membrane and four in the borders. Thickness deviations from the average did not exceed 2 µm in any of the membranes used.

Gas Permeability Measurements

Fig. 1 shows the experimental set-up. The design of the feed part of the set-up confers the possibility of performing pure gas permeation experiments.

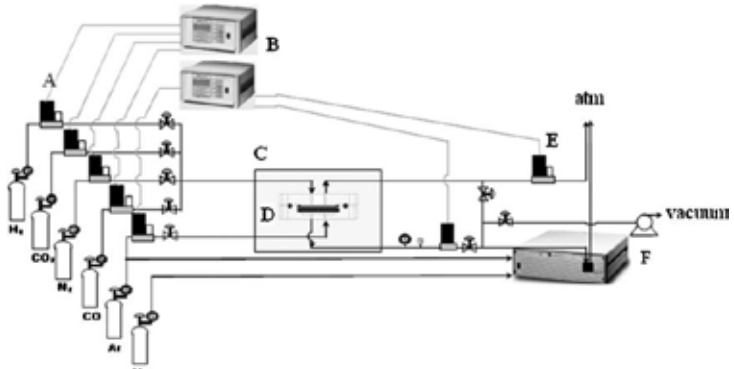

Fig. 1. The experimental permeation set-up: (A) mass flow controller, (b) control box, (c) heating oven, (d) membrane test cell, (e) backpressure regulator, (f) gas chromatograph.

RESULTS AND DISCUSSION

Gas permeability coefficients of membranes were calculated by using a constant volume-variable pressure gas permeability device. Permeability measurements were performed according to the steady-state method at 35 °C. In this study, single gases (H_2, N_2, CO_2, and CH_4) were used to measure gas separation performances of membranes. The circularly cut test specimens used in permeability tests were masked with a self-adhesive aluminum foil. And the vacuum pump were used. The membrane was sealed and tightened. The gas pressure fed to the system was kept constant at 3 ± 0.2 bar. Gas was fed to the system by a valve in the upper part of the cell and the pressure change in the lower part was recorded with the data recording program. The gas permeation of polymeric membranes is described by the solution–diffusion model [9]. The gas transport occurs when the gas molecules are dissolved in the membrane surface, and molecules diffuse across the membrane by way of the cavities present in the polymer. The permeability results from the contribution of these two mechanisms, and can be described by Equation (1):

$$P = D \times S \quad (1)$$

where *P* is the permeability of membrane in Barrer (1Barrer = 1×10^{-10} cm^3 (STP)-cm/cm^2 s cmHg), D is the diffusion coefficient, and S is the sorption coefficient. Typically, the selectivity (α) is defined as the relation of the permeability for the components A and B. Ideal selectivity, $\alpha_{A/B}$, is the ratio of individual permeability coefficients for the gas pairs. The general selectivity of a material defined in Equation (2) is a function of diffusivity (D_A/D_B) and selectivity ratios (S_A/S_B).

$$\alpha_{A/B} = \frac{P_A}{P_B} = \frac{D_A}{D_B} \times \frac{S_A}{S_B} \quad (2)$$

CONCLUSIONS

PEBA/GO, PEBA/rGO and PI/GO, PI/rGO mixed matrix membranes were prepared by the adding 0.1; 0.2 and 0.3 wt.% of graphene oxide (GO) in PEBA and PI polymer matrix with solution-casting method. All membranes were prepared with good stability for gas permeation tests. The gas permeability measurements of MMMs were performed at 35 °C and 3 bar feed pressure for H_2, N_2, CH_4, and CO_2 gases. H_2/N_2 and CO_2/N_2 selectivities of membranes was determined by time-lag method. For PEBA/GO and PEBA/rGO membranes, it was found that CO_2 permeability increased and CO_2/N_2 and CO_2/CH_4 selectivity values increased as GO and rGO concentrations increased. For the PI/GO-0.3 and PI/rGO-0.3 membranes, it was found that the higher selectivity values were measured. In the continuation of this study, Cu-MOF based MOFs will be prepared and performed the gas permeability measurements for the enhancing of selectivity values.

ABSTRACT

The performance of a SAPO-34 membrane for separation of H_2 from CO_2 and CH_4 was investigated in this work. In particular, a mass transport model that takes into account the competition between surface and gas translation diffusion was proposed for describing the mixture permeation [1]. It was found that the presence of CO_2 and CH_4 drastically reduce the hydrogen permeation in mixture compared to its behavior as pure gas. In fact, although hydrogen presents a higher diffusivity than carbon dioxide and methane, the much stronger CO_2 and CH_4 adsorption is prevalent, exerting a hindering effect on H_2. In addition, permeation of CO_2 and CH_4 was improved by the presence of faster hydrogen. These two effects caused a significant difference in membrane behavior from single gas to mixture. In fact, CO_2/H_2 selectivity was increased, whereas H_2/CH_4 was decreased.

Keywords: Membrane selectivity, Gas separation, Surface diffusion

INTRODUCTION

Hydrogen represents a green alternative to the traditional fossil fuels, which have a bigger impact on environment since a large amount of CO_2 is produced by their combustion. In addition, H_2 is the most present element on earth, even if it is often stored in components as hydrocarbons, from which it can be obtained from by means of steam reforming (followed by water gas shift reaction), dehydrogenation and partial oxidation. All these processes provide H_2 mixed with other species, especially CO_2 and CH_4; therefore, a purification stage is necessary. A possible solution for H_2 separation from gas mixtures is represented by zeolite membranes, as showed in several works reported in the literature [2-3]. This work analyzed the potentiality of a SAPO-34 membrane to separate H_2 from carbon dioxide and methane, focusing on the reciprocal interaction between the permeating species in binary mixture.

MODELING

An already validated model was used for mass transport [1]. This model pairs surface and gas translation diffusion, which are considered to be dependent on each other. Eq.1 provides the overall molar flux, which is expressed as the sum of the two contributions, considering a dependence of porosity and tortuosity on the adsorption coverage [4].

$$N_{Overall} = -\left(\rho C_{\mu s} D_{SD}^{0} e^{-\frac{E_{SD}}{RT}} \Gamma \frac{d\theta}{dz} + \frac{\varepsilon(C_\mu)}{\tau(C_\mu)} \frac{1}{\zeta} I \frac{1}{RT} \sqrt{\frac{8RT}{\pi M}} e^{-\frac{E_{GT}}{RT}} \frac{dP}{dz}\right) \quad (1)$$

In a mixture consisting of species *i* and *j*, surface diffusion contribution can be obtained by the Maxwell-Stefan equation [5]

$$-\rho\theta_i \frac{\nabla\mu_i}{RT} = \sum_{j=1}^{n_{species}} \frac{C_{\mu,j}N_{SD,i} - C_{\mu,i}N_{SD,j}}{C_{\mu s,j}C_{\mu s,i}D_{ij,SD}} + \frac{N_{SD,i}}{C_{\mu s,i}D_{i,SD}} = -\rho \sum_{j=1}^{n_{species}} \Gamma_{ij} \nabla\theta_j \quad (2)$$

Table 1. Surface and gas translation properties of each species [1]

	Surface diffusion	Gas translation diffusion
H_2	E_{SD} = 7197 J mol^{-1} D^0_{SD} = 2.32E-8 m^2 s^{-1}	E_{GTD} = 10981 J mol^{-1}
CO_2	E_{SD} = 7818 J mol^{-1} D^0_{SD} = 2.89E-9 m^2 s^{-1}	E_{GTD} = 20432 J mol^{-1}
CH_4	E_{SD} = 6459 J mol^{-1} D^0_{SD} = 2.74E-10 m^2 s^{-1}	E_{GTD} = 15800 J mol^{-1}

RESULTS AND DISCUSSION

Fig.1 shows the results in terms of H_2, CO_2 and CH_4 permeability as a function of temperature for two different equimolar binary mixtures (i.e., H_2:CO_2 and H_2:CH_4). It can be observed that hydrogen permeability is drastically reduced in the whole temperature range investigated by the remaining component, which is more strongly adsorbed and, therefore, hinders H_2 surface diffusion contribution in terms of lower coverage. Moreover, also H_2 gas translation contribution is reduced by a reduction of the effective porosity and a higher effective tortuosity. At 303 K, hydrogen permeability diminished of 76 and 71% in presence of CO_2 and CH_4, respectively (from about 2160 to 520 and 620 Barrer). The higher H_2 permeability drop in mixture with CO_2 is due to its stronger adsorption compared to methane. On the other hand, permeation of both CO_2 and CH_4 is favored by the presence of faster H_2. This can be attributed to the very high value of hydrogen diffusivity that promotes the permeation by surface diffusion of the other components. These two combined effects causes a significant increment of CO_2/H_2 selectivity and, at the same time, a drastically reduction of H_2/CH_4 selectivity with respect to the ideal values. In particular, CO_2/H_2 selectivity passes from about 1.4 to 9, whereas H_2/CH_4 from to 13.4 to 2.6 at 303 K and 10^6 Pa of feed pressure.

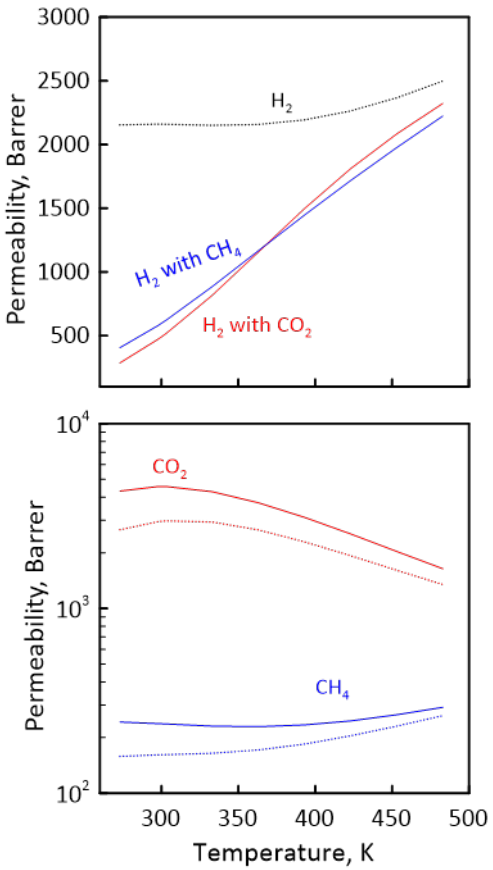

Fig. 1. H_2, CO_2 and CH_4 permeability as a function of temperature as pure gases (dotted lines) and in equimolar binary mixture (solid lines) at 10^6 Pa of feed pressure.

CONCLUSIONS

Permeation of hydrogen in mixture with carbon dioxide and methane is strongly affected, being significantly diminished if compared to what happen as single gas. In particular, the adsorbed carbon dioxide and methane reduce H_2 permeation of more than 70% at 303 K. At the same time, CO_2 and CH_4 are advantaged by the presence of the faster H_2 that promotes their permeation. Selectivity is significantly changed in mixture (e.g., CO_2/H_2 passes from 1.4 to 9 at 303 K and 10^6 Pa), making this material suitable for hydrogen upgrading.

ABSTRACT

The increase of the energy efficiency is one of the main challenges which is facing the manufacturing sector since the rising price of fossil fuels and political framework of the decarbonization roadmap. In this sense, the recovery of hydrogen from industrial waste streams is presented as a great niche of opportunities due to the wide range of applications of hydrogen as energy vector. Among hydrogen-containing off-gases, coke oven gas (COG), ammonia purge gas (APG) and methanol purge gas (MPG) stands out since the high hydrogen concentration (>50 vol.% H_2). Nevertheless, the recovery of hydrogen requires a purification system. In this study, the synthesis and characterization of mixed matrix membranes (MMMs) are analyzed as an alternative to improve the separation performance of pristine polymer membranes. ZIF-8 and ZIF-90 were selected as fillers with potential to improve H_2-selectivity and Matrimid® 5218 as high-performance polyimide. The permeability and selectivity of the membranes were evaluated by continuous permeation experiments with multicomponent gas mixtures whose composition correspond to the industrial waste streams. Furthermore, the influence of the temperature on transport parameters in gas permeation was studied.

Keywords: Hydrogen recovery, Mixed matrix membranes, Coke oven gas, Methanol purge gas, Ammonia purge gas

INTRODUCTION

The search for new renewable energy sources and sustainable use of fossil fuels are the main challenges in the energy transition to low carbon economy [1]. In this sense, the industry is an energy intensive sector which accounts 29.4% of global greenhouse gas emissions [2]. To overcome this problem, attention has been paid to hydrogen as energy vector with different purposes such as: a) the production of clean energy using fuel cells (power-to-power), b) to be blended in the natural gas grid or synthetic natural gas production (power-to-gas), c) in transport sector (power-to-fuel) and d) as feedstock in the manufacturing sector (power-to-feedstock) [3-4]. Thus, the recovery of hydrogen from industrial waste streams (COG, APG and MPG) by means of low cost and low energy consumption membrane technology has been widely studied [5]. The composition and properties of the waste streams are found in Table 1 [6].

Table 1. Composition of industrial waste streams.

	Gas composition (vol.%)						
Stream	**H_2**	**N_2**	**CO_2**	**CO**	**CH_4**	**T (ºC)**	**P (bar)**
APG	58.6	25.7	-	-	15.7	15-30	>100
COG	60.2	4.7	2.1	6.8	26.2	15-30	5-20
MPG	63.1	11.3	11.1	3.4	11.2	15-45	70

However, the membrane separation performance of commercial alternatives is not able to meet fuel cell purity specifications. Thus, research has focused on developing tailor-made membranes with higher performance. Inorganic fillers such as zeolitic imidazole framework (ZIF) have been proposed to increase the H_2-selectivity due to their small pore size [7].

This work provides the comparison of pristine polymer and mixed matrix membranes as hydrogen recovery technology. The membranes were characterized by the calculation of the permeability and selectivity by the analysis of the gas permeation experiments.

MATERIALS AND METHODS

The membranes were prepared by the well-known solvent-casting method. The polymer and ZIF-8, ZIF-90 (15 wt.% of ZIF) were weighted and dissolved separately in dichloromethane. In addition, the solution of ZIF was sonicated to prevent the agglomeration of the particles which could lead to the formation of defects in the mixed matrix membranes. Then, the polymer solution was added to the ZIF solution and sonicated to obtain a homogeneous mixture. Finally, the Matrimid®-ZIF solution was poured in the Petri dish and left-over night at room temperature to evaporate the solvent.

The membranes were placed in the membrane modules inside the thermostated chamber to ensure isothermal operation. The feed and sweep gas flowrates were controlled using mass flow controllers while needle valves together with pressure transducers allow to set the permeate and feed pressures. Then, once the steady state has been reached, the composition of the permeate and retentate streams were measured by using a gas chromatograph (GC-BID) which consists of two separation columns and a barrier ionization discharge detector of ppb quantity level. The schematic representation of the experimental setup is shown un Figure 1.

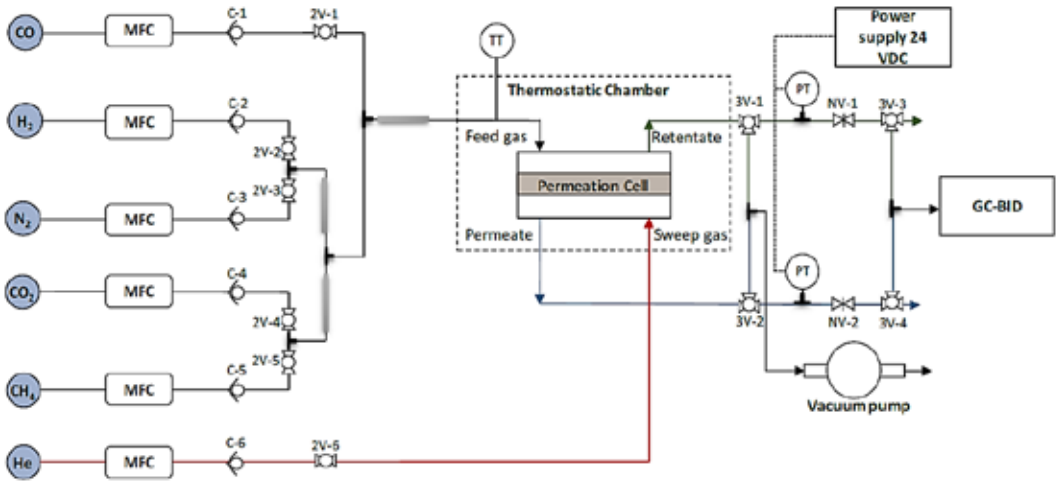

Fig. 1. Experimental set-up. MFC, mass flow controller; C, check valve; 2V, 2-way valve; 3V, 3-way valve; TT, thermocouple; PT, pressure transducer; NV, needle valve; GC-BID, gas chromatograph. Feed (black), sweep gas (red); permeate (blue); retentate (green).

RESULTS AND DISCUSSION

Results confirmed that the addition of ZIF-8 and ZIF-90 to Matrimid® increases the gas separation grade of pristine polymer membrane. On the one hand, the increase in permeability (≈50% compared to pristine polymer) is related to the increase in the free volume of the polymer, while the increase in selectivity (≈20% for H_2/CO_2 and 40-80% for H_2/N_2, H_2/CH_4 and H_2/CO compared to pristine polymer) is related to the formation of hydrogen-selective micro channels in the mixed polymer-ZIF matrix. Therefore, solution-diffusion transport mechanism is improved by molecular sieving enhancing the permeation of hydrogen compared to bulk compounds (N_2, CH_4, CO). Since ZIF-8 and ZIF-90 have close pore openings, 3.4 and 3.5 Å respectively, the contribution of the molecular sieve to the transport mechanism of both fillers is similar. However, ZIF-90 is able to offer greater resistance to the mass transport of carbon dioxide, increasing selectivity. This is attributed to the strong interaction of the carbon dioxide molecule with the aldehyde group of the 2-carboxyaldehyde imidazole bonds of the ZIF-90, which hinders its diffusion through the membrane [8]. Figure 2 shows an illustration of transport mechanisms in mixed matrix membranes.

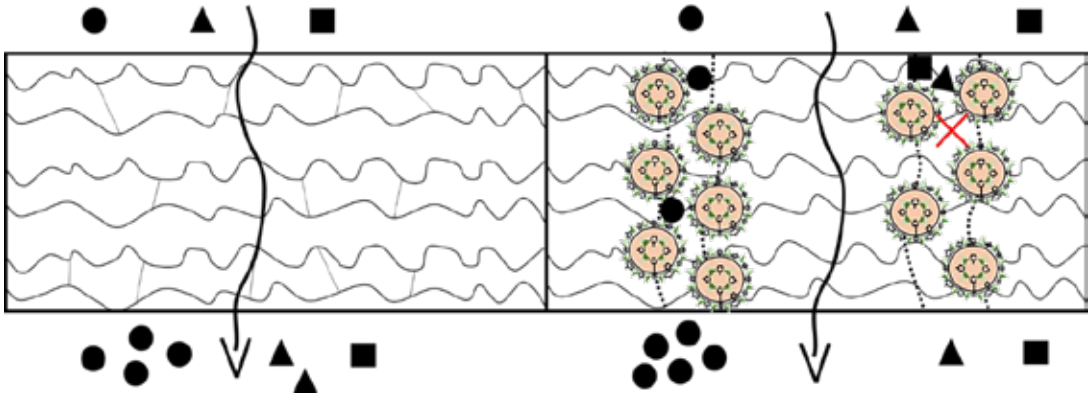

Fig. 2. Illustration of solution-diffusion (left side) and molecular sieve (right side) transport mechanisms. Circle: H_2; Triangle; CO_2; Square: N_2, CH_4, CO.

CONCLUSIONS

The addition of ZIFs as fillers to the polymer matrix is a novel alternative to surpass the separation performance of the polymeric membranes. In this sense, Matrimid®-ZIF MMMs deliver higher H_2 permeabilities and selectivity. Nevertheless, MMMs must cope with some challenges before industrial scale-up. The selection of the optimum ZIF wt.% ratio is a key point since higher loadings could lead to a significant decrease in selectivity and manufacturing issues. Moreover, further investigation on the synthesis of mixed matrix hollow fiber membranes and the design of the membrane configuration system is required. Therefore, this study aims to increase the knowledge on the synthesis and the separation performance of high performance mixed matrix membranes for hydrogen purification.

ABSTRACT

Linear alkyl benzenes (LABs) are used in alkyl sulfonates production, which are utilized in biodegradable detergents and emulsifiers. Catalytic dehydrogenation of heavy paraffin molecules ($C_{10} - C_{14}$) is the most well-known path of LAB production. In this study, a radial flow Pd/Ag membrane reactor (RF-MR) is pseudo-dynamically modeled and its outputs are compared with an industrial conventional reactor to prove RF-MR efficacy in the enhancement of olefins and hydrogen yields. Steady-state and pseudo-dynamic RF-MR simulations. It is shown that olefin production increases in RF-MR compared to that of RF-TR mainly due to hydrogen permeation through the Pd/Ag membrane. Finally, the optimal RF-MR operating conditions were obtained *via* a multi-objective genetic algorithm optimization.

Keywords: Heavy paraffin dehydrogenation, Radial flow membrane reactor, Pseudo-dynamic model, Pd/Ag membrane, Genetic algorithm

INTRODUCTION

Linear alkyl benzenes (LABs) are routinely used in the production of biodegradable detergents and emulsifiers. Catalytic dehydrogenation of heavy paraffin molecules ($C_{10} - C_{14}$) is widely used in LAB production. In chemical industries, dehydrogenation of heavy paraffin typically occurs in gas phase axial or radial plug flow adiabatic reactors in the presence of hydrogen [1].

Membrane dictates selective mass transfer under pressure, temperature, or electric potential driving force. Membrane reactor is a unit that allows simultaneous catalytic reaction and permeation processes. Nowadays, membrane reactors are extensively used in chemical and biochemical industries including hydrogen production from hydrocarbons [2, 3]. Limited studies are conducted on modeling and optimization of heavy paraffin dehydrogenation process in membrane reactors. Bayat *et al.* proposed a RF-MR with sweep gas to produce ultra-pure hydrogen and statically modeled the RF-MR and optimized it using NSGA-II method [4]. Later, Bayat *et al.* also dynamically modeled the same reactor [5].

In this paper, a radial flow Pd/Ag membrane reactor is pseudo-dynamically modeled and its process outputs are compared with those of an industrial conventional reactor. Finally, the model is optimized using genetic algorithm to obtain the optimal operating conditions for olefins and hydrogen production.

MODEL DESCRIPTION

A pseudo-dynamic mathematical model of a radial flow fixed bed Pd/Ag membrane reactor is developed. Kinetics of heavy paraffin dehydrogenation and catalyst deactivation equation were reported elsewhere [6, 7]. Axillary equations are listed in Table 1. The radial differential element of the membrane reactor is shown in Figure 1(a) and dominant reactions of the overall dehydrogenation of heavy paraffin process is represented in Figure 1(b). Important assumptions of the model are: (a) gas phase are ideal, (b) external reactor shell wall is insulated, (c) gas phase moves radially, (d) no mass and heat transfer occurs between catalyst particles, (e) molecular diffusion is negligible compared to bulk flow, (f) only hydrogen permeates through the membrane, (g) no pressure drop occurs in permeation side. Mass, energy, and Ergun momentum balance, kinetics and catalyst deactivation were simultaneously solved *via* backward Euler method.

Table 1. Governing equations

Reaction side equations		
Component mass balance	$(N)_i = (N)_{i+1} + (a \times \rho_b \times -r_j \times A_{c_1} - P_{per} \times \begin{cases} 0, & J \neq H_2 \\ J_{H_2}, & J = H_2 \end{cases} \quad j = 1,2,\dots,n) \times \Delta r$	(1)

Energy balance	$(T_{gp})_i = [(T_{gp})_{i+1} + ((P_{per} \times U_{Sh} \times (T^s - T) + P_{per} \times C_{P_{H^2}}(T^s - T) \times \begin{cases} 0, & J \neq H_2 \\ J_{H_2}, & J = H_2 \end{cases}) \times \Delta r)]/F_{tp} C_{Pg}$	(7)
Hydrogen permeation rate	$J_{H_2} = \frac{Q_0 . \exp(-\frac{E_{H_2}}{RT})}{\delta_{H_2}} (\sqrt{P_{H_2}^{Tube}} - \sqrt{P_{H_2}^{Shell}})$	(8)
Additional correlations	$A_{c_1} = \theta_1 \times NOS \times r \times L$	(10)
	$A_{c_2} = \theta_2 \times NOS \times r \times L$	(11)
	$P_{per} = 2 \times NOS \times L$	(12)

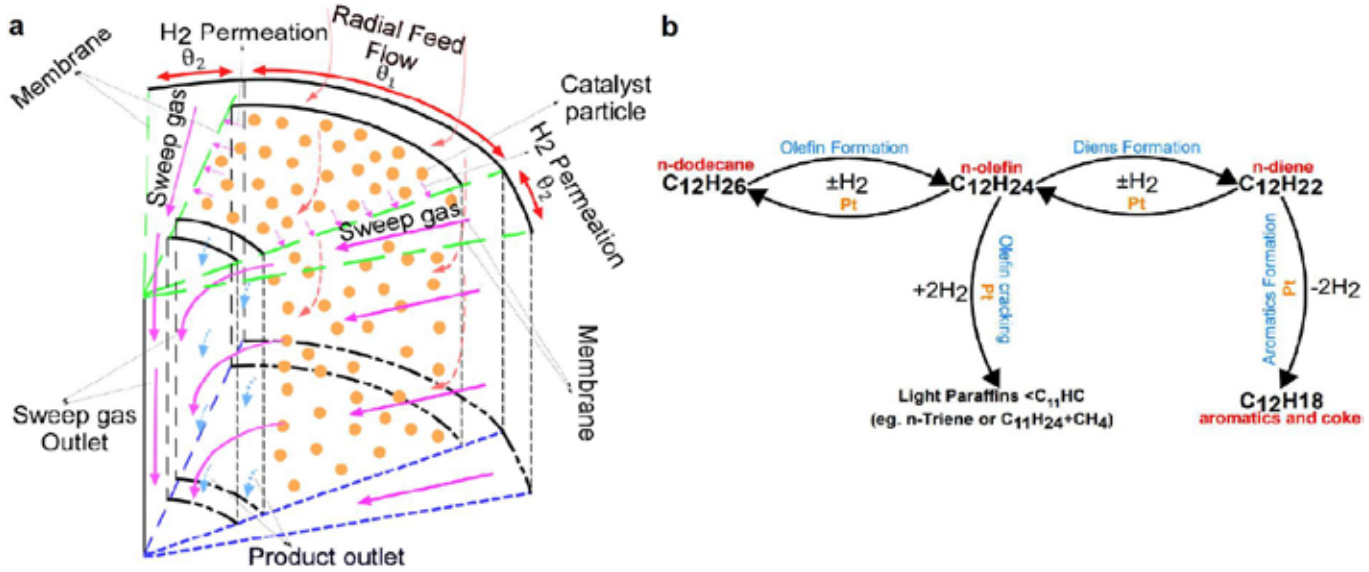

Figure 1. (a) A differential element of membrane reactor and (b) Overall paraffin dehydrogenation process reactions

RESULTS AND DISCUSSION

Steady-state and pseudo-dynamic simulations were performed on RF-MR model and tube side (reaction side) and shell side (permeation side) output parameters were obtained. Figure 2(a) compares paraffin and olefin molar flow

rate *vs.* mass of catalyst for RF-TR and RF-MR. Clearly, hydrogen permeation through the Pd/Ag membrane and its subsequent reaction rate enhancement increases olefin production in RF-MR compared to that of RF-TR.

Figure 2(b) demonstrates radial hydrogen permeation flux and hydrogen partial pressure in both reaction and permeation sides. Hydrogen partial pressure in reaction side decreases due to selective removal of hydrogen from reaction side while hydrogen partial pressure in permeation side increases due to selective addition of hydrogen. Driving force for Hydrogen permeation decreases radially resulting in hydrogen permeation flux decline.

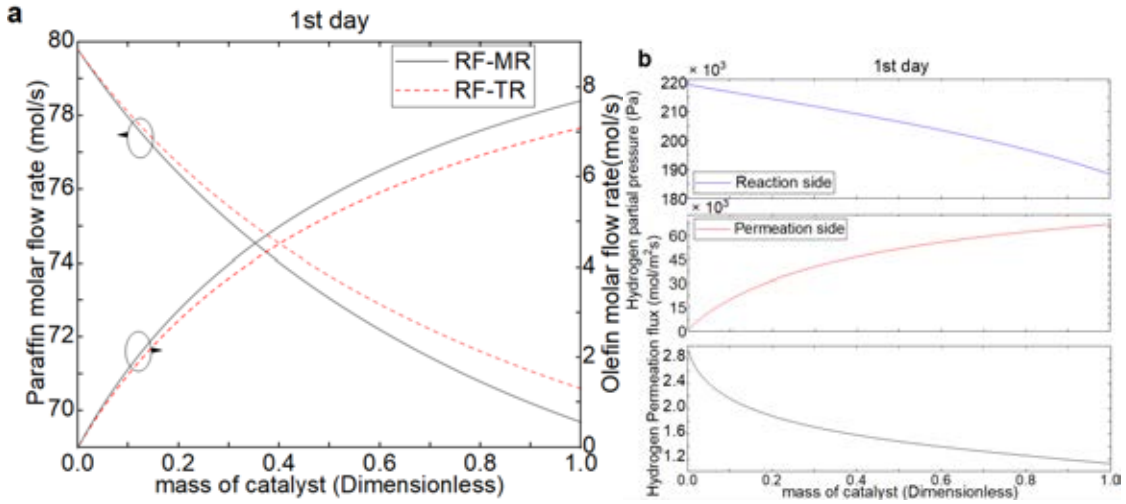

Figure 2. (a) Paraffin and olefin molar flow rate profiles in RF-MR and RF-TR and (b) Hydrogen partial pressure and hydrogen permeation flux according to mass of catalyst

CONCLUSIONS

Steady-state and pseudo-dynamic simulations and validation of RF-MR were performed. Membrane integration in the reactor resulted in 8.46 and 0.07% increase of olefin and hydrogen production compared to those at RF-TR, respectively. Finally, multi-objective RF-MR optimization using genetic algorithm method revealed 22.9 and 0.55% olefin and hydrogen production compared to those at RF-TR, respectively

ABSTRACT

Due to low outlet pressure level of hydrogen production facilities, high-pressure hydrogen storage systems today still require an additional gas compression unit. However, typical mechanical compressors decrease the overall system efficiency, emit noise, and increase investment costs as well as operational expenditures due to regular maintenance. In this work a novel electrochemical hydrogen compressor based on hydraulic cell clamping is presented. In comparison to the state-of-the-art mechanical cell clamping, according to this design variant, a hydraulic medium whose pressure level is e.g., 15 bar above the hydrogen outlet pressure level, surrounds the single cells of a stack entirely and compresses the cells to ensure the contact of the active components. A laboratory device was realised with a single cell offering a 25 cm^2 active area that showed a pressure increase from 0 bar at the anode to 10 bar at the cathode. Due to homogeneous operation condition related to pressure, current density, and temperature distribution over the active cell area, the novel design seems promising for future devices, especially in large scale.

Keywords: Electrochemical hydrogen compressor, Stack design, Hydraulic clamping

INTRODUCTION

In the framework of the transition of the world's energy economy towards a wide use of renewable and sustainable energy systems, the importance of hydrogen as an energy carrier that can be stored in large scale, increases tremendously. Even if more renewable energy systems (RES) will be installed in the grids and peak power will quickly increase in the near future, it is most likely to experience times when the actual renewable power is too low to cover the demand. To overcome periods in which just little power can be supplied by RES, especially, wind and water turbines as well as photovoltaics that are highly dependent on current weather situations, hydrogen can be used to cover the energy demand. E.g., electrical energy generation can be facilitated by hydrogen driven fuel cells, turbines, or other energy systems. Further, hydrogen can also be used e.g., as a feed stock for the industry, as a fuel for the transport sector, or to generate heat for industrial applications or private households. If the hydrogen was produced from renewable sources, such as from RES driven water electrolysis, the entire conversion chain can be carbon neutral.

However, to store the so-called green hydrogen, it needs to be compressed, e.g., up to 1,000 bar in hydrogen refilling stations for fuel cell driven passenger cars. For this purpose, the use of mechanical compressors is state-of-the-art. However, the mechanical hydrogen compression is achieved as simultaneously also the temperature of the gas increases. If heat recuperation is not applied the hydrogen compression leads, therefore, to significant losses on system level. Further, due to e.g., friction, losses as high as up to 12% of the stored chemical energy were reported as losses for hydrogen compression [1]. Furthermore, vibrations arising from rotating pistons or turbine blades etc. lead to relevant noise emissions. Beside the mentioned losses, the moving parts in mechanical compressors as well as the high-pressure gaskets underlie continuous wearing and degradation. To ensure safety and full operability of a mechanical hydrogen compressor, regular maintenance is necessary which also increases operational costs for such devices.

In this work, a new concept for an electrochemical compressor for hydrogen utilising polymer electrolyte membrane (PEMEC) is presented as a promising alternative for mechanical compression. The principal design of PEMECs is similar to PEM fuel cells (compare to Fig. 1). At the anode of PEMEC hydrogen is fed and hydrogen oxidation reaction (HOR) happens at the surface of platinum based electrocatalysts. During HOR, hydrogen molecules are split into protons and electrons. Protons will then be transported through the gas-tight and electrical insulating PEM. A voltage source drives electrons over an external circuit. The back reaction, respectively, the hydrogen evolution reaction (HER) during which the protons and the electrons form hydrogen molecules again, happens also on platinum based electrocatalysts at the cathode of PEMEC. By supplying sufficient voltage to a PEMEC, it becomes possible to increase the pressure level in the cathodic compartment. The electrochemical process happens at low temperatures like e.g., 80 °C and is entirely quiet. By using highly stable materials like CNF based Pt or Pt alloy catalysts degradation is limited, and a long-term operation can be ensured [2]. A high compression efficiency above 50% has

already been reported [3]. Although first companies provide hydrogen compressors based on PEMEC to the market, this technology is not yet widely used, especially, due to a high need of further developments and high costs. In this work we present a novel design approach for PEMEC based on hydraulic cell clamping, which is modular, scalable and has the potential to lead to significant cost reductions for future hydrogen storage devices.

MATERIALS AND METHODS

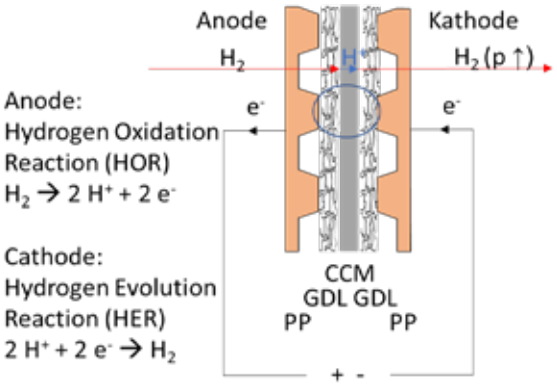

Fig. 1 Schematic design and principal of a PEMEC cell

Like typical PEM fuel cells, the reported PEMEC consists of layered electrode structure comprising a pole plate (PP), a gas diffusion layer (GDL), and a catalyst layer. However, to ensure contact of the catalyst layer to the electrolyte, typically the catalyst layer is directly attached to the PEM forming a catalyst coated membrane (CCM). Several PEMEC cells can be connected to each other as a stack. To contact the different layers in PEMEC, massive pressure plates at each end of a stack are mechanically clamped by tie bolts.

This study is about a novel PEMEC design based on hydraulic cell clamping instead of mechanical clamping. The concept was earlier reported for PEM fuel cells and PEM electrolysers and was now adapted as an alternative for modular and large-scale PEMEC stacks [4, 5]. Here, the clamping is achieved by a hydraulic medium that entirely surrounds each PEMEC single cell of a stack. The pressure level of the hydraulic medium is controlled to be always 4-15 bar above the cathode pressure level in order to induce compression forces to the active cell components. Such a stack is encapsuled in a pressure housing to keep the pressure of the hydraulic medium. A laboratory scale single cell device was worked out like shown in Fig. 2. In this PEMEC a 25 cm^2 square design was achieved. The used materials comprise gold coated copper pole plates, GDLs type 1500 by Caplinq, and a Nafion™ 212 based CCM with a loading of 0.25 mg cm^{-2} platinum for each side.

Prior to in-situ investigations, the laboratory cell was analysed according to the pressure distribution at different pressure levels of the hydraulic medium. To determine pressure distribution sensitive film Prescale LLLW by Fuji was utilised. For our analyses the investigated PEMEC cell was assembled with pressure sensitive film instead of a CCM. Like the CCM the film overlaps the gasket system that is arranged around the active area of the PEMEC cell.

The presented PEMEC was further investigated and characterised according to voltage-current characteristic in different load points and under different operation conditions related to temperature and outlet pressure. The necessary hydrogen for these experiments was provided by a former fuel cell test bench that delivers dry gas with a 5.0 quality at room temperature. Hydrogen flux to the cell's anode is controlled by a mass flow controller type LMD 500-03 by GCE. The pressure level of the hydrogen stream is 200 mbar at the inlet of the investigated cell. The hydrogen was fed to the PEMEC cell without circulation (dead-end operation). The outlet pressure was adjusted by an overflow valve. Cell and gas temperature can be assumed to be at room temperature as the utilised test bench does not provide the possibility to heat up the gases or the cell at this moment. Polarisation curves were determined using a potentiostat/galvanostat type Ivium Vertex 5A connected to an additional booster type Ivium Boost 10012. The measured data of the potentiostat/galvanostat was used to determine the polarisation curves.

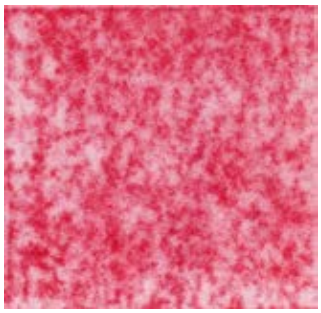

Fig. 2 Exemplary scan of pressure sensitive film applied to a 25-cm^2 PEMEC single cell based on hydraulic clamping with a pressure level of 4 bar

RESULTS AND DISCUSSION

Fig. 2 shows exemplarily the results gathered with pressure sensitive film type Prescale LLLW for a cell clamping with the hydraulic medium being at a pressure level of 4 bar, while the anode and the cathode is at ambient pressure. It can be seen that the cell compression is even over the active cell area. Like in our earlier studies on PEM fuel cells it can be expected that current density and temperature distribution is also homogeneous over the active area for out PEMEC test cell.

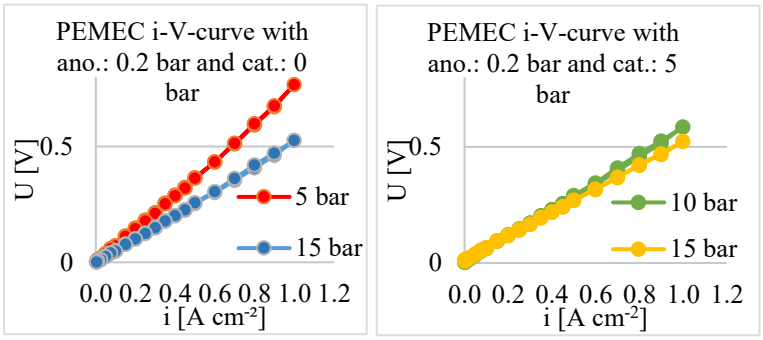

Fig. 3 Exemplary polarisation curves of the novel PEMEC single cell up to 1 A cm^{-2} dependent on hydraulic clamping pressure level as well as hydrogen outlet pressure

After the tightness of the cell's gasket system was checked up to 20 bar for the hydraulic medium and up to 10 bar for the cathode compartment, when at the same time the anode compartment was at atmospheric pressure level, in-situ measurements were performed. Polarisation curves were determined at hydrogen outlet pressures of 0 bar and 5 bar, respectively. Fig. 3 shows exemplarily polarisation curves dependent on different hydraulic media pressure level. As can be seen from Fig. 3 the increase of the hydraulic pressure level leads to a decrease in Ohmic over potential and, therefore, to more efficient PEMEC operation. For a pressure increase from 0 bar to 5 bar no significant cell voltage increase was analysed, due to predominate Ohmic losses.

CONCLUSIONS AND OUTLOOK

In experiments it was shown that our prototype based on the new way of PEMEC clamping realised a hydrogen compression from 0 to 5 bar. The use of our novel system design based on hydraulic clamping for PEMEC leads to advantageous operation conditions like homogenous cell compression distribution. From this an even current density as well as even temperature distribution over the active cell area can be expected. For prospective prototypes with higher hydrogen outlet pressure level, larger cell area and more than one cell, this could be beneficial. However, such studies will be performed in a later step after our small-scale device is fully understood.

Further, the performance indicated by the polarisation curves was appropriate for ambient and dead-end operation conditions as well as for the use of dry hydrogen feed gas. However, in comparison to earlier work in the field of PEMEC based on state-of-the-art cell types and due to low temperature level, the cell voltage of our device seems higher. Therefore, a revised experimental setup is being established soon, in order to also determine polarisation curves at higher cell and gas temperature as well as to analyse the effect of feed gas humidification.

ACKNOWLEDGEMENT

The research leading to the presented results has received funding from the Ministry for Environment, Agriculture, Conservation and Consumer Protection of the State of North Rhine-Westphalia under the framework of the "Sonderprogramm Umweltwirtschaft im Rahmen der Corona-Hilfe" (funding number UW-01-027A for ProPuls and UW-01-027D for Westfälische Hochschule University of Applied Sciences).

ABSTRACT

Pd-based membranes attract great attention to be used as independent separators or combined with catalysts in a membrane reactor for H_2-production. The membrane fabrication was improved for years, reaching ultra-thin Pd-films with high permeability and selectivity. However, commercialization at industrial level is still scarce due to the limited knowledge about their economy, lifespan and environmental concerns. In this context, the current study expands the unique life cycle assessment focused on the preparation of Pd-based composite-membranes by Electroless Pore-Plating (ELP-PP) in literature. Based on this, the current research go into deep when the membrane incorporates Pd-CeO_2 as intermediate layer and the total length of the membrane is increased up to 100 cm. The associated environmental impacts were estimated through ReCiPe methodology by using Simapro 8.5. Climate change, human toxicity, acidification, freshwater ecotoxicity, metal depletion and fossil fuel resources depletion were the most relevant impacts generated during the membrane manufacturing, although they were reduced up to 50% respect to membranes without ceramic intermediate barriers. Moreover, CeO_2 doping reduces the number of ELP-PP recurrences, hence further improving the environmental sustainability. Finally, an additional reduction of the environmental impacts was also achieved by scaling-up the process for the preparation of longer membranes.

INTRODUCTION

As a clean energy vector, hydrogen is one of the most promising alternatives to facilitate the above-mentioned progressive transition towards a net-zero carbon emissions system. Among other multiple reasons, the possibility to be produced from a wide variety of feedstock by diverse technologies, some of them very mature, could definitively promote its penetration in the industry with assumable risks. In fact, most of the current hydrogen is produced by methane steam reforming, although many other hydrocarbons can also be considered with similar technologies. The use of biomass-derivate compounds and wastes to generate hydrogen could be especially attractive for a circular economy. However, in all these processes involving traditional thermochemical routes, hydrogen is not directly obtained in its pure form but accompanied by other sub-products such as carbon monoxide, carbon dioxide, methane, or steam water, among others. Therefore, down-stream additional purification steps are always required to adjust the hydrogen purity for each particular final application [1]. In this context, Pd-based membranes provides the possibility to reach an ultra-high purity in a wide variety of operating conditions, including the combination of both production and separation steps in a unique device so-called membrane reactor. The continuous separation of hydrogen throughout the membrane from the bulk reaction promotes its generation by an equilibrium displacement towards the products. This technology simultaneously aims to facilitate the process intensification and increase their overall efficiency. Great efforts are being carried out during last years to reduce as much as possible the metal thickness of these membranes by using different ceramic particles as intermediate layer [2], among other alternatives, although environmental implications of diverse fabrication strategies are certainly scarce in literature. Only a pioneer work addressing a systematic environmental analysis throughout LCA to fabricate Pd-based membranes by Electroless Pore-Plating can be found [3]. This study completes the preliminary study by analyzing the influence of diverse CeO_2 particles and membrane scale-up on the main environmental impacts.

MATERIALS AND METHODS

Different composite Pd-based membrane containing CeO_2 intermediate layer onto PSS tubular supports were prepared by ELP-PP and fully characterized in terms of morphology and permeation capacity. Raw CeO_2 particles and doped ones with Pd nuclei before their incorporation on the membrane by vacuum-assisted dip-coating (VA-DC) were considered for the preparation of the intermediate layer. Moreover, diverse membrane lengths up to 100 cm

were also considered by scaling-up the fabrication process. Taking into account all the raw materials and energy requirements, as well as the residues generated during the fabrication, LCA analyses were performed according to standards ISO-14040 and ISO-14044 to determine the effects of each material and energy input/output used in the previously described membranes manufacturing process on both human health and the environment.

RESULTS AND DISCUSSION

First, a complete characterization of the membranes are analyzed. As it can be seen, the use of doped Pd-CeO_2 particles as intermediate layer significantly improve the membrane characteristics by reducing the final thickness of the Pd film reached by subsequent ELP-PP, while simultaneously increase the H_2-permeance, always maintaining a complete selectivity to hydrogen. A Summary of the main properties evaluated for the membranes are presented in Figure 1.

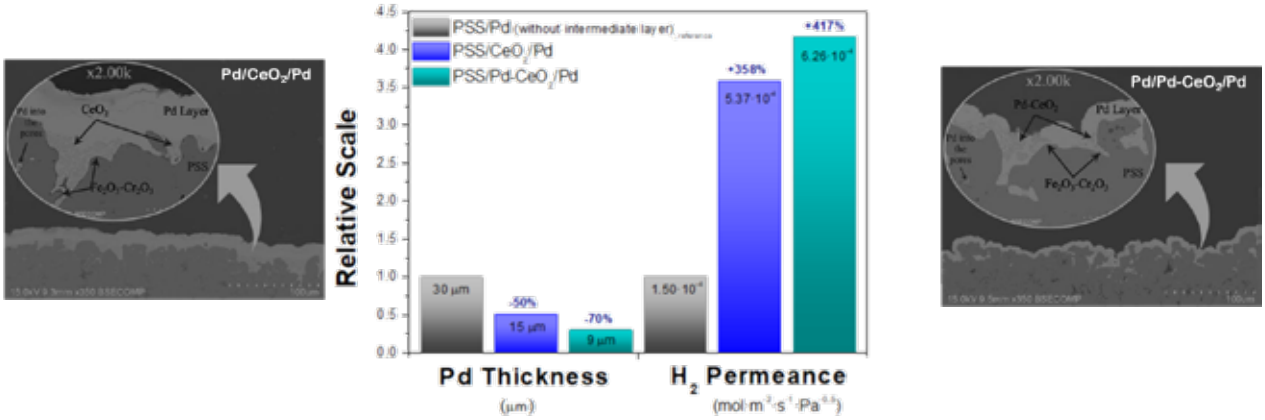

Figure 1. Summary of most relevant properties of Pd-membranes analyzed in this work.

For these membranes, the positive effect of doping the CeO_2 particles on both Pd-thickness and H_2-permeance was also relevant in case of analyzing the main environmental impacts generated during the membranes' fabrication. As it can be seen in Figure 2, all the considered impacts were reduced in a relevant amount.

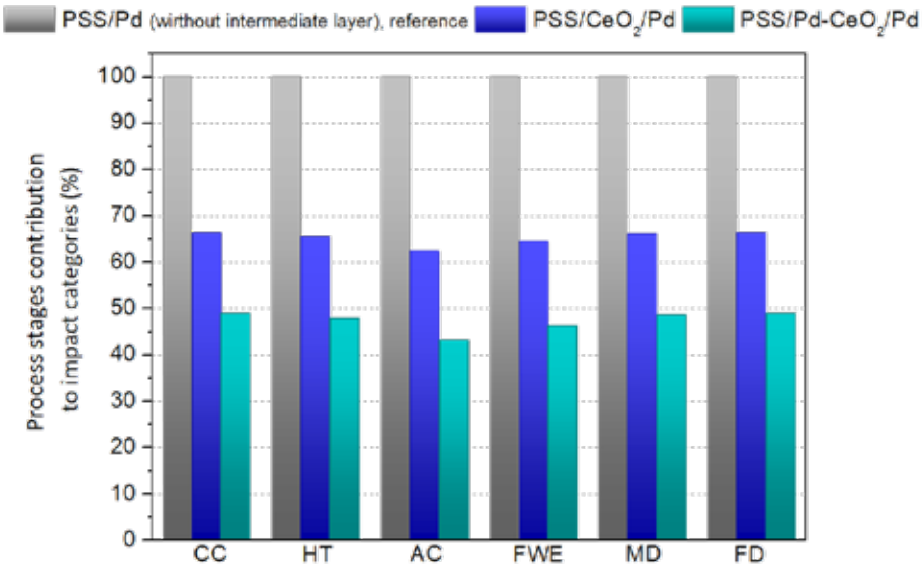

Figure 2. Main environmental impacts extracted from LCA on the membrane fabrication strategies.

Finally, the influence of scaling-up the selected fabrication strategy, Pd incorporation by ELP-PP onto PSS supports containing Pd-CeO_2 intermediate layers, was also performed and evaluated by LCA. First, it should be highlighted that similar properties in terms of morphology, homogeneity of layers in axial direction and permeation capacity per membrane length, were reached for all the prepared membranes, independently of their total length. However, further improvements in their sustainability were observed for longer membranes. Greater improvements were reached while increasing the membrane length from 3 to 25 cm, while minor effects were obtained for longer membranes, despite the main environmental impacts further decrease up to 100 cm (Figure 3).

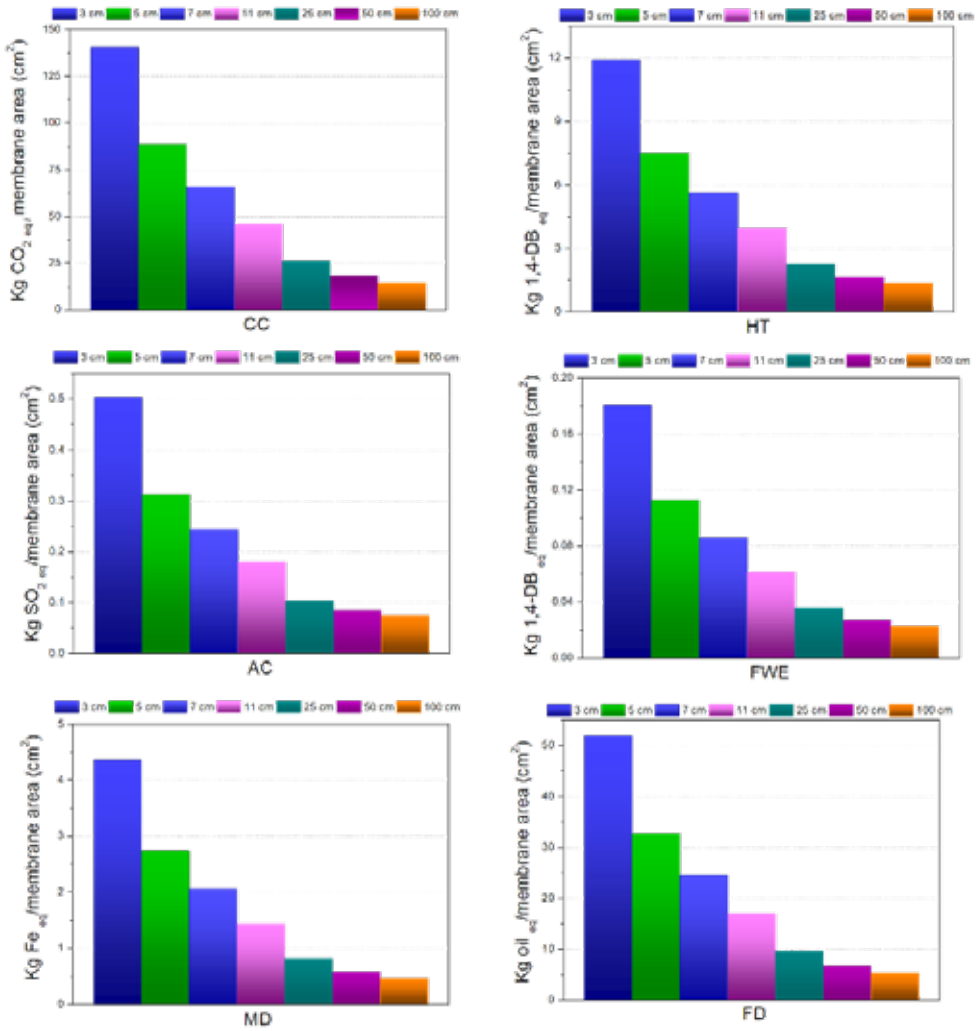

Figure 2. Evolution of environmental impacts during scaling-up the membrane length.

CONCLUSIONS

The main conclusions extracted from the current research can be summarized in:

- The use of CeO_2-based intermediate layers allows reducing the required palladium amount to reach a fully dense membrane (up to -70%) while increasing the H_2-permeance (up to +417%) without losing selectivity.
- This strategy also allows limiting the most relevant environmental impacts below 50% related to the referred value (ELP-PP membranes with absence of any intermediate layer) due to the minor number of ELP-PP recurrences and associated drying steps (with noticeable energy demand).
- A further drastic reduction of the most relevant environmental impacts can be reached during the membrane fabrication scale-up from 3 to 25 cm total length, while only slight improvements are predicted for longer dimensions up to 100 cm.

ABSTRACT

This study introduces the experimental results of a high-temperature electrochemical hydrogen purification (ECHP) cell through poly 2.2-m-phenylene-5.5-bibenzimidazole/metal organic framework (PBI/MOF) composite membranes in the temperature range of 140°C-180°C. Synthesis of ZIF-8 and UiO-66 MOFs was conducted through a typical solvothermal method, and composite membranes containing 2.5 wt. %. MOF was fabricated. Experiments were conducted with pure hydrogen (H_2) and reformate gas mixtures containing H_2, carbon monoxide (CO), and carbon dioxide (CO_2). A gas chromatography device (GC) was used to analyze the gas composition at the exit of the ECHP cell. The final output H_2 purity was found to be >99.9 % for the H_2/CO_2/CO mixed-phase and >99.7% for the H_2/CO mixed phase.

Keywords: Electrochemical hydrogen separation, Metal-organic framework, ZIF-8, UIO-66

INTRODUCTION

Removing the carbon footprint in terms of using clean and renewable resources and reducing the usage of fossil fuels is an emerging trend in energy applications. H_2 stands out among the innovative energy sources. However, due to the widespread conventional production of H_2, the produced H_2 must be separated from other impurities. To obtain efficient results from fuel cell applications, high purity H_2 needs to be used, and for easy transportation, H_2 must be compressed. The electrochemical H_2 purification (ECHP) system is a remarkable and efficient technology that can separate H_2 from a reformate gas mixture and compress it in one step [1]. The ECHP systems are relatively portable and have no moving parts, and they can operate without notable noises regarding vibration. The ECHP cell can separate H_2 from a gas mixture by H_2 oxidation reaction (Eq. 1) and H_2 evolution reaction (Eq. 2) occurring at the cathode side. Impurities leave the cell from the anode exit. Only protons pass through the proton-conducting membrane towards the cathode and recombine with electrons from the external circuit to form H_2. The overall reaction of the cell is shown in Eq 3.

Anode side: $H_2(LP) \rightarrow 2H^+ + 2e^-$ (1)

Cathode side: $2H^+ + 2e^- \rightarrow H_2$ (HP) (2)

Overall cell reaction: H_2 (LP) $\rightarrow H_2$ (HP) (3)

Various studies have been conducted in recent years to investigate H_2 purification at higher temperatures, as proton conductivity at low operating temperatures is achieved with humidified Nafion® membranes. At high temperatures, the tolerance to CO and the reaction rate increases significantly. Proton conduction is often accomplished through phosphoric acid-doped polybenzimidazole (PBI) membranes. High-temperature PBI-based systems have an advantage over Nafion-based systems in their ability to operate in the presence of higher levels of contaminants, especially CO. For the improvement of proton conduction, one of the well-known approaches is the doping of metal-organic frameworks (MOF) within the membrane [2]. In this study, the PBI membrane was doped with ZIF-8 and UIO-66 to enhance the proton conductivity of PBI [3]. The performance of ECHP and the purification rate of H_2 using a gas chromatography device were performed with the experiments carried out in the temperature range of 140-180°C. The effects of H_2 concentration and operating temperature on the ECHP performance were studied to prove the feasibility of the high-temperature ECHP system.

EXPERIMENTAL SET-UP AND PROCEDURE

ZIF-8 and UIO-66 types of MOFs were synthesized through the solvothermal method [4]. The PBI polymer was dissolved in DMAc under a magnetic stirrer at 75°C. Then, UIO-66 and ZIF-8 powders (2.5 wt. %) were added to the PBI solution and mixed for 15 min. The prepared suspension was ultrasonicated for about 30 min to provide a uniform dispersion of MOF powders and then it was cast to the petri dish. Membranes were dried overnight at 100°C. Before

conducting the ECHP cell performance tests, the membranes were immersed in H_3PO_4 for ten days. MEAs were prepared using the ultrasonic coating method [5]. High-temperature H_2 purification tests were executed using the HT-ECHP test station. The performance tests were obtained at 140, 150, 160, 170 and 180°C with various gas streams, including, reformate gases RG-1 (H_2:CO_2:CO-75:25:0), RG-2 (H_2:CO_2:CO-72:26:2) and RG-3 (H_2:CO_2:CO-95:0:5). H_2 purity level was determined by a gas chromatograph with a TCD detector (Ar as carrier gases) located at the cathode exit of the ECHP cell.

RESULTS AND DISCUSSION

Proton conductivity is an important parameter influencing the performance of the ECHP system. The proton conductivities of the PBI-ZIF8 and PBI-UiO66 membranes were determined as 0.311 and 0.316 $S \cdot cm^{-1}$ at 160°C, respectively. Figure 1 illustrates the H_2 purity results of the PBI/MOF composite membranes at different temperatures. The highest H_2 purities of 99.999 % were achieved with PBI/UIO-66 membranes for RG-1 gas.

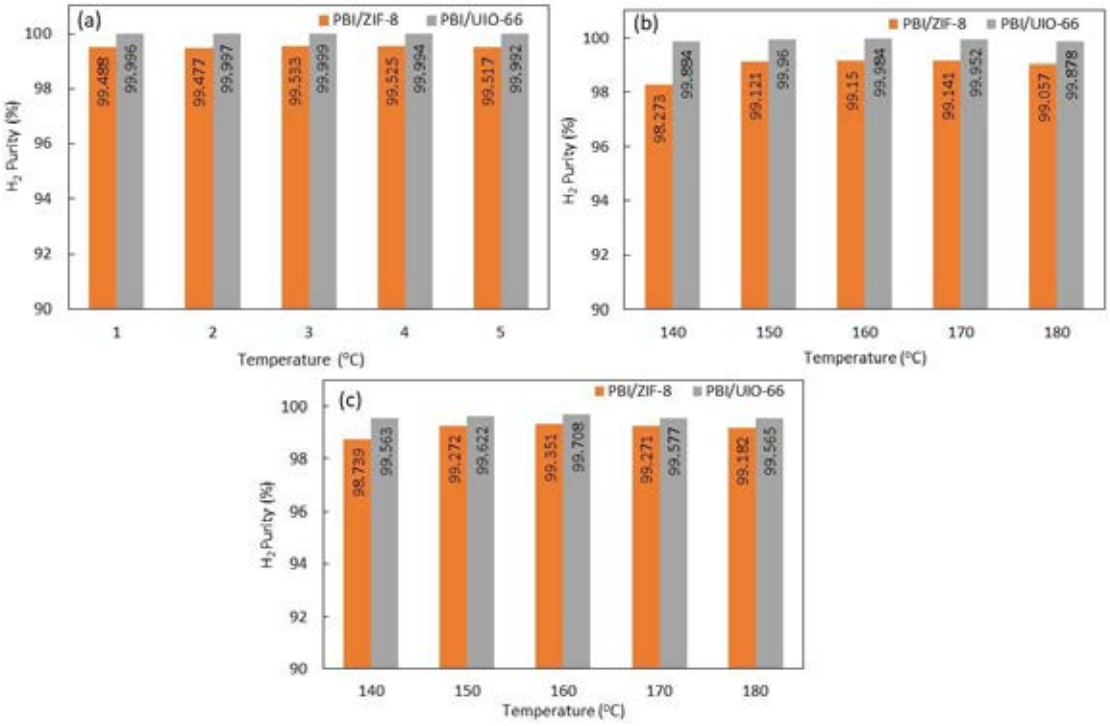

Fig. 1: H_2 purity results of the ECHP system with reformate gases a) H_2:CO_2:CO (75:25:0), b) H_2:CO_2:CO (72:26:2) and c) H_2:CO_2:CO (95:0:5)

The highest degree of purification was obtained as 99.999% (RG-1 @160°C) and 99.533 % (RG-1@160°C) for PBI/UiO-66 and PBI/ZIF-8 membranes, respectively. With the increase in temperature, a slight decrease in H_2 purification degrees was observed. The performance loss at high temperatures can be related to the conversion of CO_2 to CO by the reverse water-gas shift (RWGS) reaction because of the high operating temperature. It has been determined that the increase in the amount of CO in the gas stream causes a decrease in the degree of H_2 purification. Because of its low heat of adsorption, CO is more easily adsorbed on the Pt surface than H_2. As more CO is adsorbed on the catalyst surface, less active sites may be available for H_2 oxidation. Therefore, a decrease in ECHP cell performance occurs. However, the harmful effect of CO on the H_2 purification was less pronounced for the PBI/UiO-66 and PBI/ZIF-8 membranes [6].

CONCLUSIONS

In this study, PBI/ZIF-8 and PBI/UIO-66 composite membranes were successfully prepared for ECHP application. It has been proved that the proton conductivity of the PBI membrane can be improved through the MOF fillers. The performances of the prepared ECHP cell were determined using pure H_2 and different reformate gas mixtures in the temperature range of 140-180°C. The results show that the ECHP system, which can operate at high temperatures without the need for humidification, has great potential for the recycling and purification of H_2 in the future.

ABSTRACT

In this study, PtRu/GNP, PtIr/GNP, and RuIr/GNP bimetallic catalysts were synthesized by microwave-assisted synthesis method, and their performances on the high-temperature electrochemical hydrogen purification (HT-ECHP) were compared. The structural and electrochemical characteristics of the bimetallic catalysts were examined by the TGA, XRD, XPS, and CV techniques. ECHP Tests were performed with reformate gas mixtures containing hydrogen (H_2), carbon monoxide (CO), and carbon dioxide (CO_2) at temperatures between 140-180°C. The gas at the exit of the ECHP cell was analyzed with the gas chromatography device (GC), and high H_2 purity was achieved.

Keywords: Electrochemical hydrogen purification, Bimetallic catalyst, Graphene nanoplatelet, High temperature

INTRODUCTION

In order for hydrogen (H_2) to be used efficiently in innovative and promising applications such as fuel cells, it must be supplied in high purity and H_2 needs to be pressurized for easy storage and transport. In this context, electrochemical hydrogen purification (ECHP) is considered a promising technology to meet the global demand for H_2 and become a widely used resource, as it provides both purification and compression in one step. The ECHP has almost the same configuration as the proton exchange membrane fuel cell (PEMFC), and the catalyst layer plays a critical role in achieving the desired operating conditions. Since H_2 containing gas mixture is fed to the ECHP by the anode, specifically the anode side catalyst contacts with the impurity containing reformate gas, it must have a high tolerance to impurities and be low cost to facilitate commercialization [1]. Alloying Pt metal with another transition metal such as Ruthenium (Ru), Iridium (Ir), etc. is an attention-grabbing approach since it provides decreasing cost by reducing the Pt-loading as well as the enhanced catalyst stability [2]. In a recent study [3], the performances of Pd/C, Pt/C, and PtPd/C catalysts for ECHP application were compared and because of the electrochemical characterization analyses, it was stated that the bimetallic PtPd/C catalyst exhibited higher catalytic activity. Furthermore, it is a well-known fact that high operating temperatures yield improved catalyst tolerance to impurities inside the reformate gas and accelerated reaction kinetics for both H_2 oxidation (HOR) and H_2 evolution reactions (HER) [4]. In the present study, the influences of the graphene nanoplatelet (GNP) supported bimetallic PtRu, PtIr, RuIr catalysts on the HT-ECHP performance were compared. To examine the performances of the prepared catalysts on ECHP, the membrane electrode assembly (MEA) prepared using the synthesized catalysts was integrated into the ECHP test cell and performance tests were conducted with H_2:CO_2:CO (75:22:3) containing reformate gas mixture at the temperatures between 140-180°C.

EXPERIMENTAL SET-UP AND PROCEDURES

The bimetallic PtRu/GNP, PtIr/GNP, RuIr/GNP catalysts were prepared by microwave-assisted synthesis method since it provides a more uniform distribution of the metal nanoparticles on the support material, uniform heat distribution and rapid synthesis [5]. Firstly, 100 mg GNP support material was dispersed in the 48 ml EG and 12 ml IPA mixture with ultrasonic mixing for 1 h. Then, an adequate amount of $H_2PtCl_6.6H_2O$, $RuCl_3.xH_2O$, and $IrCl_3.xH_2O$ metal salts were added into the solution to obtain 30% metal content and mixed ultrasonically for 10 min. The final solution was washed with acetone and DI water to remove impurities and then left to dry in an oven at 100 ℃ overnight.

The structural characterization of the catalysts was performed by the Thermogravimetric Analysis (TGA), X-ray Diffraction (XRD), X-ray Photoelectron Spectroscopy (XPS) methods while the electrochemical characterization was conducted by Cyclic Voltammetry (CV). TGA method was performed to examine the thermal stability of the prepared catalysts and to determine the metal loading on the GNP support material, while the crystalline structure of the catalysts was investigated by XRD analysis. CV was conducted to examine the electrochemical stability and to calculate the electrochemical active surface area (ECSA) of the synthesized catalysts.

Ink solutions containing synthesized catalysts, PTFE binder, IPA and DI water were added to the beaker and mixed ultrasonically for 30 minutes. Prepared ink was coated on the commercial carbon paper by the ultrasonic coating method, which provides homogeneous distribution and minimizes the catalyst loss. Gas diffusion electrodes (GDEs) were attached on both sides of phosphoric acid doped PBI membranes by hot pressing method at 150°C and 172 N/cm^2 for 15 minutes. The obtained MEAs were integrated into the HT-ECHP cell and were tested in the ECHP test system with H_2:CO_2:CO-75:22:3 reformate gas at the temperatures between 140-180°C. The reformate gas was fed to the cell from the anode side, and the gas from the cathode outlet was sent to the gas chromatography device to observe the purification rate. Besides, the polarization curves were obtained by keeping the limiting voltage of the DC power supply at 1.4 V.

RESULTS AND DISCUSSION

The thermal behavior of the PtRu/GNP, PtIr/GNP, and RuIr/GNP is illustrated in Fig. 1a. According to TGA results, the metal loading on the support material was obtained as 17.11%, 17.10%, and 22.63% for the PtRu/GNP, PtIr/GNP, RuIr/GNP catalysts, respectively. The difference between the obtained metal amount and the targeted 30% metal amount can be explained by the incomplete reduction of the metal salts that are used as precursors to the metals.

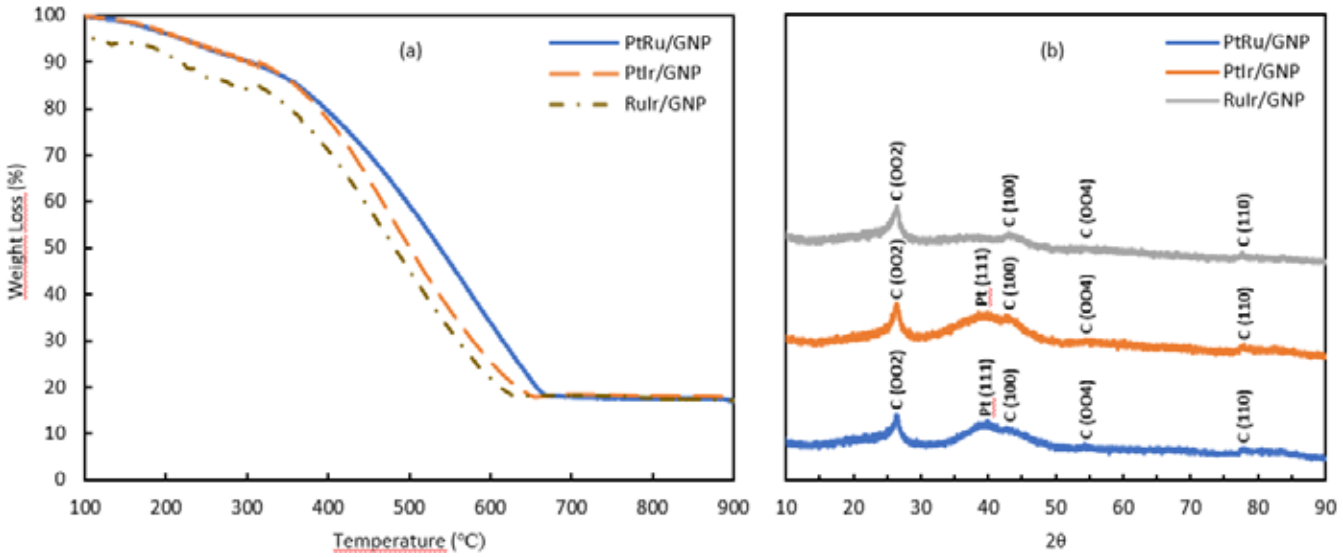

Fig. 1. a) Thermal analysis and b) XRD analysis of the PtRu/GNP, PtIr/GNP, and RuIr/GNP bimetallic catalysts

Fig. 1b illustrates the XRD pattern of the prepared catalysts and the corresponding planes to the 2θ diffraction peaks [6]–[8]. Some plane-associated peaks did not appear in the XRD graph, this may be caused by the amorphous nature of the catalysts or the broadening of the peaks due to the very small size of the catalyst nanoparticles [6]. XPS was performed to examine the chemical composition of the PtRu/GNP, PtIr/GNP, and RuIr/GNP catalysts. XPS results demonstrate that bimetallic catalysts were successfully synthesized. The CV analysis was performed with a potentiostat by three-electrode system which uses glassy carbon (GC) disk electrode (0.0707 cm^2) as working electrode (WE), Ag/AgCl filled with saturated KCl solution as the reference electrode (RE), and Pt coil as the counter electrode (CE). The CV measurements were conducted between 1.2 V to -0.25 V with a scan rate of 100 mV/s at 25 °C in 0.1 M $HClO_4$ electrolyte solution for 1000 cycles. Fig.2. shows the CV result of each catalyst. After 1000th cycles, the ECSA loss of the bimetallic catalysts was calculated as 74.55%, 46.60%, and 77.39% for PtRu/GNP, PtIr/GNP, and RuIr/GNP, respectively.

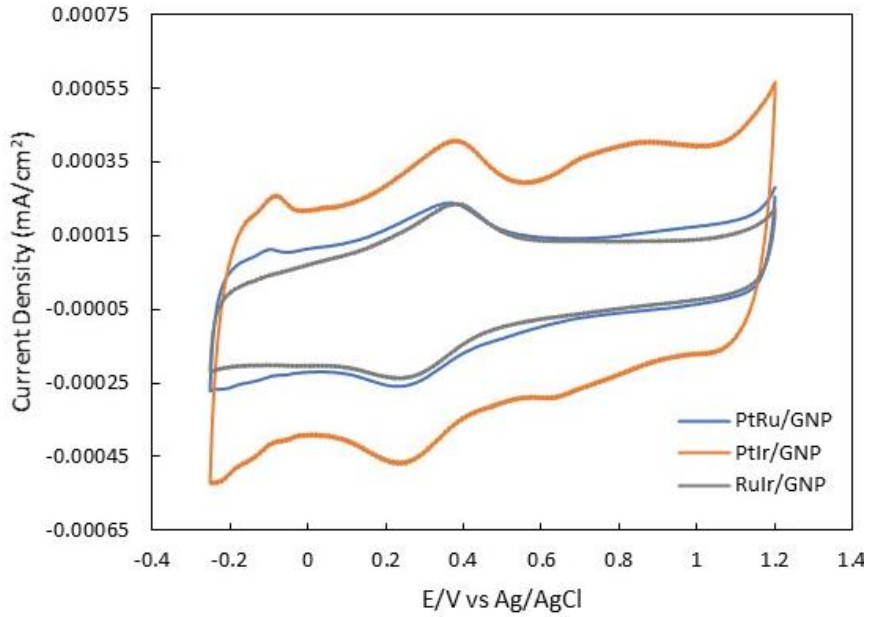

Fig. 2. CV analysis of the PtRu/GNP, PtIr/GNP, and RuIr/GNP bimetallic catalysts

CONCLUSIONS

In present study, bimetallic catalysts were prepared for the ECHP system. Catalysts were synthesized by reducing Pt, Ru and Ir nanoparticles on GNP support by microwave heating method. Successfully synthesized PtRu/GNP, PtIr/GNP, and RuIr/GNP catalysts were characterized using electrochemical and physical analysis methods. In accordance with the obtained results, it was indicated that the prepared bimetallic PtRu/GNP, PtIr/GNP, and RuIr/GNP catalysts perform better electrocatalytic activity in the ECHP system. The gas at the exit of the ECHP cell was analyzed with the gas chromatography device (GC), and high H_2 purity was achieved.

ABSTRACT

Hydrogen plays a key role in both the chemical and energy industries. However, it is essential for H_2 to be in high purity in order to be used. In countries with large coal reserves, H_2 is separated from the syngas ($CO+H_2$) obtained from coal gasification. The separation process includes units that adjust the required operational temperature and pressure with high energy needs and costs. The use of Pd-based dense metallic membranes allows the production of ultra-high purity H_2 without significant changes in temperature and pressure. However, sulfur compounds in coal-derived syngas limit the use of these membranes. Sulfur sticks to Pd atoms disrupt the membrane structure and prevent the dissociation of hydrogen on the membrane surface. Therefore, developing a thin Pd film, coated on low-cost support with an additional layer that will protect this film from sulfide compounds will make an important contribution to the literature and improve the applications of these membranes. In this study, a new membrane structure was developed by coating a thin layer of Pd film on low-cost α-Al_2O_3 tablets and growing a secondary UiO-66 layer on Pd. The experimental data proved the effect of the UiO-66 layer in preventing the Pd layer from sulfur compounds.

Keywords: Dense metallic membranes, Pd, Metal-organic frameworks, Hydrogen

INTRODUCTION

Although the focus is on clean and renewable energy sources, fossil fuels are still used in large quantities all around the world. Especially in countries with large coal reserves, energy production will continue to be obtained by burning coal until clean energies are adapted to industry. Rather than burning coal as a direct energy source, it is a more preferred method to use it with gasification [1]. The gasification process transforms the coal into syngas (mainly CO and H_2) that can be used in the energy or chemical industries , a gas mixture rich in H_2 is obtained in the presence of water-gas shift reaction [2]. In order for these gases to be evaluated in the following processes, they must be obtained as pure as possible at the end of this process or prepared in such a way as to achieve certain ratios. It is possible to reduce the H_2:CO ratio to the required levels by separating a certain amount of H_2 in the syngas. In addition, the synthesis gas released as a result of gasification contains sulfurous compounds that cause pollution, especially H_2S, in nonignorable amounts.

Commercial methods such as pressure swing adsorption (PSA), which are used to separate hydrogen from the gas mixture it is in, require huge capital and energy. For these reasons, dense metallic membranes, which can separate the desired gases in high purity under pressure and temperature conditions of the gas mixture, without requiring an additional energy input or high budgets, have started to attract attention. Especially Pd (Palladium) membranes have come to the fore with their high hydrogen permeability and high activity against hydrogen [3]. Pd is an important transition metal with a hydrogen absorption capacity of 900 times its volume. However, the H_2S existing in the gas mixture where the hydrogen is desired to be decomposed causes the Pd membrane to become unusable [4]. In this study, MOF (metal-organic framework) was used to overcome this problem.

MOFs are a type of lattice-structured materials. Lattice-structured materials are crystalline and porous solid materials constructed from organic "struts" whose chemical structures are interconnected by "joints" (organic or metal oxide-based). MOFs are highly efficient in retaining sulfide compounds, thanks to their extraordinarily large surface areas and metal knots [5,6].In addition, since their pore diameters are much larger than the lattice spaces in metal membranes, the resistance to diffusion is much lower than the use of metal membranes. In the literature, it can be seen that some of the MOFs that show high H_2S holding capacity without any defect in their structures are as follows: MIL-47, MIL-53, MIL-68, MIL-100, MIL-101, MOF-5, UiO-66 [7–10]. In studies with these MOFs, especially on CH_4/H_2S mixtures, it has been reported that almost all of the H_2S is retained and the MOFs preserve their structure. In addition, it has been observed that due to their high surface area, they can work for a long time and their regeneration is easily performed. In line with these results, it has been stated that MOFs can be used for natural gas purification [7,11]. Among

the mentioned MOFs with H_2S holding capacity, UiO-66 could be synthesized in 12 hours without the need for high temperatures and autoclaving. UiO-66 has now become the MOF of the first choice in many applications mostly because it is more resistant to temperature and pressure increase compared to other MOFs [12]. For the reasons mentioned, it was preferred to use UiO-66 as the Pd protective layer in the study.

In this study, the development of a sulfur-resistant double-layer Palladium-based dense metallic membrane for the separation of hydrogen from the sulfide-containing syngas is discussed. Pd is not resistant to sulfur, so the presence of sulfur causes defects in its structure and prevents the membrane from working. To solve this problem, a double-layered structure is used. The first layer is Pd-based metal, while the second layer consists of a thin MOF structure. The aim is to keep the sulfur impurity in the syngas in the MOF structure and prevent it from reaching the membrane surface and thus destructing the structure. With this study, Pd membrane structure with MOF protection layer was introduced in the literature.

MATERIALS AND METHODS

Al_2O_3 was preferred as the membrane support material. Powder α-Al_2O_3 (Alfa Aesar, activated, neutral, Brockmann Grade II) was pressurized to form a tablet shape, sintered at 600℃, and made ready for use. After that, tablets were cleaned with acetone to get rid of the oil and dirt that may be on the surface and dried. Pd film, which will act as a membrane, was coated on the prepared tablets by the electroless plating (ELP) method. The coating process on the dried tablets was carried out in two stages as seeding and plating by a method similar to Gade et al [13]. Seeding was carried out by keeping the support material in the prepared Pd-acetate solution for a short time. The tablet, which was removed from the acetate solution, was thrown into the H_2O_2 solution to get rid of the acetates, and then kept in the reducing solution. Then after being kept in an oven for 24 hours, the dried tablet was placed in the plating solution. Finally, they were left to dry at 120°C overnight.

The second layer, sulfur resistant MOF, was prepared after the hydrogen-selective Pd dense membrane layer developed. After surface conditioning with Pd acetate, the Pd coated samples were kept in the UiO-66 solution at 120°C for 12 hours. After washing with acetone to get rid of DMF residues, the UiO-66 coated Pd dense membrane became ready to use.

RESULTS AND DISCUSSION

Palladium dense metallic membranes synthesized by the electroless plating method. 3 separate plating bath was used for more than 1-hour cycle to increase the stability of the membranes. SEM analysis which is given in Figure 1. indicates that produced Pd films are very dense and have little porosity. After the application of the MOF layer onto the Pd dense metallic surface as described before, the whiteness of UiO-66 particles was observed on the sample surface. The SEM result of the study is given in Figure 2. indicates that the second layer has been successfully created. The UiO-66 MOF layer showed a nearly homogeneous distribution. With the continuation of the experimental studies, homogeneity will be tried to be achieved perfectly.

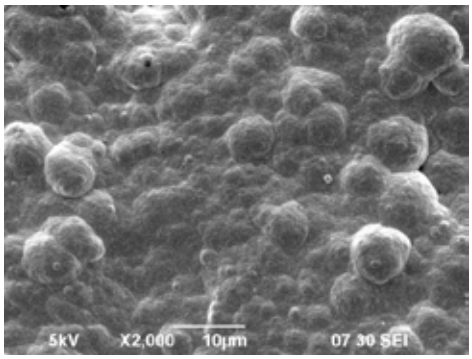

Figure 1. Pd coating morphology

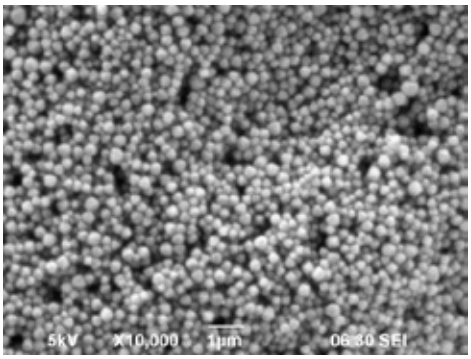

Figure 2. UiO-66 coated membrane

The study aims to form a UiO-66 layer on the Pd surface, thereby reducing the interaction of Pd with sulfur. In this context, the surface was exposed to a sulfur compound to test the function of the UiO-66 layer formed on the surface. The XRD result for the changes in the surface as a result of this process is given in Figure 3. As a result of the interaction of the Pd surface with SO_2, there are peaks compatible with PdS, Pd_4S, and $Pd_{16}S_{17}$ on the surface. The presence of these peaks was not observed in the UiO-66 coated sample, which was exposed to SO_2 under the same conditions as the Pd surface. This situation proves the conclusion of the study's hypothesis that the UiO-66 structure will protect the Pd surface.

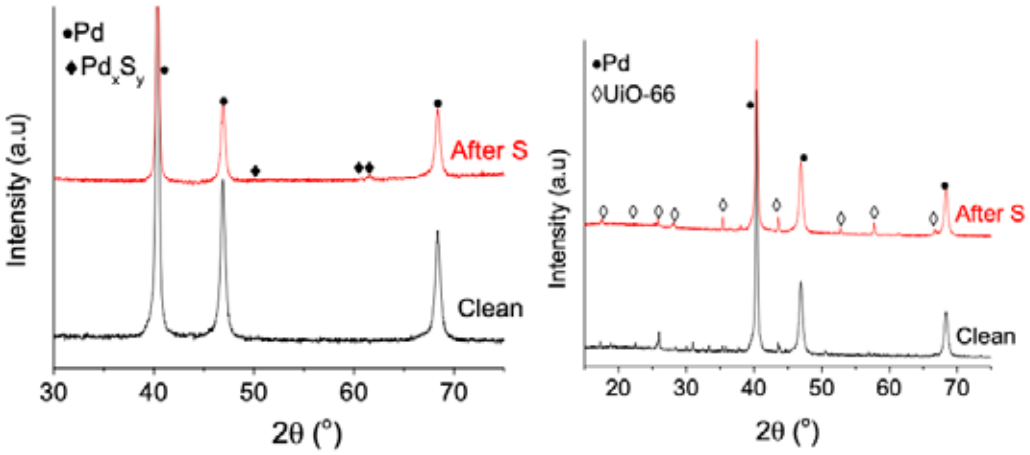

Figure 3. XRD profiles of Pd surface (left) and Pd-UiO-66 surface (right) clean and after sulfur exposure

CONCLUSIONS

Highly selective hydrogen-permeable palladium membranes are cost and energy-effective for industrial applications. However, their weakness towards sulfur compounds makes them an undesired and not preferred option. To overcome this problem, and relatively easy synthesized, resistant to temperature and pressure changes MOF type, UiO-66 was used. Thanks to the developed double-layered structure, the UiO-66 lattices in the upper layer retain the sulfide compounds while protecting the Pd metal in the lower layer from damage. Thus, H atoms that can pass through the Pd metal cavities are separated from the gas mixture, allowing ultra-pure H_2 to be obtained.

ABSTRACT

In this paper, we investigate Pd-Mn-Ag ternary system for potential alloys as separation membranes. For this purpose, thin film membranes of varying compositions were produced via magnetron sputtering. These were evaluated via four probe resistivity measurements up to temperature of 450°C. A reactivity index ρ_{H2}/ρ_{Ar} was used as a measure of the suitability of the thin film as separation membrane. Here ρ_{H2} and ρ_{Ar} are the resistivity of the film under hydrogen and argon respectively. The temperature at which this index was maximum was taken as potential operating temperature of the membrane. The preliminary results show that alloys with compositions confined to a triangle where Pd >=38 are candidates for possible hydrogen separation membrane
Keywords: Hydrogen separation, Dense metallic membranes, Palladium alloys

INTRODUCTION

Hydrogen can be produced by a variety of methods; steam reforming of methane, biomass gasification etc [1]. The resulting mixtures can contain hydrogen which would vary depending on the case. In biomass gasification, hydrogen content is not more than 40% [2]. In steam reforming of methane or coal, hydrogen is typically 75 % [3]. More recently hydrogen generated via water electrolysis from renewable sources are injected into natural gas pipelines where, the fraction in the pipeline can vary from 5 to 20%H_2 [4].

To separate hydrogen from these sources in a purity level suitable for PEM fuel cells, it is necessary to use separation membranes adapted to the process. So, for steam reforming of natural gas we need separation membranes with typical operation temperature of 350-550 oC [5]. This temperature in the case of hydrogen injected in gas pipelines are close to ambient temperatures.

PEM fuel cell requires hydrogen which should be at least 99.97% pure, free from CO (< 25 ppm) and sulfur (< 2.5 ppm) [6]. Dense separation membrane already satisfies these requirements as it would separate hydrogen which is extremely pure. Currently separation membranes in use are Pd-Ag alloys, where Pd content is more than 75%.

The current work was undertaken to investigate in Pd-Mn-Ag system so as to identify possible compositions suitable for separation purposes. Following the previous studies [7-9], the current work involves fabrication of thin film membranes via sputter deposition and fast screening of membranes via resistivity measurement.

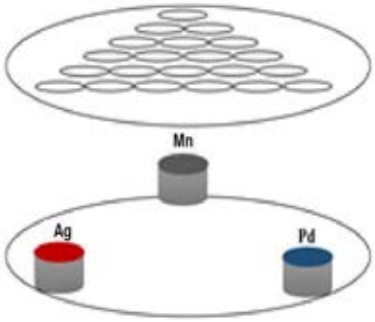
EXPERIMENTAL

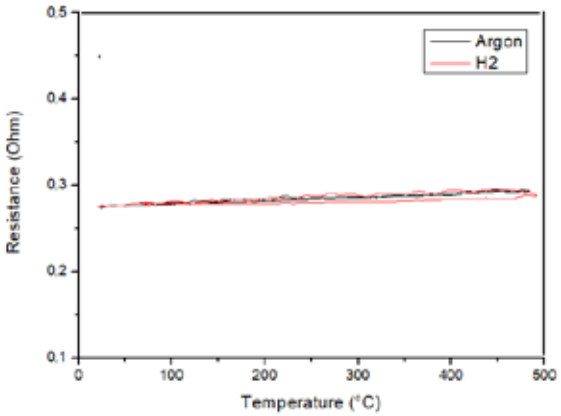
Targets used for sputter deposition were palladium, silver and manganese each in 2-inch diameter. Sputter targets were 300 mm forming an equilateral triangle, the head inclined 45°. Above the targets there were 21 glass substrates 18 mm in diameter placed in substrate magazine in triangular form mimicking the targets underneath. This would allow the deposition of thin film membranes each with a different composition. Sputtering was carried out in with an argon flow maintained at 5mTorr pressure (the base pressure was $5x10^{-8}$ Torr).

Thin film membranes are first subjected to stabilization treatment. This was carried out under argon (1 bar) by heating the membranes 2.5 °K/min to 450 °C, then holding it at that temperature for 9 hours followed by cooling with 1.6 K/min to room temperature.

Thin films were then screened via resistivity measurement. Measurements were taken with 4 probe technique using Keithley 2700 data acquisition system. The measurements are first taken under argon while heating the thin film to 450 °C (heating rate: 3K/min) and cooling it down to room temperature (1.6 K/min). At the end of experiment, argon was discharged, and hydrogen (again 1 bar) was loaded into the reactor. The measurements were then repeated with hydrogen under exactly the same heating and cooling conditions. Results were expressed in terms of

a reactivity index, i.e., ρH2/ρAr, where ρH2 and ρAr are resistance values measured under hydrogen and argon atmospheres at a given temperature.





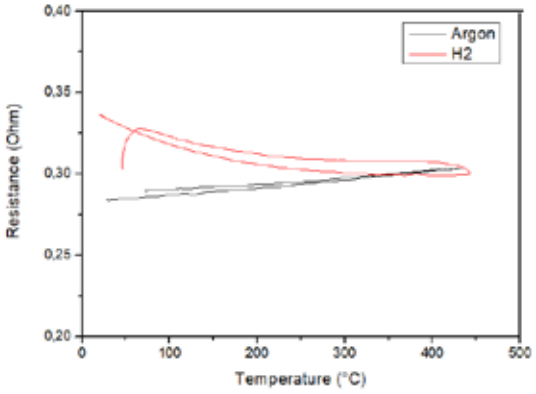


Figure 1 Schematic representation of sputter deposition of thin film membranes in combinatorial geometry

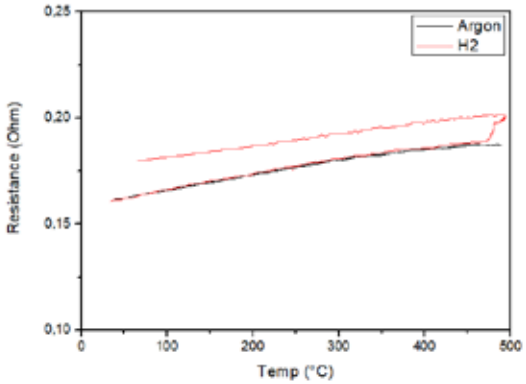
RESULTS AND DISCUSSION



Typical examples of the resistivity curves under argon and hydrogen are given in Fig.2. Here three examples are given. Fig. 2(a) refers to Pd23Mn34Ag43 where the resistivity under argon and hydrogen traces the same curve implying that the values are the same at all temperatures. Therefore ρH2/ρAr=1 implying that the thin film does not react with hydrogen. Fig. 2(b) refers to Pd38Mn21Ag41 where resistivity under argon traces a similar curve. However, under hydrogen there is a fast rise of resistivity reaching a maximum at approx. 80oC. The resistivity then gradually decreases reaching almost the same value as that under argon at 450°C. Upon cooling the curve traces back almost the same curve and therefore continues to rise and reaches its highest value at room temperature. Fig. 2(c) is altogether a different example. This curve refers to Pd14Mn49Ag37. The curve under argon and hydrogen are almost the same up to 430°C. But the resisvity makes a jump at this temperature and continues to rise upto 450oC. Upon cooling the resistivity decreases at some distance above the argon line.

(a) Pd23Mn34Ag43

(b)Pd38Mn21Ag41

(c) Pd14Mn49Ag37

Figure 2. Resistivity curve under argon(black) and hydrogen (red) in selected thin film membranes;

a) Pd23Mn34Ag43 where ρH2/ρAr=1 at all temperatures.
b) Pd38Mn21Ag41 where ρH2/ρAr>1 reaching a maximum at T =80oC.
c) Pd14Mn49Ag37 where ρH2/ρAr>1 at T>= 430oC

A map of reactivity index is given in Fig. 3 which refers to the temperature of 300°C. The area mapped here implies that a triangle defined with Pd >=38, i.e., a triangular region close to Pd corner is the most active region in this ternary diagram. Here ρH2/ρAr> 1. The value is even higher close to Mn-Pd line.

It should be noted that Pd content of 38 at % is quite low as compared to the commercial alloy Pd77Ag23. However, these are just candidate compositions and further work is needed to see if they have acceptable hydrogenpermeability.

In this respect membranes lean in Pd content is of particular interest and provided that they have permeability values comparable to that of Pd77Ag23, they would provide a considerable saving in the cost of separation membranes.

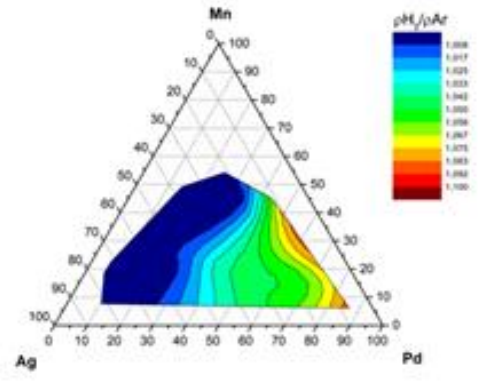


Figure 3 A map of reactivity index, ρH2/ρAr in Ag-Mn-Pd ternary system

ABSTRACT

In the present time, hydrogen is generally produced from natural gas using the conventional reactors that have some disadvantages such as thermodynamic equilibrium equation, high temperature, and carbon deposition. To overcome these disadvantages, the interest in the membrane reactors that provides both hydrogen production and hydrogen separation in the same unit is increasing, therefore the produced hydrogen is permeated from the reaction side to the permeation side continuously, and thus this decreases the thermodynamic equilibrium limitation. In this study, a mathematical model of a membrane reactor was coupled with the models of the balance of plant components (compressor, boiler, burner, pump, blower, and two mixers), and a system-level energy analysis was conducted. Molar flow rates, temperatures, and pressures for all states in the system were found. In addition, the effects of reaction temperature on H_2 production, CO_2 production, H_2 yield, and system efficiency were investigated. When the membrane reactor operating temperature increases from 673 K to 773K, the H_2 production, collected CO_2, H_2 yield, and system efficiency are increased by 9.88%, 1.48%, 9.94%, and 9.86%, respectively.

Keywords: Membrane reactor, Hydrogen production, Energy analysis

INTRODUCTION

Hydrogen can be produced by different methods (thermochemical, electrolytic, photonic, and biological processes) [1]. The mostly used method in industrial applications is the steam reforming process from natural gas. This method generally includes the use of a steam reformer, two-stage water-gas shift reactors, and a purification unit [1, 2]. In recent years, membrane reactors have attracted attention due to enabling production and separation of hydrogen in the same reactor in addition to overcoming the disadvantages of the conventional reactors such as being limited to thermodynamic equilibrium and carbon deposition problem [1, 3]. Membrane reactors can be combined with different technologies such as fuel cells or carbon dioxide capture systems. In the literature, some studies related to integration of membrane reactors with fuel cell systems can be found. However, few studies related to membrane reactor integrated with the CO_2 capture system are found. For example, Parvasi et al. [4] developed a 1-D model of a membrane reactor system that provides hydrogen production and separation for fuel cell vehicles. The results demonstrated that this system produces 5 kg/day of pure hydrogen for a 500 km range. To produce 1 kg of pure hydrogen, the total requirement amounts of methane and water were calculated as 50 kg and 70 kg, respectively. Shirasaki et al. [5] investigated a case study related to hydrogen production and CO_2 capture in Tokyo Gas Company. This company developed a large-scale membrane reactor system that has 40 Nm^3/h nominal hydrogen production capacity. The off-gas including high CO_2 concentration (90%) can easily be liquefied and captured. Therefore, this company designed and assembled CO_2 capture apparatus that includes a gas compressor, gas-liquid separator, chiller, and tank. This system was integrated with the large-scale membrane reactor system. The results showed that total CO_2 emissions for hydrogen production were reduced by 50% with only 3% energy loss. In this study, a model of a membrane reactor was integrated with the balance of plant components (compressor, boiler, burner, pump, blower, and two mixers). Energy analysis of this system was conducted and parametric analysis was doneto study the effects of membrane reactor operating temperature on the H_2 production, collected CO_2, H_2 yield, and system efficiency.

SYSTEM LEVEL MODELING

Fig. 1 shows the schematic of the membrane reactor system modeled in this study. This system includes a membrane reactor, a pump, a boiler, a compressor, mixers, and a burner. In this study, firstly, the 1-D membrane reactor model was developed and validated for 773 K using the data of the reference study [6]. After that, this membrane reactor

model was used in the system- level model. In the boiler and burner, methane and air are burned with complete combustion, and the hot product gases are used to heat the water and methane. Heated feed gas is fed to the membrane reactor and hydrogen is produced. The other gases (retentate gas) that do not pass through the membrane and enters the Mixer-2. Finally, three exhaust gases (outlet gas of boiler, outlet flue gas of burner, and the retentate gas) are mixed in the Mixer-2.

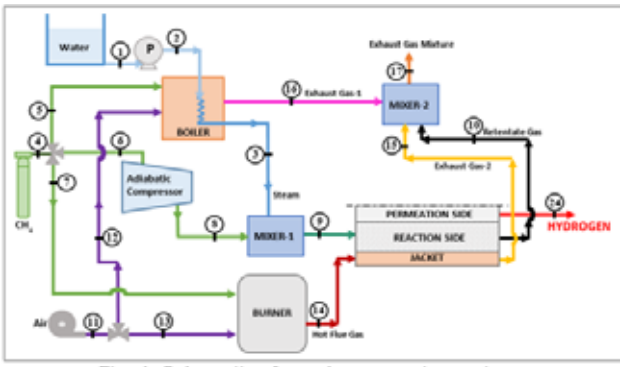

Fig. 1. Schematic of membrane reactor system

Reaction Kinetics and Hydrogen Permeation in Membrane Reactor

The membrane reactor consists of the reaction and permeation sides. On the reaction side, the feed gas enters the catalyst filled reactor after passing the Mixer-1, and three steam reforming reactions occur here. These chemical reactions are steam-methane reforming, water-gas shift, and direct steam-methane reforming reactions. Their reaction kinetic equations are given as follows:

$$R_1 = k_{0,1} exp\left(\frac{-E_1}{RT}\right)\left[P_{CH_4}P_{H_2O} - \frac{P_{H_2}^3 P_{CO}}{K_{eq,1}}\right]/\left(P_{H_2}^{2.5}\cdot DEN^2\right) \quad (1)$$

$$R_2 = k_{0,2} exp\left(\frac{-E_2}{RT}\right)\left[P_{CO}P_{H_2O} - \frac{P_{H_2}P_{CO_2}}{K_{eq,2}}\right]/\left(P_{H_2}\cdot DEN^2\right) \quad (2)$$

$$R_3 = k_{0,3} exp\left(\frac{-E_3}{RT}\right)\left[P_{CH_4}P_{H_2O}^2 - \frac{P_{H_2}^4 P_{CO_2}}{K_{eq,3}}\right]/\left(P_{H_2}^{3.5}\cdot DEN^2\right) \quad (3)$$

All coefficients used here are taken from the study of Xu and Froment [7]. Some portion of the produced H_2 in the reaction side passes through the H_2 selective membrane to the permeation side, whereas the retentate gas that does not pass through the membrane and leaves from the outlet of the reaction side. The hydrogen flux passing through the membrane is calculated by using the Sieverts-Fick Law.

$$J_{H_2} = \frac{B_{H_2}}{\delta}\left(P_{H_2,ret}^{0.5} - P_{H_2,perm}^{0.5}\right) \quad (4)$$

Mass and Energy Balance Equations for All Components

Mass and energy balance equations for steady-state conditions are given in Eqs (5) and (6). These equations are applied for all components used in this model.

$$\sum \dot{m}_i - \sum \dot{m}_e = 0 \quad (5)$$

$$\sum \dot{m}_i \cdot \left(h_i + \frac{V_i^2}{2} + gz_i\right) - \sum \dot{m}_e \cdot \left(h_e + \frac{V_e^2}{2} + gz_e\right) + \dot{Q}_{cv} - \dot{W}_{cv} = 0 \quad (6)$$

where $\dot{n}$ and MW are defined as mole flow rate (mol/s) and molecular weight (g/mole). $\bar{h}$, Q, and W are defined as specific enthalpy (J/mole), rate of heat transfer (J/s), and rate of work transfer (J/s), respectively.

RESULTS AND DISCUSSION

In this study, a system level model for a membrane reactor-based hydrogen production system was developed and the energy analysis was applied to all components. In our previous study, a 1-D model of the membrane reactor was developed and validated using the study of Alavi et al. [6], and the input parameters for the membrane reactor used in this system model were taken from this study. Then, the design and operation parameters were defined according to the membrane reactor conditions. Table 1 shows the molar flow rates, temperatures, and pressures of all states.

Table 1. Molar flow rates, temperatures, and pressures for all states at the reaction temperature of 773

State No.	Molar Flow Rate (mol/s)	Temperature (K)	Pressure (bar)	State No.	Molar Flow Rate (mol/s)	Temperature (K)	Pressure (bar)
1	444.86	400	3	10	552.45	820	10.10
2	444.86	400.32	29.29	11	7440.50	865.88	10.10
3	444.86	930.25	29.29	12	2232.10	865.88	10.10
4	347.22	400	10.10	13	5208.30	865.88	10.10
5	104.17	400	10.10	14	4427.10	950	10.10
6	138.89	400	10.10	15	4427.10	951.88	10.10
7	104.17	400	10.10	16	2075.90	1168.50	10.10
8	138.89	503.97	29.29	17	7055.40	1002.90	10.10
9	612.93	773	29.29				

Effect of Reaction Temperature

Table 2 shows the effect of reaction temperature on the molar flow rate of produced H_2 and collected CO_2, H_2 yield, and system efficiency. When the temperature increases, the molar flow rates of produced H_2 and collected CO_2 increase. The reason for the increase in H_2 production is that the higher hydrogen permeating flux occurs with the increasing temperature. Moreover, temperature affects the reaction rates of the reforming reactions. When the temperature increases, the reaction kinetics increase, and thus the amount of CO_2 in the retentate gas increases. Consequently, temperature has a positive effect on the system efficiency and hydrogen yield.

Table 2. Calculated values of some variable according to the changing reaction temperature at 29.29 bar reaction pressure

Variable	Calculated Values		
	T=673 K	T=723 K	T=773 K
Molar Flow Rate of Produced H_2 at State 24 (mol/s)	150.80	158.08	165.71
Molar Flow Rate of Collected CO_2 at State 17 (mol/s)	262.52	264.43	266.41
Hydrogen Yield, η_{H_2}, (%)	43.43	45.53	47.75
System Efficiency, η_{system}, (%)	13.07	13.70	14.36

CONCLUSIONS

In this study, the energy analysis of this system was conducted and parametric analysis was done to study the effects of membrane reactor operating temperature on the H_2 production, collected CO_2, H_2 yield, and system efficiency. The results showed that when the temperature increases, the rates of produced H_2 and collected CO_2, H_2 yield, and system efficiency increase. When the membrane reactor operating temperature increases from 673 K to 773 K, the H_2 production, collected CO_2, H_2 yield, and system efficiency are increased by 9.88%, 1.48%, 9.94%, and 9.86%, respectively. The best molar flow rates of produced H_2 and collected CO_2 were found as 165.71 mol/s and 266.41 mol/s, respectively, at 773 K and 29.29 bar. In a future study, this system can be integrated with a HT-PEMFC system and its energy and exergy analyses can be conducted.

ABSTRACT

Metal hydride-hydrogen system can provide efficient solution for hydrogen separation from the impure gas mixtures. The present study reports the effect of various absorption/desorption conditions on the hydrogen separation and alloy poisoning characteristics of $La_{0.9}Ce_{0.1}Ni_5$. The experiments is being conducted by varying absorption pressure in the range of 5-20 bar, absorption temperature between 20-30 °C and desorption temperature between 60-90 °C. According to the experimental outcomes, absorption kinetics improves with increase in the absorption pressure and decrease in the absorption temperature. For 20 bar and 20 °C, 12.8232 g of hydrogen get absorbed for 10% impure gas mixture. The desorption temperature played a significant effect on the bed poisoning characteristics of the reactor bed. Desorption kinetics improves with increase in the bed temperature, and is significant for 80-90 °C. For lower range of desorption temperature (60-70 °C), the bed poisoning was significant. Even for 10% impurity, the reaction kinetics of alloy decreases significantly after 4-5 purification cycle. However, for higher desorption temperature (90 °C), the alloy regenerated itself and the bed poisoning is delayed. The system is capable of delivering 99.9995% pure hydrogen for an impurity range from 5-15% for gaseous impurities like CO_2, CH_4, N_2, Ar etc.

Keywords: Metal hydride, Hydrogen storage, Hydrogen purification, Alloy poisoning, Alloy regeneration

INTRODUCTION

In order to restrict the global rise in the temperature within 1.5 °C, the world is shifting their energy dependency to renewables like, wind, solar, hydro, hydrogen etc. Hydrogen is available in plenty in the form of hydrocarbons and chemical compounds; however, it has to be extracted through certain processes for the end user application. However, in most of the extraction processes, the hydrogen delivery is not 100% pure [1]. Hence, it becomes essential to purify hydrogen for end user application. There are several well established hydrogen purification techniques such as membrane diffusion, pressure swing adsorption, cryogenic separation, catalytic purification, metal hydride based purification, etc. available for hydrogen purification from gas mixture (hydrogen & other gases) of different impurities level, [1-4]. In comparison to different purification techniques, metal hydride (MH) based hydrogen purification technique is the simplest one to purify/separate hydrogen through thermally driven procedure, wherein the purification process is accomplished in three simple steps, i.e. absorption, flushing and desorption [5].

Schweppe et al. [6] reported the poisoning effect of O_2, CO_2, H_2S, CO or N_2 gases on $LaNi_5$ alloy used for hydrogen storage application. They used Sieverts apparatus, which was attached with a diffusion pump, to perform experimental studies related to reactor activation, absorption and alloy poisoning. It was observed that the presence of N_2 in the void space of the reactor, did not affect the rate of hydrogen absorption at all, while for the other prefilled gases, the initial rate of reaction got reduced by a range of 2 times to 10 times. However, O_2 critically damaged the absorption characteristics of the alloy by forming an oxide layer on the surface of $LaNi_5$ alloy. Similarly, Oztek [7] tested Mg_2Ni, VTiNi and $LaNi_5$, as a separation platform to purify hydrogen from a mixture of hydrogen and helium. Considering the reversible characteristics of $LaNi_5$ on interaction with the mixture, it was considered as suitable alloy for hydrogen separation. Further, Lin et al. [8] explored $LmNi_{4.8}Al_{0.2}$ alloy from AB_5 group of alloys, and studied its anti-poisoning characteristics for hydrogen storage application. The alloy was activated in the presence of pure hydrogen, and then they were exposed to CO and H_2S, each 1000 ppm as impurity with pure hydrogen. The poisoning effect of CO was more dominating as compared to H_2S.

Several studies have been reported on bed poisoning and hydrogen separation through metal hydride systems. However, the studies related to optimizing the operating parameters for a particular metal hydride and alloy regeneration are lagging in the literature. This motivates for the present study, wherein the hydrogen purification parameters and alloy regeneration has been discussed for $La_{0.9}Ce_{0.1}Ni_5$.

EXPERIMENTAL SETUP

The experimental setup was developed to carry out detailed purification study on the $La_{0.9}Ce_{0.1}Ni_5$ based MHHPS, wherein the impure sample preparation, absorption of impure mixture, flushing, desorption and sample collection for gas chromatography were carried out using a single gas circuit of specific configuration, as depicted in Fig. 1. The experimental setup mainly comprised of a MH reactor of embedded cooling tube (ECT) design with 6 ECT, Coriolis mass flowmeter to record amount of gas transferred, high & low temperature recirculating baths, vacuum pump, valves & fittings for gas and HTF circuit, gas cylinders, gas regulators, gas chromatograph and data acquisition system.

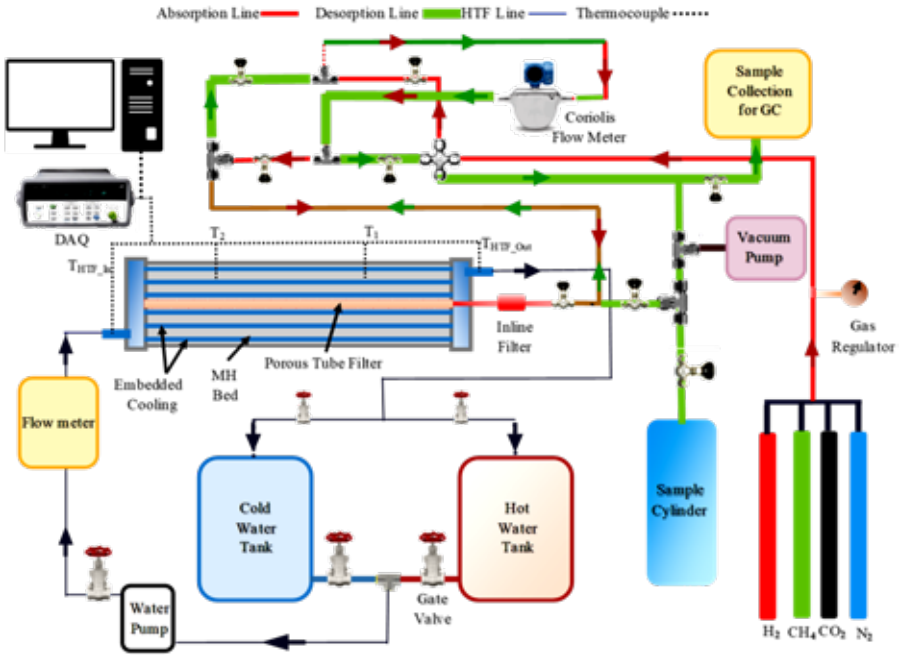

Fig. 1. Schematic of experimental test setup

REACTOR ACTIVATION AND EXPERIMENTAL PARAMETERS

Table 1. Experimental Parameters

Type of Study	Half Cycle	Operating parameters	Value
Parametric Study with Impure Hydrogen	Absorption	Supply pressure (P_s)	5, 10, 15 and 20 bar
		Absorption temperature (T_a)	20, 25 and 30 °C
		HTF flow rate	4 lpm
		Impurity level	5%, 10%, 15%
	Desorption	Desorption temperature (T_d)	60, 70, 80 and 90 °C
		HTF flow rate	4 lpm
	Purification Cycle	No. of Cycle	25 Cycle

Parametric studies with impure hydrogen was performed to obtain optimum absorption, desorption and flushing temperatures. The experimental parameter is summarised in Table 1. Before activation, the reactor was tested with argon gas at 80 bar to ensure leak proof system. Further, it was heated up to 90 °C, and evacuated up to 0.02 mbar to ensure no moisture was present in the alloy bed. The reactor activation was performed at hydrogen supply pressure (P_s) of 30 bar and 25 °C absorption temperature (T_a). In the first activation cycle, 14.4501 g hydrogen was absorbed in 527 s, while the peak bed temperature recorded was around 44 °C. Considering slow reaction kinetics, reactor was again evacuated keeping the bed at 90 °C. Further, the activation cycle was repeated 3 times to ensure the complete activation of the MH bed, where in amount of hydrogen absorbed was recorded as 15.4484 g, 15.8293 g & 15.5207 g, respectively in 2nd, 3rd and 4th activation cycle, with absorption time of 190 to 200 s. The repeatability in the amount of hydrogen absorbed and bed temperature variation during 2nd, 3rd and 4th activation cycle presented in Fig. 2, depicts the successful activation of the MH reactor with 1.2 kg of $La_{0.9}Ce_{0.1}Ni_5$, having storage capacity of 1.32 wt.%. The uncertainties in the experimental measurements were estimated using the method adopted by Moffat J Robert [8]. The uncertainties in measuring HTF flow rate and H_2 supply pressure were ± 1.67% and ± 3.0%, respectively, while the uncertainty in assessment of H_2 storage capacity was ± 2.5%. The error in the thermocouple reading was recorded ± 0.5 °C.

The detailed study and experimental outcomes will be reported in the full manuscript.

ABSTRACT

In recent years, one of the most important sources used as fuel for energy production is hydrogen. Especially, research in hydrogen technologies has gained importance with the increase in commercialization applications of fuel cells. When it comes to the development of hydrogen technologies, it is of great importance to carry out studies in the field of purification and storage of hydrogen as well as production methods. Considering the disadvantages of conventional compressors, which are widely used in the world, electrochemical hydrogen compressor technology that can pressurize hydrogen with an electrochemical method is the best alternative. In this study, the development of low-cost, long-life materials and compressor systems for the compression of hydrogen were investigated. In this study, Nafion 117 membrane and commercial Pt/C electrocatalyst were tested in the EHC system.

Keywords: Hydrogen, Polymer electrolyte membrane, Electrocatalyst, Pressurization, EHC, Compression

INTRODUCTION

Considering the increase in energy need and the problems experienced with the consumption of fossil fuels, the alternative energy source to be used should be both environmentally friendly and sustainable. Researches conducted for this purpose have highlighted hydrogen technologies as the most important candidate for energy production. Nowadays, for the sustainability of hydrogen technologies, medium and long-term policies based on hydrogen are prepared in many countries as well as the most developed countries, and detailed studies are carried out for their implementation. Within the scope of these studies, the evaluation of the existing methods used in all stages from the production of hydrogen to its purification and storage, elimination of deficiencies, and the development of new methods are important for ensuring integrity in this field.

Lee et al. tested the Nafion 115 membrane in the EHC system to purify H_2 from the reformate mixture. They operated the system between 30-70 ^oC and 1-3 atm supply pressure. They found that hydrogen purity increased with applied current and temperature [1].

Rohland et al. investigated an electrochemical compressor to increase the cathode pressure to 43 bar in a study. In their research, the surface area of the electrode is 100 cm2 and they used Nafion 117 as the membrane. They measured the cathode pressure at current densities of 100 to 150 mA cm−2. The results showed that increasing current density leads to a higher hydrogen flow rate at the cathode side [2].

MATERIALS AND METHODS

MATERIALS

Commercial Nafion 117, Sulfuric acid (Sigma, 97%), Hydrogen peroxide (Sigma, 35%), Nafion solution (Alfa Aesar, 5 wt. %), Commercial Pt/C (Fuel cell store, 20% wt.), Isopropyl alcohol (Merck,99.8%).

METHODS

Membrane conditioning procedure; Nafion 117 membrane was kept in 3% H_2O_2 boiling at 80 °C for 1 hour. It was then rinsed with water and kept in boiling water for 2 hours. Then it was kept in 0.5 M H_2SO_4 for 1 hour. Finally, it was rinsed in deionized water boiling between 80-90 °C.

Preparation of catalyst ink; the water was added to the commercial Pt/C catalyst and mixed ultrasonically, and then Nafion ionomer was added and subjected to ultrasonic treatment again. 2-propanol was added as the solvent and mixed ultrasonically. A homogeneous ink solution was obtained.

20% Pt/C catalyst was used as both anode and anode catalyst. The amount of anode and cathode catalyst coating is equal and is 0.4 mg/cm^2. The anode side hydrogen feed is 0.2 ml/min and 1 bar. Cell operating temperature is 30°C. Hydrogen was fed with 100% moisture.

The electrochemical hydrogen pump test system and cell are given in Figure 1. The anode side output is open to the environment. At the cathode side output, pressure measurement is made with both a manometer and a pressure sensor. The cathode outlet pressurization is set by the backpressure regulator and at the same time, the outlet flow is measured with a flow meter.

Fig. 1. Electrochemical hydrogen pump test system and cell

RESULTS AND DISCUSSION

The polarization curve of the test results is given in Figure 2. In Figure W, the pressure-flow rate performance of the system is given. As can be seen from the curves, hydrogen at a value of 0.17 A/cm^2@0.75V began to pass from the anode to the cathode. In the meantime, since the set value of the backpressure regulator was 0, the hydrogen was ejected freely and the cathode side was not pressurized.

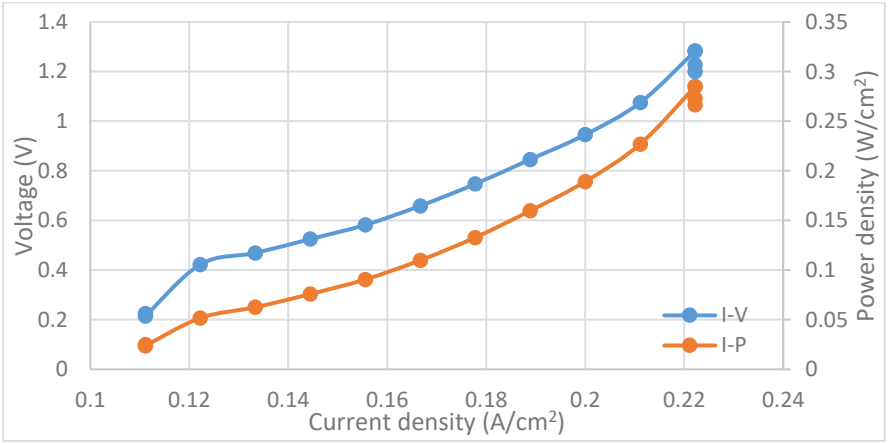

Fig. 2. Polarization curve

When the backpressure regulator value is set to 2 bar, the output flow rate is reduced to 0 and the cathode is pressurized. While the current value was 0.22 A/cm^2, the cathode pressure value reached 1.38 bar.

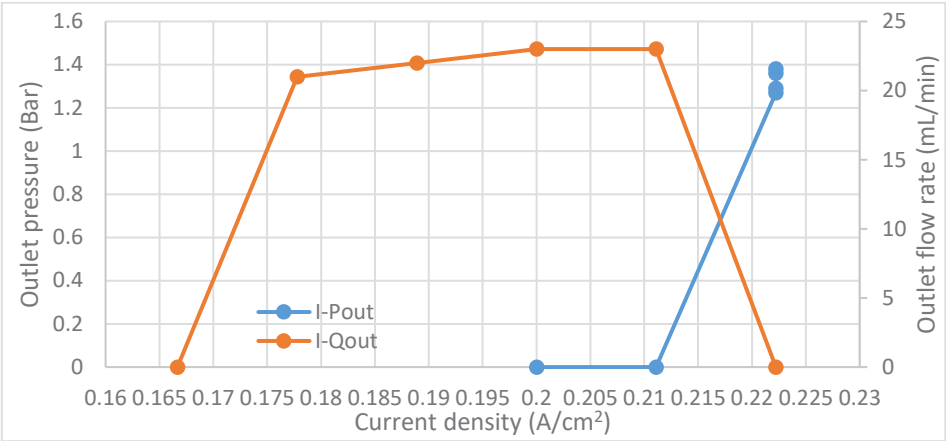

Fig. 3. Pressure-flow rate curve

CONCLUSIONS

In the study, electrochemical hydrogen pump tests were carried out using commercial Nafion 117 membrane and 20% Pt/C catalyst. In these tests carried out at room temperature, the cathode pressure value was increased by 1.38 times compared to the inlet pressure, despite the use of a catalyst with a low metal percentage. Unlike the tests generally done in the literature, the open cathode was used and both the output flow rate and the pressure value were measured simultaneously. 11.5% of the inlet flow could be transferred to the cathode side. It is predicted that when the temperature value is increased, both the output pressure and the output flow performance will increase. However, the long line at the cathode outlet reduces the rate of increase in pressure.

EVALUATION OF THE EFFECT OF TEMPERATURE, AIR EXPOSURE AND GAS MIXTURE ON Pd_{82}-Ag_{15}-Y_3 FOR HYDORGEN SEPARATION

[1]Omid Jazani, [1]Moses Adejumo, [1] Simona Liguori*
[1]Chemical and Biomolecular Engineering Dept, Clarkson University, Potsdam, NY, USA

*Corresponding author e-mail: sliguori@clarkson.edu

ABSTRACT

Hydrogen permeation and separation properties of a ternary Pd-alloy are evaluated at temperature and pressure range of 300 °C and 600 °C and 2 – 5 bar (abs), respectively. The membrane Pd_{82}-Ag_{15}-Y_3 is unsupported, prepared by cold rolling and it is characterized by ~ 35 µm of thickness. The membrane shows good thermal and chemical stability when exposed to air and at different temperature. In particular, its surface area increases by 2.5x from room temperature to 600 °C indicating a potential improvement of hydrogen permeation. The permeation characteristics of the membrane and the effects of the other gases on hydrogen permeation will be investigated by varying temperature and pressure evaluating the effects of dilution, depletion, concentration polarization, and competitive adsorption on the H_2 permeating flux.

Keywords: Ternary alloy membrane, Pd-based, Hydrogen separation

INTRODUCTION

In the view of a significant reduction of greenhouse gases emissions amidst fossil fuel exploitation, the use of sustainable energy sources is a mandatory option as well as the use of alternative fuels for the transportation sector. In this context a strong interest has been addressed towards the possible development of a global 'hydrogen economy', by considering hydrogen as the energy carrier of the future and as reliable fuel source for transportation. Currently, hydrogen is mainly produced by the methane steam reforming, which is an energy-intensive process emitting approximately 9 $kgCO_2/kg_{H2\text{-}produced}$ [1]. Alternatively, highly pure hydrogen can be produced in a membrane reactor (MR), which can be implemented at lower operating conditions than conventional reactors. The MR has the co-benefits to produce a stream mainly composed by CO_2, which can be easily captured, thus generating blue hydrogen [2-3]. In this contest, the membrane plays the main role. Dense metal membranes are commonly used for high purity hydrogen separation due to their unique characteristic of being completely selective toward hydrogen permeation and the most metal used for this approach is palladium. Pure Pd membranes have shown great potential for their application to H_2 separation at high temperature. However, they are affected by problems such as the embrittlement, deposition of carbonaceous impurities, and poisoning by CO and H_2S, which often result in a mechanical failure of the membrane and in low chemical stability [4]. It has been reported that the use of Pd-alloy membranes (mainly Pd-Ag, Pd-Cu and Pd-Au) decrease these issues and even increase the permeability of H_2 compared to pure Pd [5-7]. The Pd-Ag alloy system is the most widely studied. It is a stable alloy with face centered cubic (FCC) structure, which reduces the temperature for metallic hydride formation, which causes hydrogen embrittlement and affecting membrane permeability. However, although considerably better than pure palladium, Pd-Ag still has relatively low strength and expands significantly on hydrogen absorption [5]. So, the development of Pd-Ag-based ternary alloys aims to improve these challenges. In this study, a self-supported Pd_{82}-Ag_{15}-Y_3 membrane has been considered, where yttrium was added to improve the permeability characteristics of the membrane and increase its strength.

In this work, the effects of temperature, air exposure, and several gases on the H_2 permeation flux are studied in detail. In particular, the negative effects (concentration polarization, dilution, depletion, and competitive adsorption on the Pd surface) through which each gas can reduce the H_2 permeating flux are analyzed by performing permeation tests of binary mixtures of H_2 with He, Ar, N_2, CH_4, CO, CO_2, and H_2O. Next, the study is extended to ternary and quaternary mixtures to explore the cumulative gases effects on the H_2 permeating flux. Scanning electron microscopy (SEM), energy dispersive system (EDS) and atomic force microscopy (AFM) were performed on the pristine and used membrane to characterize the membrane.

MATERIALS AND METHODS

Disc foils of Pd_{82}-Ag_{15}-Y_3 with a diameter of 25.4 mm were used for this work. The thickness of the membrane was approximately 35 µm. The membrane was self-supported and prepared by cold-rolled technique. The total active area corresponds to approximately 1.79×10^{-4} m^2. Figure 1 shows the details of the membrane module. A porous disc made of Hastelloy-X with a pore size of 0.2 µm is placed on the hole of the membrane module to mechanically support the

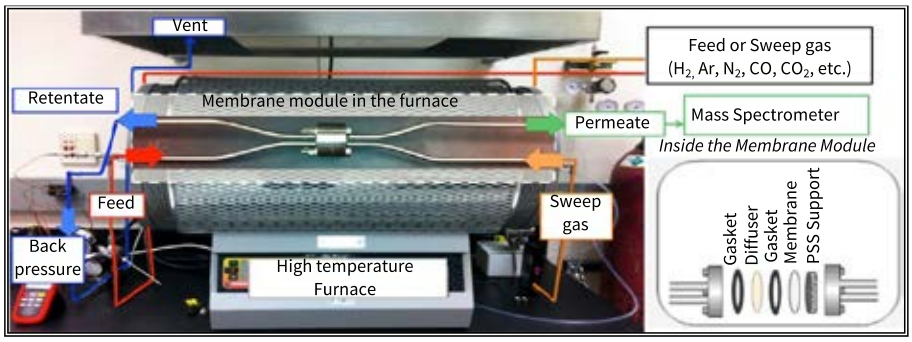

Figure 1. System for testing metallic membranes

membrane foil and it is placed in a custom-made membrane module. The membrane module is sealed with two graphite gaskets, between which a diffuser (alumina fiber, APA-3, Zircar Ceramics) is placed to evenly distribute the gas flow onto the membrane. The membrane module was heated using a Carbolite oven and the temperature was monitored via a K-type thermocouple (Omega Engineering) housed on the retentate side of the membrane system.

The operating temperature are varied between 300 °C and 600 °C, while retentate pressures are changed between 2 bar (abs) and 5 bar (abs). The permeate pressure is kept constant at 1 bar (abs). The gases such as H_2, He, Ar, N_2, CH_4, CO, CO_2, are regulated and supplied to the system via Aalborg GFC17 thermal mass flow controllers, while H_2O is supplied by a peristaltic pump. A HP 7890 GC is utilized for analyzing the permeate stream. Before beginning the testing, the GC is calibrated using the standard addition method [8] in order to obtain accurate molar compositions for the permeate stream.

The permeating characteristics of the membrane are evaluated by the hydrogen permeating flux through the membrane – when pure hydrogen and mixtures are fed. The ideal selectivity is also analyzed to measure the extent of membrane selectivity toward hydrogen.

RESULTS AND DISCUSSION

The effect of temperature and air treatment on the Pd_{82}-Ag_{15}-Y_3 membrane are investigated to evaluate the stability of the membrane. In particular, temperature was varied from 300 °C and 600 °C while exposing the membrane to the air.

Figure 2 shows the SEM images of the Pd_{82}-Ag_{15}-Y_3 membrane at different temperatures. Cracks and polishing lines are present on the surface of the membrane and the cracks increased by increasing the temperature. These surfaces defects are due to the production method, and they are emphasized during the temperature increase. The EDS analysis indicates that the membrane surface was affected by oxygen and the amount of oxygen increased with the increasing of the temperature. However, as reported by literature the formation of some oxides can increase the hydrogen permeation flux [9] due to the membrane morphology change (AFM).

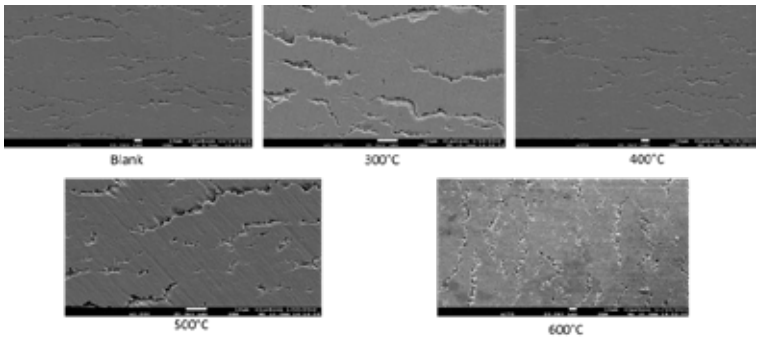

Figure 2. SEM analysis of Pd_{82}-Ag_{15}-Y_3 membrane at different temperature.

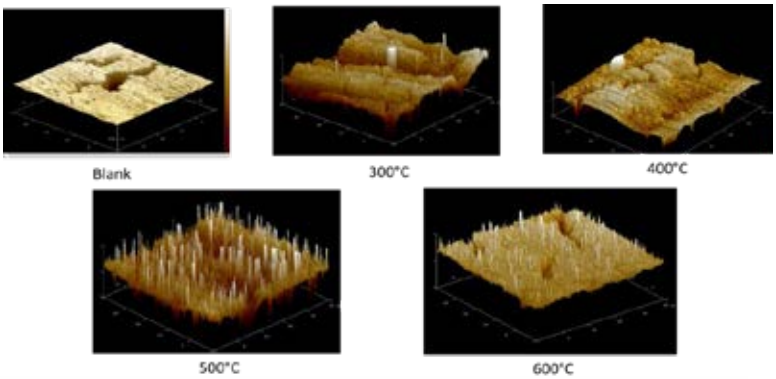

Figure 3. 3D AFM images of Pd_{82}-Ag_{15}-Y_3 membrane at different temperature.

The surface and morphology of the Pd_{82}-Ag_{15}-Y_3 membrane were evaluated by the AFM. In figure 3, the 3D AFM images of the membrane is shown. It is possible to note that the roughness of the membrane as well as the surface area increase with the increasing of the temperature. In particular, the surface area improved from 271 μm^2 at 300 °C to 625 μm^2 at 600 °C. It is worth mentioning that the cracks participated in calculating the roughness. It is postulated that more peaks and active areas enhances the hydrogen permeation. So, it can be concluded that if the membrane will show a decline in performance, an air treatment at high temperature can be performed to restore the initial permeation characteristics of the membrane.

The next step will be the evaluation of the permeation characteristics of a ternary Pd-alloy membrane at different temperatures and pressures, such as 300 – 600 °C and 2 – 5 bar, respectively. Additionally, the effect of concentration polarization, dilution, and competitive adsorption on hydrogen permeation is analyzed in the presence of other gases. Finally, the membrane will be characterized by SEM, EDS, AFM and X-ray diffraction (XRD) analysis.

CONCLUSIONS

A self-supported ternary Pd-alloy membrane, i.e. Pd_{82}-Ag_{15}-Y_3, was used in this work to analyze the effect of temperature, air exposure and mixture gases on H_2 permeation. Initial testing was performed to investigate the stability of the membrane in presence of air at different temperature. The SEM shows that the membrane is affected by superficial cracks, which increase with the temperature increasing, while the EDS shows the formation of some oxides on the surface. However, the formation of oxides and the presence of cracks on the surface can paradoxically increase the hydrogen permeation flux due to the membrane morphology change. Indeed, AFM analysis shows an increase of surface area by 2.5x, which indicates a potential increase of the hydrogen permeation.
The effect of the gas mixture on hydrogen permeation through the ternary membrane will be studied in detail at different temperature and pressure. If the membrane will show a decline in performance, an air treatment at high temperature will be performed to restore the initial permeation characteristics of the membrane.

ABSTRACT

The energy world is moving beyond fossil fuels and should power our entire society with clean energy in the future. For hydrogen to become a widespread energy carrier that can provide an emissions-free transportation fuel, it must be produced from the clean energy sources. Therefore, clean hydrogen production and storage is currently undergoing extensive research. However, none of the present widely-use hydrogen production processes, besides electrolysis, are sufficiently pure to enable immediate use of hydrogen as an energy carrier in fuel cells or in storage. Therefore, purification of hydrogen is mandatory, especially on a large scale. This paper gives a brief literature overview of the current state-of-the-art electrochemical hydrogen purifiers (EHPs), with emphasis on their performance diagnostics, including current technology issues, challenges, and different approaches with suggestions for potential solutions and improvements in future.

Keywords: electrochemical hydrogen purifier, performance diagnostics, polarization curve, electrochemical impedance spectroscopy, gas chromatography

INTRODUCTION

The most likely application of electrochemical hydrogen purifier (EHP) is the purification of hydrogen gas commonly produced by reforming gas streams, coal gasification, and other large-scale hydrogen productions from oil and biomass sources. Most industrial techniques of hydrogen post-treatment upon production use different purification steps, such as condensation of impurities (cryogenic processes), adsorption of impurities (pressure-swing adsorption), or using a perm-selective membrane (a membrane separation process) to remove hydrocarbon residues from hydrogen mixture fuels [1]. However, EHP enables hydrogen purification in only one step, with the theoretical possibility of simultaneous compression as well. Furthermore, besides their silent work due to lack of moving parts, EHP offers numerous advantages, such as its scalability, instant remote control-ability, high-purity hydrogen in only one step operation at low cell voltages (up to 0.5 V) with a high separation efficiency compared with classical technologies currently used in industrial scale [2,3]. The most common pollutants of hydrogen can be as follows: a small percentage of inert gases, such as nitrogen (N_2) or argon (Ar), methane (CH_4), carbon dioxide (CO_2) and monoxide (CO), ammonia (NH_3), and sulphur impurities. For instance, inert gases influence hydrogen dilution, deplete the hydrogen content on the anode side and have detrimental effect on cell lifetime. On the other hand, CO_2 presents the main impurity in hydrogen reformate. It reacts with hydrogen in gaseous phase through reverse water gas shift reaction (RWGS) so the formation process of CO is unavoidable. Additionally, RWGS reaction can be further accelerated in the presence of a catalyst. However, formed CO molecules easily poison catalyst surface by blocking their sites for main reaction implementation [1]. In this paper, an overview of the experimental investigations' findings of hydrogen purification from various mixtures under different operating conditions is provided, right after EHP working principle briefly given in the next section.

PRINCIPLE OF ELECTROCHEMICAL HYDROGEN PURIFICATION

In general, the gas mixture is being fed to the anode side of the EHP at a pressure slightly above atmospheric pressure, where hydrogen oxidation reaction (HOR) occurs on platinum catalyst sites and splits hydrogen molecules into protons and electrons. Hydrogen protons are selectively transported across the membrane, while electrons are transferred through an external circuit to the cathode side of the cell. Since proton conduction of membrane is a function of water content, the membrane chain must be moistened so protons can be transported from the anode to the cathode side through the network of hydrogen bonds. On the cathode side, protons and electrons combine together in a hydrogen evolution reaction (HER) to evolve high-purity hydrogen gas, Fig. 1. A net electrochemical reaction is energy neutral since it does not bring out any new products. As the process does not occur spontaneously, an external power source is required to drive the electrochemical reactions, and the process continues as long as the driving force, i.e. electrical energy supplied to the EHP exceeds the internal energy of the system itself. It has to be emphasized that pure hydrogen can be separated with or without

pressurization. The simplest way to supply hydrogen to the EHP is in dead-end mode to assure long-term operation.

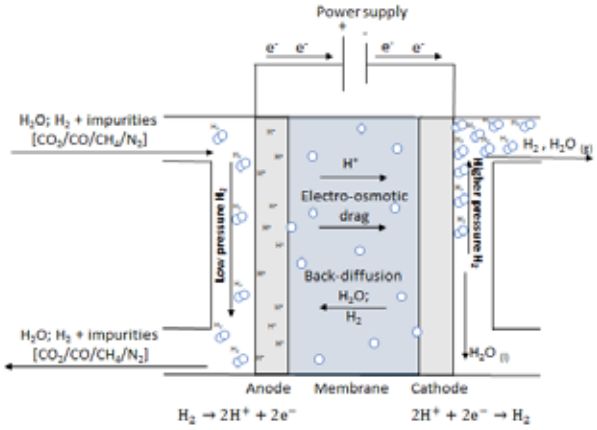

Fig. 1. Schematic representation of electrochemical hydrogen purification

EHP PERFORMANCE DIAGNOSTICS

In general, real-time characterization of the EHP membrane at constant current/voltage is used to better understand the processes within the cell and impact of various operating conditions on the cell performance, while the outlet gas composition in real-time operation is mostly examined by a gas chromatography. Researchers mainly combine different diagnostic methods, primarily polarization (*I-V*) curve measurements to get insight into the EHP overall voltage, and/or electrochemical impedance spectroscopy (EIS) measurements to distinguish and evaluate individual voltage losses. As non-optimal values of various operating parameters (pressure, temperature and humidification) can have deterioration impact on long-term performance decay and potential membrane failure [2], their optimization to obtain effective operation with high hydrogen purity is the main goal of the most studies. In 1980, Sedlak et al. [4] presented the hydrogen compression and purification pioneer study, which theoretically and experimentally observes energy efficiency of hydrogen separation from H_2/N_2 mixture. Their experiments were conducted at room temperature under cell pressure difference of 11.7 bar. With the fact that high-pressured pure H_2 stream abstraction was obtained from a low-pressure feed stream, they proved for the first time that solid polymer electrolyte cell functions as a single-stage purifier/compressor as long as it has proper membrane support structure. Due to its negligible effect on performance, they concluded that CH_4, N_2, and CO_2 simply act as diluents, while hydrogen sulfide (H_2S) is the only hazardous pollutant that must be removed before the gas stream enters the cell. Guided by Sedlak work, Lee et al. [5] based their work on hydrogen separation from $H_2/N_2/CO_2$ mixture via electrochemical method that also uses proton exchange membrane (PEM), while the compression process was left out in their investigation. Polarization curve results were used for characterization of purification process under various temperatures (30-70°C) and feed pressures (1-3 bar). Under the same conditions, they also evaluated N_2 and CO_2 permeation, as a major factor that degrades hydrogen purity, using the time-lag method. However, despite the fact that RWGS is unavoidable in the CO_2 presence, they did not report any information regarding CO. Ibeh et al. [6] conducted hydrogen separation from H_2/CH_4 mixtures at negligible compression difference between anode and cathode of PEM fuel cell, using two different membrane electrode assembly (MEA) setups with different catalyst loadings to investigate methane adsorption and blockage of the active sites. They compared polarization curves at three different temperatures obtained with H_2/CH_4 and H_2/Ar mixtures at the same conditions and proved that methane acts as inert gas without causing any catalyst degradation. Doucet et al. [7] based their study on feasibility of hydrogen separation from H_2/C_2H_4 mixtures also with PEM fuel cell. Their results showed that the bulk of hydrogen reacts with ethylene (C_2H_4) to form ethane (C_2H_6) so the authors suggest the usage of different catalyst materials which have a lower rate of hydrogenation or different selectivity for hydrogen to improve the separation process. Grigoriev et al. [8], thirty years after Sedlak work [4], reported experimental work of hydrogen compression and separation from H_2/N_2 mixture using EHP based on solid polymer electrolyte technology. Because they have conducted their research up to 130 bar, they suggested catalyst impregnation with zirconium particles to obtain larger membrane resistance. Using current-voltage characteristics, they reported a deterioration of compression efficiency as a function of small hydrogen concentration in the mixture which affects the creation of mass transport limitation. Kim et al. [9] in their study used EHP at high operating temperatures (160 °C) to provide improved hydrogen separation from the H_2/CO_2 mixture. Therefore, instead of perfluorosulfonic-acid (Nafion) membrane, they used polybenzimidazole (PBI) membrane. By polarization and EIS measurements, they compared EHP performance of Nafion membrane at different levels of humidification with non-humidified PBI membrane to prove that humidification is not required for PBI, while the catalyst tolerance of PBI membrane on CO is also much higher. Nordio et al. [10] reported an experimental study on hydrogen separation from H_2/CH_4 and H_2/inerts

mixtures. They confirmed Ibeh's finding regarding the fact that methane acts inert and has no impact on catalyst inhibition. Furthermore, using polarization curve and EIS analysis, they confirmed the obtaining of 100% pure hydrogen during EHP operation. Also, they investigated the elevated temperature effect on EHP performance. In their following paper [11], they focused on the negative effect on EHP performances closely related to CO formation responsible for catalyst inhibition in case when the system works with H_2/CO_2 mixtures under the different operating conditions. Authors confirmed that higher voltage and operating temperature have negative impact on catalyst, as well as higher concentration of impurities.

CONCLUDING REMARKS AND PERSPECTIVES

Considering all of these literature findings, there is still a knowledge gap regarding the optimal operating conditions and their unclear impact on EHP efficiency, especially when compression and purification occur simultaneously, as high-pressure environment in combination with purification process can contribute to unavoidable deterioration of catalyst layer and increase of mass transport losses. Therefore, further real-time characterization under various operating conditions definitely should be extended, not only on measuring the output at constant current/voltage and analyzing the polarization curves, but also on more often usage of EIS analysis to effectively distinguish and evaluate individual voltage losses (the ohmic resistance, charge transfer and mass transfer resistances). It could be done through the coupled equivalent circuit model application, novel or at least modified version of some already common model in literature. In order to evaluate the gas permeability of the membrane in EHPs, the linear scanning/sweep voltammetry (LSV), as the established diagnostic method for the measuring the fuel cells hydrogen crossover (back to the anode from the cathode in EHPs) during the fed with nitrogen (at anode in EHPs), is imposed also as a candidate for the testing in further EHP diagnostic studies. Foregoing, it is necessary to improve catalyst microstructure and to maximize catalyst active surface at the same time to obtain higher utilization and consequently higher EHP efficiency. Furthermore, to alleviate the effect of possible CO catalyst contamination, further evaluation of various existing recovery strategies in literature, like alloying of Pt with other transition/noble metals, formation of core-shell structures, modification of catalyst support materials, and “air/O_2 bleeding” to oxidize CO, is needed to improve assessment of catalyst recovery rate.

ABSTRACT

In today's world, the increase in the amount of energy needed with the increase in the human population and the depletion of fossil fuels has pushed researchers to search for alternative fuels. Hydrogen is expected to take an important share among the alternative fuels in the future. However, it has some challenges in terms of its storage and pressurization. In this study, the effect of back diffusion on the performance of a PBI membrane-based electrochemical hydrogen compressor operating at 160 °C. Pressure values are calculated and validated with experimental results; and the change of flux, voltage and cell efficiency with time are presented.

Keywords: Electrochemical hydrogen compressor, modeling, compression, back diffusion polarization curve, reformate gas, PBI membrane

INTRODUCTION

Green energy resources and technologies are crucial since the number of available fossil fuels will be insufficient to meet the energy demands of the growing global population in the coming years. Many studies on green hydrogen production systems have been published in the literature [1]. The produced hydrogen needs to be compressed if hydrogen is to be stored in a pressurized tank. In this regard, the electrochemical hydrogen compressor (ECHC) emerges as a technology that can be used both in hydrogen refueling systems for vehicles and for pressurizing hydrogen in containers [2]. In addition to pressurization, the fact that it can purify hydrogen in the situation of reformate gas feeding makes this technology more advantageous. PBI membrane is known to be used in high-temperature fuel cells due to the high mechanical and thermal resistance it provides [3], therefore the use of PBI membrane in the electrochemical hydrogen compressor also has the benefits of the aforementioned advantages.

There are several studies on the modeling of ECHCs. With a highly efficient PEM-based electrochemical hydrogen compressor, compressing to 54 bar is conceivable, and with an upgraded sealing structure and cell design, this value can be increased to above 100 bar [4]. Chouhan et al. [2] showed that with a Nafion 115 membrane type-based ECHC operating at room temperature, the values exceeding 150 bar may be obtained at a low operating voltage of 0.1 V. Back diffusion, which is one of the most critical factors determining ECHC performance, was also highlighted in their study, and its impact on performance was investigated. Because working at lower voltages reduces the relevant compression ratio, the value of back diffusion decreases, resulting in better ECHC efficiency. Rohland et al. [5] achieved compression up to 43 bar in a low-temperature ECHC having Nafion 117 as the membrane.

The aim of this study is to observe the pressure change with time for a given temperature and cell voltage, and to examine the change of voltage, flux and cell efficiency with time considering the effect of back diffusion.

EXPERIMENTAL SETUP

All pressurization experiments were carried out with a single cell of 100 cm^2 active area at 160 °C and hydrogen with a high purity (99.999% purity) was fed to cell. Firstly, current and voltage data were recorded at pressure values between 0-38 bar. For each pressure value, the experiments were repeated three times. In the second part of the experiment, the voltage fed to the cell was kept constant and the pressure and current values were recorded against time. The maximum pressure values that can be reached at 0.1 V, 0.2 V, 0.4 V, 0.6 V, 0.8 V and 1 V constant voltage were recorded as 10 bar, 14 bar, 22 bar, 30 bar, 36 bar and 38 bar, respectively.

MATHEMATICAL MODELING COMPRESSION OF ECHC

To calculate the net molar flow rate of hydrogen, the forward molar flow rate, which expresses the amount of hydrogen

passing from the anode part to the cathode part, must be calculated. This value is calculated using Faraday's law as shown in the Eq. (1) [2].

$$\dot{n}_f = \frac{I(t)}{z \cdot F} \tag{1}$$

where $\dot{n}_f$ is the hydrogen generated with unit of mol/s, I is the current in unit of Amperes, F is Faraday's constant and it is equal to 96485 C/mol, .

Eq. (2), a combination of Fick's and Henry's laws, is used to calculate the backward flux. As can be seen in Eq. (2), while back diffusion is directly proportional to the cell active area, pressure difference and the permeability coefficient of the membrane, it is inversely proportional to the membrane thickness.

$$\dot{n}_b = \frac{D_H \cdot A \cdot (P_c(t) - P_a)}{d} \tag{2}$$

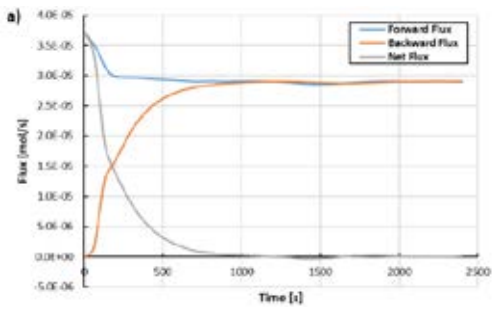
where $\dot{n}_b$ is the backward hydrogen flux in unit of mol/s, D_H is the permeability constant, P_c *and* P_a are the pressure of cathode and anode, respectively, *A* is the active area, and *d is* the thickness of the membrane.

As shown in Eq. (3), the net molar flow rate of hydrogen is obtained by subtracting the backward flux from the forward flux. Using the ideal gas law, the expression for the pressure change over time is obtained as shown in Eq. (4).

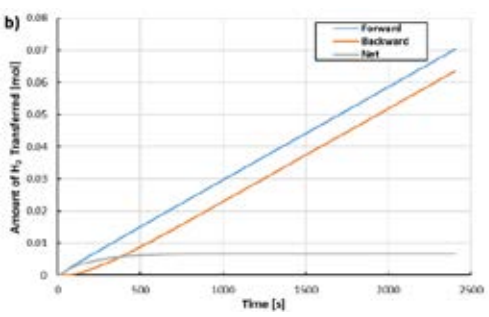
$$\dot{n}_n = \dot{n}_f - \dot{n}_b = \frac{I(t)}{2 \cdot F} - \frac{D_H \cdot A \cdot (P_c(t) - P_a)}{d} \tag{3}$$

$$P_c(t+1) = \left(\frac{R \cdot T \cdot I(t)}{2 \cdot F \cdot V_c} - \frac{R \cdot T}{V_c} \cdot \frac{D_H \cdot A}{d} \cdot P_c(t) + \frac{R \cdot T}{V_c} \cdot \frac{D_H \cdot A}{d} \cdot P_a \right) \cdot \Delta t + P_c(t) \tag{4}$$

where R is the universal gas constant (8.3144 J/mol·K), T is the operating temperature (K), V_c is the cathode volume (m^3), $\cdot \Delta t$ is the time difference (s). Two essential performance assessment factors for ECHC are voltage Eq. (5), flux Eq. (6) and cell Eq. (7) efficiency [2].



$$\eta_{voltage} = \frac{E_{Nersnt}}{E_{cell}} = \frac{\frac{RT}{zF} \ln\left(\frac{P_c}{P_a}\right)}{E_{cell}} \tag{5}$$



$$\eta_{flux} = \frac{\dot{n}_n}{\dot{n}_f} = \frac{\dot{n}_f - \dot{n}_b}{\dot{n}_f} \tag{6}$$

$$\eta_{ECHC,cell} = \eta_{voltage} \cdot \eta_{flux} \tag{7}$$

RESULTS AND DISCUSSION

The forward and backward flux, the amount of accumulated hydrogen, the pressure value reached and finally the time-dependent flux, voltage and cell efficiency with a constant cell voltage of 0.1 are shown in Fig. 1. The pressure value reached in the modeling is 11.26x10^5 Pa (absolute pressure), and the obtained values have been validated with experimental results. It is thought that the minor differences between the test and modeling results are due to the voltage losses experienced in the cables during the experiment. It is found that when the voltage increased, the membrane's gas permeability constant increased as well. This situation was evaluated for 6 different cell voltages.

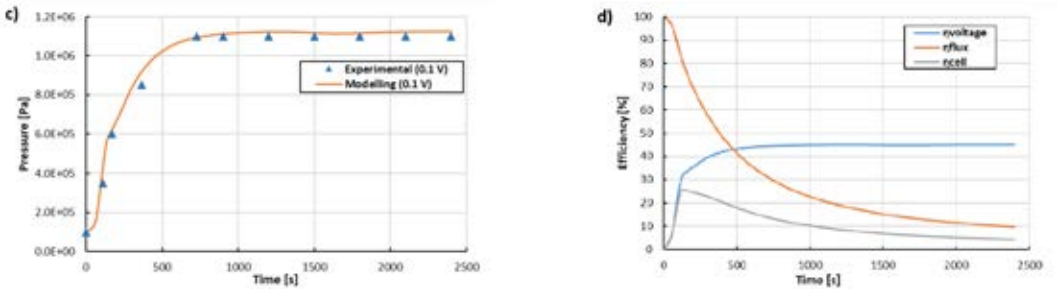


Fig. 1. a) Forward and backward flux in mol/s, b) amount of H_2 transferred in mol, c) time dependent pressure curve, d) current, voltage and cell efficiency at 0.1 V.

CONCLUSIONS

The pressure value and the membrane gas permeability coefficient increased with the increase of the cell voltage. At constant 1 V cell voltage, the highest value of 38 bar pressure has been reached. In a future study, a current-voltage curve will be created by developing a mathematical model of electrochemical hydrogen compressor with the obtained values.

ABSTRACT

Nowadays, the application of the principles of Process Intensification Strategy is gradually leading to a revolution of the conventional H_2 energy production processes and, among a number of alternative technologies, membrane engineering is playing a crucial role in the substitution of traditional devices used in the process engineering with membrane-based units. According to the requests of the Circular Economy and in the framework of the so-called H_2 Economy, H_2 generation coming from derived of biomass as renewable sources may play an interesting role as a valid option to the fossil fuels exploitation. In this work, the production of blue H_2 via reforming reactions of a synthetic biogas mixture was performed in a Pd-Ag membrane reformer packed with a novel Ni-Ru/La-Y-ZrO_x catalyst at 673 K and between 150 and 250 kPa of reaction pressure. As best result, 99% of CH_4 conversion was reached at 673 K, 250 kPa and S/C = 2/1, recovering 40% of H_2 with a purity > 99.9999%, meanwhile collecting a CO_2 reach stream in the unpermeated stream, to be further captured.

Keywords: Hydrogen, Biogas steam reforming, Membrane reactor technology, Pd-based membranes

INTRODUCTION

In light of the growing interest toward the so-called H_2 Economy [1], the production of H_2 – generally seen as the energy carrier of the future – from renewable sources may represent a viable option to the fossil fuels dependence, meanwhile contributing to allowing the process decarbonisation in various areas [2]. In the last decades, H_2 production and purification technologies are attracting considerable interest and, among them, membrane reformers (MRs) technology received a growing attention, because able to combine the exploitation of renewable sources with the simultaneous production and purification of H_2 via reforming reactions [3]. In a MR, the presence of a H_2 perm-selective membrane allows its selective removal from the reaction toward the permeate side, involving the so-called “shift-effect” on the reaction system, responsible for higher reaction products formation and further feed product conversion than an equivalent conventional reformer (CR) (for thermodynamically equilibrium limited reactions). To date, most of the production of H_2 at larger scale comes from natural gas steam reforming reaction, which involves the exploitation of fossil fuels and the consequent formation of greenhouse gases. On the other hand, biogas as a renewable source could represent an alternative to natural gas utilization in reforming processes for H_2 generation. The composition of biogas may vary largely, depending on the nature of the residual biomass (sewage treatment plants, animal waste etc.) used during the anaerobic digestion process, even though it is mostly constituted of CH_4 and CO_2, besides N_2, H_2, volatile organic compounds, H_2S etc. The combination of biogas fuel processing with MRs technology was not largely studied in literature, particularly because of the presence of H_2S as main responsible for the membrane and catalyst poisoning and consequent performance loss. However, in the last years a growing attention toward the development of high-performance reforming catalysts (showing high catalytic activity, high carbon deposition resistance etc.) was noticed. Metal catalysts such as Rh, Pd or Ru, Pt and Ni show a high activity and selectivity for H_2 generation via steam reforming of biogas (SRB) [4]. Most of the scientific literature about SRB reaction in CRs is based on Ni catalysts utilization because cheaper solution than Pt, Rh or Pd adoption. However, Ni is susceptible to a strong deactivation caused by coke formation as a consequence of the conventional high temperature operations, whereas Pt and Pd catalysts result to be more catalytically stable and Rh presents a greater catalytic activity than Ni associated to a lower coke formation tendency [5].

On the other hand, only a few studies deal with the utilization of Pd-based MRs to carry out SRB reaction. The aim of this experimental work is to perform the steam reforming of a synthetic biogas mixture containing in a self-supported Pd-Ag MR, packed with a novel, not commercial Ni-Ru based catalyst, in order to produce blue H_2 and avoid that CO_x may be released in the ambient. In particular, the catalytic performance in terms of methane conversion, and H_2 recovery, yield and purity, are analysed in the Pd-Ag MR and compared to an equivalent CR.

EXPERIMENTAL

The bench-scale membrane reformer is constituted of a stainless-steel module, housing a self-supported Pd-Ag membrane tube (Johnson Matthey, UK), with an active length equal to 10 cm and outer diameter of 10 mm, Fig. 1. 3 g of Ni-Ru/La-Y-ZrO_x catalyst are packed in the membrane lumen. The feed stream is supplied directly inside the membrane core; on the other hand, the generated H_2 permeating through the membrane is recovered in the "permeate" stream, supplying N_2 as a sweep-gas, while the unpermeated products are collected in the "retentate" stream.

Fig. 1. Unsupported Pd-Ag membrane provided by Johnson Matthey (London, UK).

The experimental campaign consisted of single gas (H_2, N_2, CO_2, CH_4) permeation tests to evaluate the perm-selectivity characteristics of the membrane by varying the temperature between 573 and 673 K, and the pressure between 150 and 250 kPa (abs.). Afterwards, the SRB reaction was carried out in the MRs at 673 K. The composition of the synthetic biogas feed stream was CH_4:CO_2:N_2 = 60:35:5, whereas the S/C feed molar ratio ranged between 1.5:1 and 2:1, and the weight hourly space velocity (WHSV) from 0.2 to 0.6 h^{-1}. All the outlet streams were analysed by a temperature programmed HP 6890 gas-chromatograph (GC). Both gas permeation and catalytic performances were evaluated in terms of H_2 permeating flux and ideal perm-selectivity, CH_4 conversion, H_2 yield and recovery, and H_2 permeate purity.

RESULTS AND DISCUSSION

Before the reaction measurements, the permeation characteristics of the fresh self-supported Pd-Ag membrane were investigated between 573 and 673 K, varying the transmembrane pressure between 0 and 250 kPa, Fig. 2.

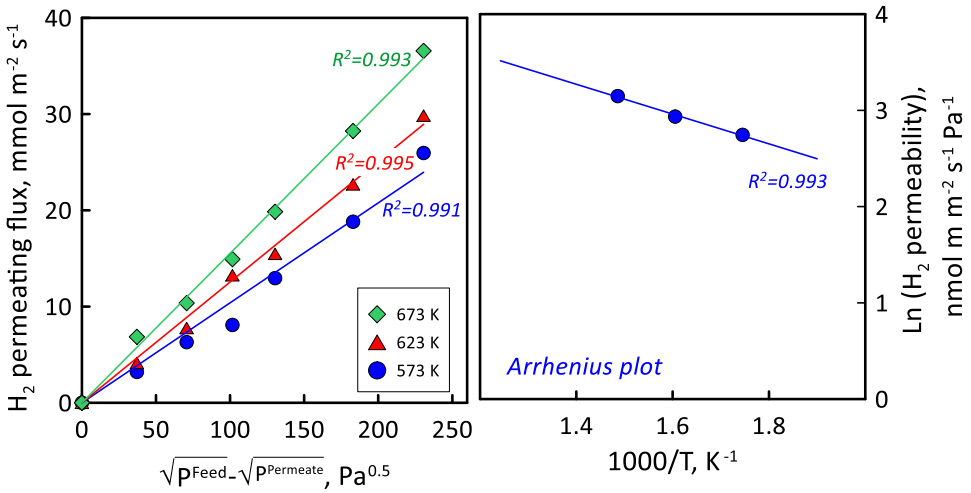

Fig. 2. Flux of hydrogen permeating through the Pd-Ag membrane as a function of transmembrane pressure at different operating temperatures; in the smaller plot: hydrogen permeability vs 1/T at 50 kPa of transmembrane pressure.

Single gas permeation measurements demonstrated that, apart from H_2, the other gases may not pass through Pd-Ag membrane, confirming that the former is fully H_2 perm-selective. This evidenced that the H_2 permeation depends on the diffusion through the Pd-Ag membrane bulk, and the Sieverts-Fick mechanism regulates the H_2 permeating flux.

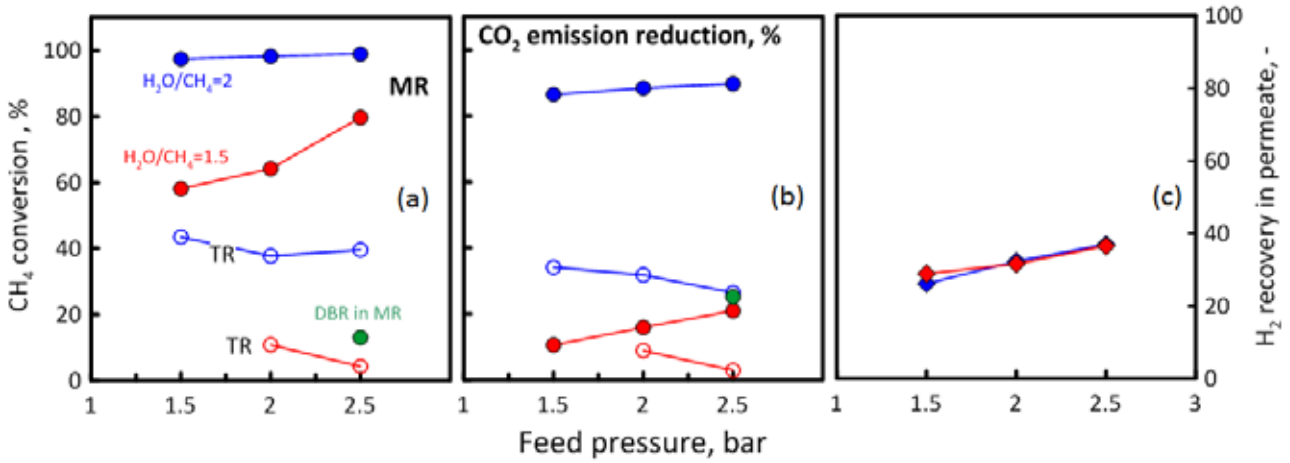

Fig. 3. SRB reaction at 673 K and as a function of feed pressure and different H_2O/CH_4 feed molar ratio: (a) CH_4 conversion in MR and CR; (b) CO_2 emission reduction in MR and CR; (c) H_2 recovery in the MR.

Fig. 3(a) points out how an increase of pressure acts differently in the traditional and membrane reformers. Increasing the feed pressure in the membrane reformer, CH_4 conversion was progressively enhanced, demonstrating that the shift effect overcame the thermodynamic one due to the removal of H_2 for permeation through the membrane. This allowed better performance in the MR with respect to the CR. In this regard, under defect of steam, methane conversion was improved from 60 to ~ 80%, whereas at stoichiometric feed molar ratio from 97 to 99%. In the meanwhile, 40% of high grade H_2 was recovered over the total produced, with a maximum CO_2 reduction equal to 85%.

CONCLUSIONS

In this study, a Pd-Ag MR was packed with a novel Ni-Ru based catalyst in order to perform the SRB reaction for blue H_2 generation. The best performance was reached at 673K, WHSV = 0.2 h^{-1} and 2.5 bar with a CH_4 conversion of 99% and 40% of CO_x-free H_2 recovery with a H_2 purity > 99.9999%, meanwhile reducing the CO_2 emission around 85%.

ABSTRACT

This paper investigates in the modeling and simulation under LabVIEW Software of stand-alone photovoltaic/wind power system using hybrid storage hydrogen and lead-acid battery. The proposed graphical programming environment has proven to be a versatile platform for the design, sizing, data acquisition, analysis and parameter identification of each compound of these systems, including PV generator, wind generator, storage systems, power converter, electrolyzer, fuel cell, gas compressor and tank for pressurized hydrogen storage. Combining solar and wind energy is a very important issue, but it depends on geographical position. The proposed system can be very useful for Engineers and experts who require a simple, fast, and accurate PV/ wind storage simulator to design their systems.

Keywords: PV/WIND-H_2-Battery System, Hybrid Storage, Hydrogen, Fuel Cell, Lead-Acid Battery.

INTRODUCTION

Along with the crisis of the exhaustion of the traditional energy resources, and with environmental damage caused by increased carbon dioxide emissions, the use of renewable energy has become the goal for energy development. Hybrid energy system (HES) describes a stand-alone energy system, which combines renewable and conventional energy sources with lead-acid batteries for chemical storage [1] and hydrogen storage which will be converted to electrical energy via fuel cells (FCs). This type of energy storage offers significant advantages over conventional batteries in terms of energy density and long-term storage. The conversion of hydrogen allows the storage of a large amount of power as well as its transport.[2].

This work presents the modeling and simulation of a hybrid photovoltaic/ wind power system with hybrid storage H_2-Battery by using the LabVIEW software which is ordinarily taken as a tool of virtual instrumentation and automation, it can also be used in the fields of simulation because it has provided a unique way of modeling and simulating with a high-level graphic programming language and can be executed much faster than in other languages [3].

A typical hybrid energy generation system is considered and shown in Fig.1, which the wind and the PV generators are connected to the load via converters (The AC/DC converter for wind generator and the DC/DC converter for PV generator). The Power will be generated by wind generator and PV system to feed load demand and the excess power will be eventually stored in both battery and H_2 tank.

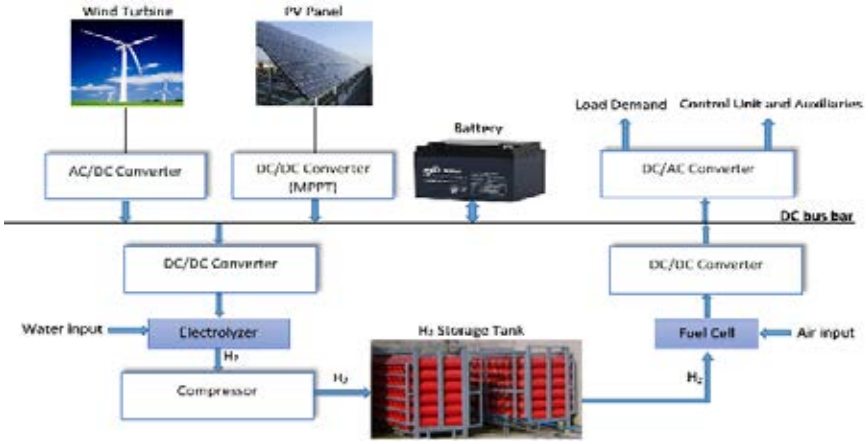

Fig. 1. Configuration of the stand-alone PV-Wind System with hybrid storage under study.

HYBRID SYSTEM MODELING USING LABVIEW SOFTWARE

The used model in photovoltaic system is one-diode model, the relationship between current and voltage [4],the power output of wind turbine P_t(W) [5], the charging V_c(V) of the battery (Lead-acid battery type Tudor STTH-180),the normalized inverter input power $P_{in,inv}$(W) [6], the output voltage of a single cell V_{FC}(V) [7], the compressor power P_c and the basic equations (Van der Waals law) that describes the pressure inside the storage tanks P_{ht} are as follows [8]:

$$I = I_L - I_D = I_L - I_0\left(\exp\left(\frac{q(V+R_S I)}{\gamma k T_C}\right)-1\right) \quad (1)$$

$$P_t = \frac{1}{2}\rho\pi R^2 C_P(\lambda,\beta)V_V^3 \quad (2)$$

$$V_c = (2+0{,}160SOC_{bt}(1-DOD)) - \frac{I_b}{C_{10}}\left(\frac{6}{1+I_b^{0.6}} + \frac{0{,}480}{(1-SOC_{bt})^{1.2}} + 0{,}036\right)(1-0{,}025\Delta T) \quad (3)$$

$$P_{in,inv} = \frac{P_{in}}{P_{nom}} \quad (4)$$

$$V_{FC} = E_{Nernst} - V_{act} - V_{ohm} - V_{conc} \quad (5)$$

$$P_C = C_P T_{cp,in}\left(\left(\frac{P_{cp,out}}{P_{cp,in}}\right)^{\frac{\gamma-1}{\gamma}} - 1\right) / \left(\frac{U_c^2}{2}\right) \quad (6)$$

$$P_{ht} = \frac{nRT_{ht}}{V_{ht} - (n.b)} - a\frac{n^2}{V_{ht}^2} \quad (7)$$

RESULTS AND DISCUSSION

The modeling and simulation of the stand-alone Photovoltaic/Wind system with hybrid storage H_2-Battery and the different from panel control under LabVIEW is presented in Fig.2 (the Simulate Button will show a simulation of the system, Next and Previous button to Navigate through the front panel). The instantaneous values of system variables are dynamically changing according to input variables (solar radiation, wind speeds and temperature). The detailed power production of each source, the state of charge (SOC) level of the accumulator and storage tank are also illustrated.

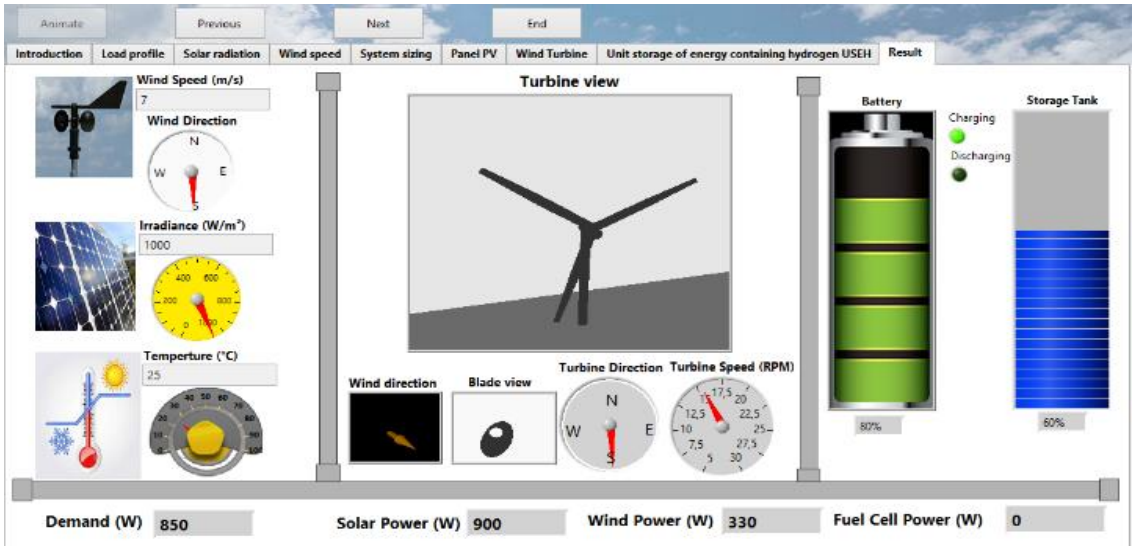

Fig. 2. LabVIEW Platform of Hybrid photovoltaic/wind system with hybrid storage (H_2-Battery)

As regards, Fig.3 shows the simulation result of our system where Fig.3.a, Fig.3.b, Fig.3.c, Fig.3.d, Fig.3.e, Fig.3.f, Fig.3.g and Fig.3.f are respectively: P(V) and I(V) curves for modules Shell SP75, wind turbine Power-Wind speed

curve of WFD500W, voltage versus time in charge and discharge at I_{10}=18 A and 25°C, efficiency η_{inv} vs normalized input power $P_{in,\ inv}$, ballard PEMFC cell voltage and power curves, electrolyzer cell voltage at 70°C , compressor output power as a function of the hydrogen flowrate for two pressure ratios and tank pressure versus stored hydrogen for various total tank volumes

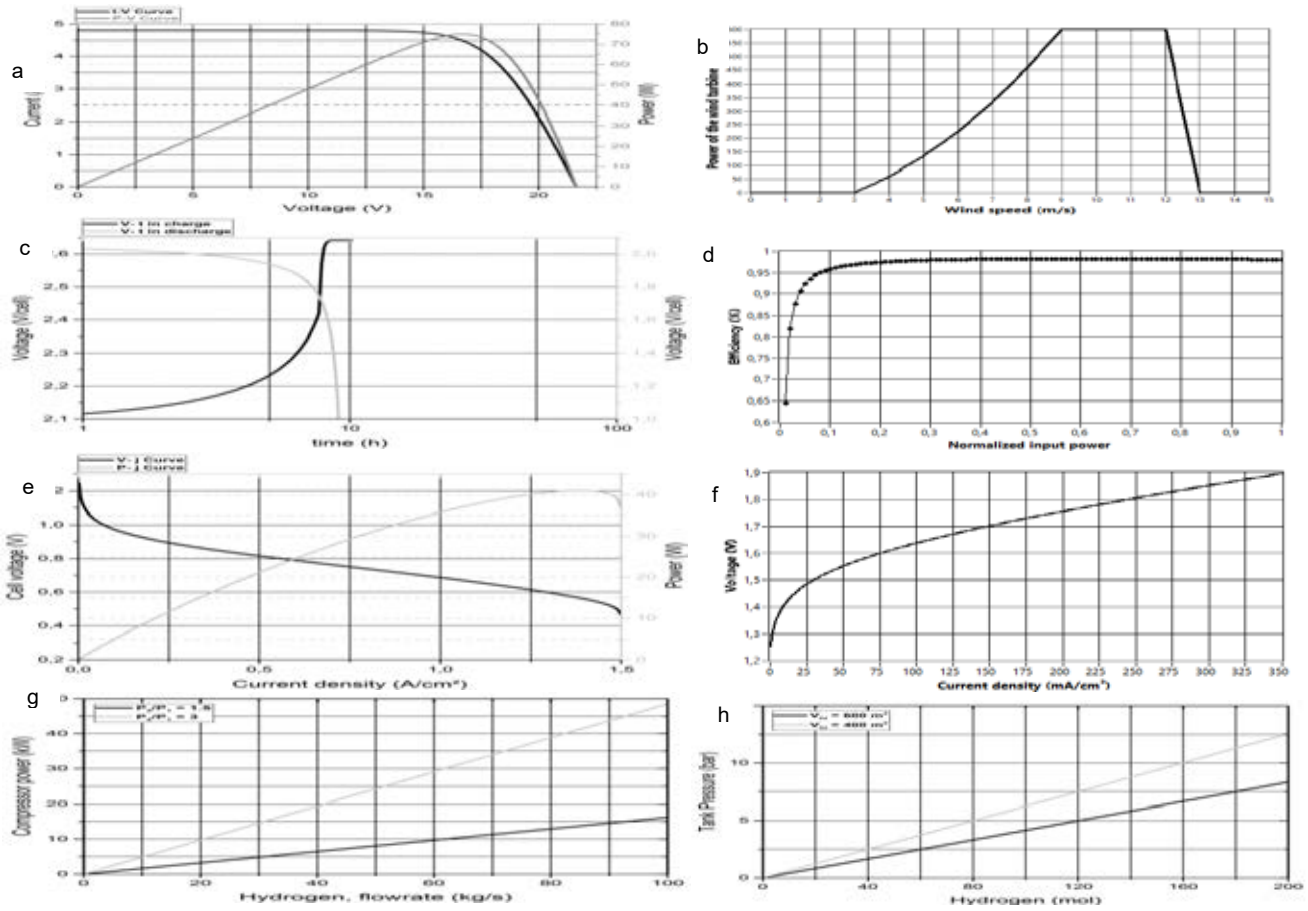

Fig. 3. Simulation result of the stand-alone Photovoltaic/Wind system with hybrid storage H_2-Battery under LabVIEW

CONCLUSIONS

This paper describes the developed platform to study the behavior of photovoltaic/wind power system with hybrid H_2-Battery storage, by using LabVIEW software. This platform permits simulation, parameters identification of different compounds of the system. Using LabVIEW is very suitable for the graphical modeling. It can help us to understand the functioning of all parts of the studied system. This platform can be easily connected with Compact Rio hardware for the date acquisition and analysis of the signals issues from the operating system.

TECHNO-ECONOMIC REQUIREMENTS FOR UNDERGROUND RENEWABLE HYDROGEN STORAGE IN POROUS MEDIA

*Jan Michalski**
Ludwig-Bölkow-Systemtechnik GmbH (LBST), Daimlerstr. 15, 85521 Ottobrunn, Germany

*Corresponding author e-mail: jan.michalski@lbst.de

ABSTRACT

This paper provides first results from the FCH JU funded HyStorIES project (**Hy**drogen **Stor**age **I**n **E**uropean **S**ubsurface) addressing the main technical feasibility questions and assessing the techno-economical potential of underground large-scale storage of renewable hydrogen in porous media by 2050. Within the project Work Package 5 (WP5) conducts an in-depth techno-economic assessment of the future scenarios for a widespread deployment of underground renewable hydrogen storage in the EU across the period 2025-2050. In this context, it models and analyses optimal design and operation of different elements of the future energy system including renewable electricity supply, production of renewable hydrogen, associated gas compression and hydrogen pipeline networks to transfer hydrogen to/from the underground storage. The preliminary analysis of expected techno-economic requirements for underground renewable hydrogen storage reveals significant energy storage needs across Europe between 40 to 700 TWh_{H2} in the long-term. In particular, the six big economies with the largest energy demand in Europe including Germany, France, Italy, the UK, Spain and Poland would account for 75% of the overall storage capacities in Europe. Based on the long-term assumption of climate neutrality in Europe the underground renewable hydrogen storage would be operated on a seasonal basis with 1-9 full cycle equivalents regardless of hydrogen demand and storage capacity in all countries.

Keywords: Underground H_2 Storage, Aquifers, Storage Needs, Energy System Modelling

INTRODUCTION

Hydrogen technologies could be one of the pillars of future European energy and transport systems, making a valued contribution to the European Union (EU) transformation to a low carbon economy by 2050. Renewable hydrogen, when combined with large scale underground storage in aquifers, depleted fields (porous media) or salt caverns, enables transportation of energy through time balancing out the impacts of variable energy production from renewable energy sources. While storing pure hydrogen in salt caverns has been practiced since the ‘70s in Europe, hydrogen storage has not yet been carried out anywhere in depleted fields or aquifers. Although many aspects will be similar to the existing industry of natural gas underground storage, technical developments are still needed to validate this solution, particularly in terms of bio- and geo-chemical impacts of storage on the subsurface and in terms of the quality of hydrogen subsequently extracted from the store. This paper presents first results from WP5 of the ongoing HyStorIES project in respect to expected underground H_2 storage needs in future European energy system based on a detailed modelling exercise of the European energy system.

MATERIALS AND METHODS

The modelling of the European energy system in WP5 is based on a simulation platform developed by LBST to perform detailed techno-economic system analyses with a flexible technology focus and geographical scope at various scales. The LENS model (**L**BST **EN**ergy **S**ystem model) optimizes the size and operation of different elements of a predefined system in a given location and for a given time frame. It is formulated as linear programming (LP) problem for the purposes of this study with the objective to minimize the overall system costs subject to a number of techno-economic constraints in each of the modelling steps. The initial model formulation is related to the analyses on the role of energy storage from the microeconomic perspective and can be traced back to the work provided in [1]. More recent studies employed an extended model version with a larger scope but in smaller technological detail in order to analyze whole supply infrastructures, e.g., for hydrogen refueling stations [2], or integrated energy system at national [3] and pan-European level [4].

The analysis is mainly based on data from the study provided in [4]. In cases with low H_2 demand level almost 90% of the concerned final energy consumption is based on electricity (ca. 4,500 TWh/a) whereas hydrogen has a small share of only 10% (ca. 550 TWh/a). In cases with high H_2 demand level power demand is still significant (ca. 65% or 3,800 TWh/a), but hydrogen-based end-user applications play a much larger role (ca. 35% or more than 2,000 TWh/a). The

overall potential for renewable electricity generation in EU-27 and the UK of ca. 11,000 TWh/a is much larger than the expected power and hydrogen demand.

The major factors influencing the storage needs taken into account in this study are (see Fig. 1):

- general H_2 demand levels in end-user sectors including transport, heating and industry (low in Cases 1, 3, 5 and 7 and high in Cass 2, 4, 6 and 8),
- demand in the power sector from H_2 re-electrification in dedicated gas turbines and fuel cells (Cases 5-8) and
- supply pathways, i.e. variable H_2 production from domestic intermittent sources (Cases 1, 2, 5 and 6) vs. constant supply from conventional H_2 production or imports (Cases 3, 4, 7 and 8).

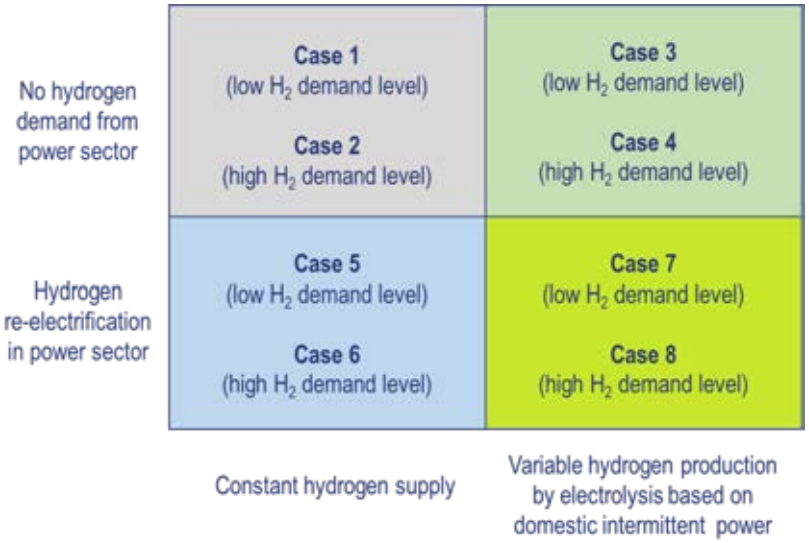

Fig. 1. Cases for analysis in respect to major impact criteria

RESULTS AND DISCUSSION

Generally, the larger the energy demand in a country the greater both the storage capacity and the range between the analysed cases (Fig. 2). In this context, the “big six” (i.e. Germany, France, Italy, the UK, Spain and Poland) account for ca. 75% of the overall required storage capacities in Europe. All other countries have a required storage capacity of less than 25 TWh_{H2} each in all cases. As expected, the largest requirements occur in Case 8 including the power sector and high variable hydrogen supply whereas the lowest required capacities can be observed in Case 1 with low constant H_2 supply and without need for H_2 re-electrification in the power sector. The largest capacity-to-input ratio occurs for Case 1 (constant H_2 supply and lower H_2 demand) with more than 4,100 h (170 days) for most countries. This means that in this case the input capacity is very small and it would take at least 4,100 h to fully fill the storage at constant input capacity. The lowest ratio ranges between 170-670 h and strongly depends on the relationship between hydrogen production profiles and thus renewable feed-in and electricity consumption patterns (or power residual load). In respect to required capacity-to-output ratio the spread between the highest and lowest case and the differences between the countries are much smaller than for storage input. Typically, output capacity correlates directly with hydrogen demand. Hence, the lowest capacities and highest capacity-to-input ratio of more than 1,200-1,600 h occur in Case 1 or Case 2 without the power sector for most countries whereas the highest capacities and lowest ratio can be observed for cases with explicit hydrogen re-electrification needs in the power sector in Case 5 to 8 (140-730 h).

The storage is operated on a seasonal basis in a similar way in all cases and in all countries. The highest number of full cycle equivalents can be observed in cases with high hydrogen demand and variable supply (Cases 5 to 8) of up to 8.5 cycles (or 43 days). In contrast, in Cases 1 to 4 the underground storage operation is characterized by ca. one cycle per year regardless of hydrogen demand and storage capacity. This means that low hydrogen demand excluding the power sector and constant hydrogen supply reduce the fluctuation of storage filling level significantly. The corresponding European electrolysis capacity for variable hydrogen production ranges between ca. 200-2,220 GW_{el}.

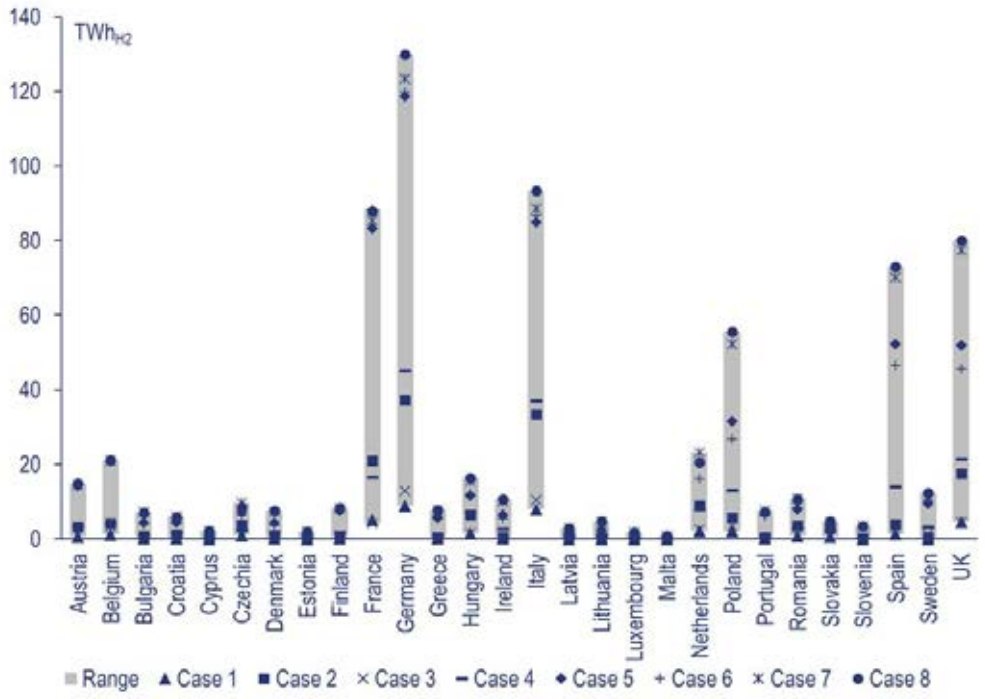

Fig. 2. Required capacity for underground hydrogen storage in selected cases.

CONCLUSIONS

The results of our analysis underline the need for large-scale underground hydrogen storage in the context of climate neutrality across Europe. According to study outcomes in Cases 5, 6, 7 and 8 ca. 1,600-2,200 TWh_{H2}/a need to be stored in European underground facilities corresponding to ca. 34%-60% of the overall annual hydrogen demand (including re-electrification in the power sector) in Europe. Since salt caverns are limited to selected countries in Europe due geological conditions aquifers and depleted gas fields might be an attractive alternative for such underground hydrogen storage. However, further analyses in the HyStorIES project will be conducted to better understand the role of hydrogen storage in porous media by taking additional constraints such as gird constraints and technology developments int account.

ABSTRACT

Hydrogen stored in liquid organic hydrogen carriers (LOHCs) like dibenzyltoluene makes it a simple and safe technology along with long term storage. In this study, a preliminary study regarding the dehydrogenation of perhydro-dibenzyltoluene with switching from a stirred batch reactor to a continuous flow microchannel reactor is presented. The performance of the reactors was investigated with a 2% Pt/Al_2O_3 catalyst. The hydrogen production percentage in the case of a continuous flow microchannel reactor was found higher (58% hydrogen production) when compared to that of a stirrer type reactor (only 12% hydrogen production) in 12 hours of operation. Moreover, the effect of microchannel bottom plate temperature on the hydrogen production was also investigated. The hydrogen production was increased from 64.15% to 82.20% with the increase in bottom plate temperature from 260 to 320°C for 0.01 mL/min flow rate of H18-DBT and 20 hours experiment. With the increase in the operating time, the hydrogen production found to increase slowly. A maximum of 88% of hydrogen was generated for a 40 hours' operation, at a bottom wall temperature of 290°C. The results revealed that a continuous microchannel reactor can be an appropriate technology for the dehydrogenation of H18-DBT.

Keywords: Dehydrogenation, Liquid Organic Hydrogen Carrier, Microchannel Reactor, Dibenzyltoluene

INTRODUCTION

Sustainable techniques for power generation and renewable energy sources will play a vital role in maintaining a healthy climate for future generations. In particular, hydrogen is attracting attention as an efficient energy source that can be produced and stored without the emission of greenhouse gases. The uses of hydrogen as a fuel are well known and hydrogen has applications as fuel in the transport sector. For use as a fuel, LOHCs store and release hydrogen through controlled hydrogenation and dehydrogenation processes. LOHCs are efficient choice for long term energy storage without any loss, safe transport, hydrogen production and generation of electric power via fuel cells in applications such as automobiles. Considered herein, dibenzyltoluene (DBT) belongs to the family of cycloalkanes and is widely used as an industrial heat transfer oil. DBT was first proposed as an LOHC in 2014 by Brucker et al [1]. Dehydrogenation of LOHCs in liquid form is typically studied in batch type reactors. However, continuous flow reactors have many advantages over batch reactors. Batch reactors has inefficient heat mass transfer and slow temperature control. The continuous flow reactors allow instantaneous heating and cooling along with very fast mixing. Continuous flow microchannel reactors (MCHRs) are primarily closely packed reactors with channel dimensions in the range of millimeters (Hydraulic diameter (D_h) < 1mm). They have high surface to volume ratios, uniform heat transfer catalyst zones and compact sizes.

However, there is no study to use microchannel reactor for LOHC (in liquid form) dehydrogenation based on the literature review. The novelty of this work lies in the implementation of a MCHRs for the dehydrogenation of perhydro-dibenzyltoluene instead of the existing studies using a stirrer type reactor. The aim of the study was to introduce the microreactor to investigate the dehydrogenation of H18-DBT (liquid form). To do that, we consider two different reactor types for the dehydrogenation of H18-DBT: a batch reactor and a continuous flow MCHR. The performances of both reactors are evaluated for hydrogen generation from H18-DBT with a 2 wt.% Pt/Al_2O_3 catalyst.

EXPERIMENTAL APPARATUS

The batch reactor (HR-8300, 10 bar operating pressure, attached mechanical stirrer) was the same as that in [2]. The continuous flow reactor was a microchannel reactor. Both a schematic of the experimental apparatus with the microchannel reactor for the dehydrogenation study and a photograph of the experimental setup are provided in Fig. 1.

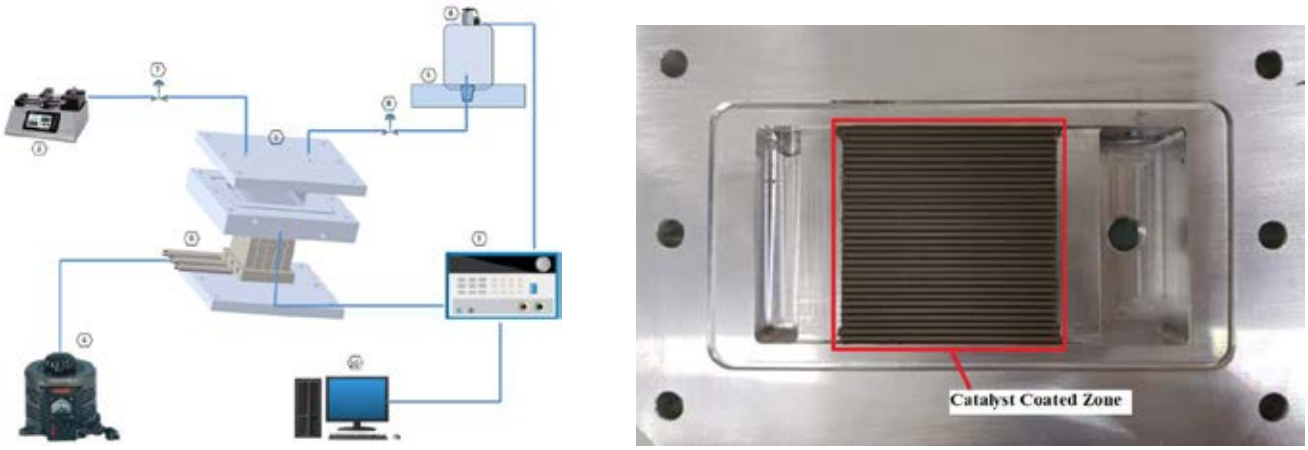

Fig. 1. Schematic of the experimental apparatus. 1 – Microchannel reactor; 2 – Syringe pump; 3 – Data logger; 4 – Power supply; 5 – Water bottle; 6 – Ultrasonic level transmitter; 7 – Check valve; 8 – Drain valve; 9 – Cartridge heaters; 10 – Computer, Photograph of the catalyst coated microchannel substrate

The experimental facility consisted of a microchannel reactor, thermocouples (TCs), valve, syringe pump, pressure transducers (PTs), data acquisition system, power supply, cartridge heaters, and a water displacement apparatus for measuring the generated hydrogen. A MCHR was designed and fabricated to carry out the dehydrogenation experiments. The material used for the MCHR was aluminum. Parallel microchannels (depth 900 μm, width 400 μm, length 50 mm) were fabricated on the aluminum plate by an electrode discharge machining process. The 2% Pt/Al_2O_3 catalyst was coated on the microchannel walls using the wash coating method [3].

RESULT AND DISCUSSION

The dehydrogenation of H18-DBT was carried out in the microchannel reactor within a temperature range of 260 to 320°C as reported previously [4]. The hydrogen production as a function of reaction zone temperature is shown in Fig. 2. The hydrogen production increased from 64.15% at 260°C to 82.20% at 320°C.

To prove the repeatability of the dehydrogenation experiments in the microchannel reactor another trial was conducted with a reaction zone temperature of 290°C. A duration of 40 h was chosen for the experiment to understand the effect of dehydrogenation reaction duration on the hydrogen production in the microchannel reactor. The supply of DBT in microchannel was stopped after a period of 20 h and the remaining DBT adsorbed to the walls of the microchannels channel reacted to produce hydrogen. The hydrogen production for the two runs match closely during the initial 20 h. Increasing the duration of the reaction to 40 h increased the hydrogen production from 78 to 88%.

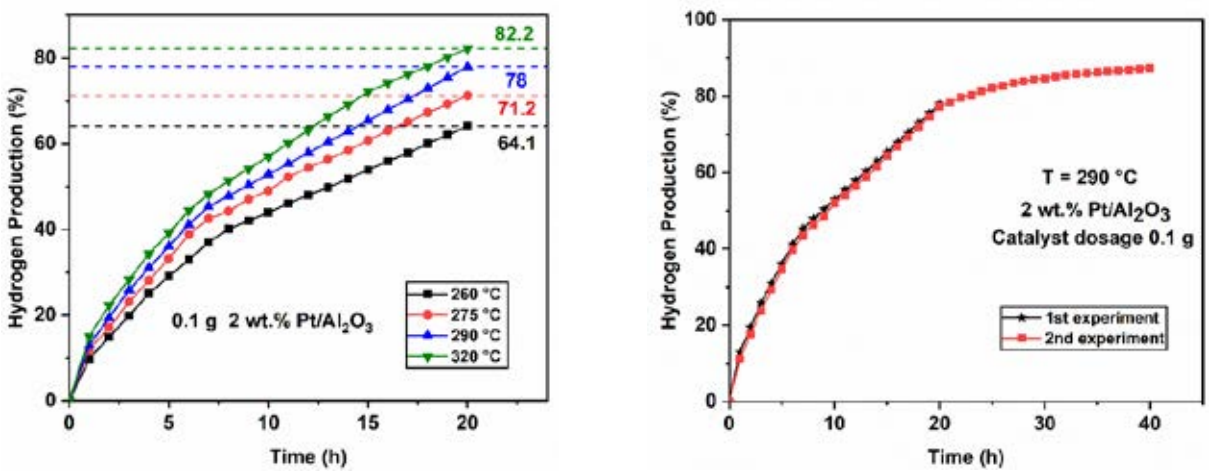

Fig. 2. Hydrogen production% from H18-DBT at different temperatures and Dehydrogenation of H18-DBT in the microchannel reactor with 20 h and 40 h of duration

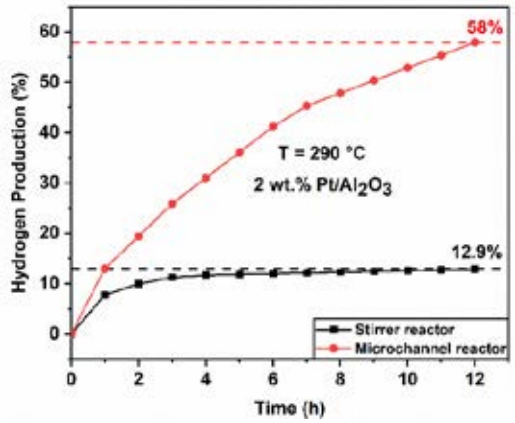

Fig. 3. Comparison of stirrer and microchannel reactor

The continuous flow microchannel reactor was introduced as an alternative to the batch type reactors. However, an exact comparison between the two reactors is not possible, as in a batch type reactor, the reactants are all added before the reaction begins and the products are discharged after reaction is completed, whereas the reactants and the products are added and discharged throughout the reaction process in flow reactors.

A comparison of the hydrogen production in the two reactors is shown in Fig. 3. For microchannel reactor, only part of the catalyst mass coated on the channel wall will actively participate in the dehydrogenation reaction. To account for this, the amount of catalyst was doubled in the case of microchannel reactor (estimated mass of 0.1 g). The hydrogen production percentage was higher for the case of microchannel reactor than the stirrer batch reactor. The initial hydrogen production after 2 h of reaction time was very high for the batch stirrer but progresses little with increased time beyond that point. The microchannel reactor almost has a linear hydrogen production trend with time. Hence, the performance of MCHR was better than the batch reactor.

CONCLUSIONS

The dehydrogenation of H18-DBT was conducted in the microchannel within a temperature range of 260 to 320°C over 2 wt.% Pt/Al_2O_3 catalyst. The reaction was compared to that in a conventional batch reactor. The reaction rate was increased with the increasing temperature and the maximum hydrogen production (82.20%) was obtained at 320°C after 20 h reaction time. The 88 % of the stored hydrogen was produced after 40 h in the microchannel reactor.

The hydrogen production of 58% in microchannel reactor at 290°C after 20 h was greater than that in the stirrer batch reactor (12%) under similar conditions. Moreover, the microchannel reactor also has the advantage of utilizing a lower amount of the catalyst.

ABSTRACT

The main drawback of large-scale metal hydride storage systems is the low thermal conductivity of most metal hydrides and the corresponding difficulties for the heat management system. In this work, the optimization of the internal heat management of a hydrogen storage tank is investigated by finite element simulations. Different design parameters of internal fins are analyzed, such as number, thickness, and length of the fins. It is found that a specific configuration of fins results in a notable improvement of heat transfer and corresponding improvement in desorption kinetics.

Keywords: Hydrogen Storage, Room Temperature Metal Hydride, Heat Transfer Management, Tank Design, AB2-Alloy

INTRODUCTION

In the last decades, hydrogen has gained more interest in the scientific and industrial community as an energy carrier due to its high gravimetric energy density. One of the main bottlenecks for hydrogen introduction in society is finding an efficient and safe hydrogen storage system. As a storage method, the solid-state storage in room temperature metal hydrides has beneficial properties such as low operating pressures and moderate working temperatures [1].

One significant drawback of metal hydrides for commercial application is that most metal hydride materials present a low thermal conductivity [2]. Therefore, most metal hydride systems have inefficient hydrogen absorption and desorption performances in scaled-up systems. Several methods to improve the thermal conductivity of the metal hydride have been investigated. Those methods integrate materials with higher thermal conductivity like aluminum or copper in foam or as a net structure, a mixture of expanded graphite and metal hydride, or an internal heat exchanger [3-7]. A different method is the integration of fins made of copper or aluminium to improve the heat exchanger [8,9].

This work investigates the optimal internal heat management design of a cylindrical metal hydride storage tank with an external heat exchanger using finite element modeling. The aim of developing such a storage system is to couple it with a 10 kW PEM fuel cell that consumes 670 g/h of hydrogen at full load. The addition of internal aluminium fins is studied, and parameters such as the number, thickness, and length of fins are evaluated and optimized to provide the required hydrogen flow to the fuel cell.

MODELING DESCRIPTION

The metal hydride storage tank was modeled in a 2D geometry with COMSOL Multiphysics 5.6. The cylindrical tank was calculated with a capacity of 0.5 kg H_2, thus containing 62.5 kg of the commercial room temperature AB2-alloy, Hydralloy C5® with a maximum experimental capacity of 1.1 wt.% H_2. This simulation implemented the hydrogen absorption and desorption kinetic behavior using the separated variables approach with the van't Hoff equation for the equilibrium pressure. Table 1 describes the essential parameters for the simulation.

Table 1. Important parameters for 2D model

Variable	Value	Name
A1	14.96 [1/s]	Frequency factor
Ea1	15.00 [kJ/mol H_2]	Dehydrogenation activation energy
R_g	8.314 [J/mol H_2]	Gas universal constant
DeltaH1	28.4 [kJ/mol H_2] [10,11]	Dehydrogenation enthalpy
DeltaS1	112.0 [J/mol H2] [10,11]	Dehydrogenation entropy
rho_bulk	3540.0 [kg/m^3]	Initial bulk density of the alloy
k_alloy	1.0 [W/m*K]	Effective thermal conductivity of the hydride bed
k_fin	117.0 [W/m*K]	Thermal conductivity of the aluminium for the fins

The objective of this study is to research the possibility of improving the desorption performance of the tank by changing the internal geometric shape of aluminium fins. Significant boundary conditions are that the external cooling

fluid is water with a temperature of 55°C and is modeled as natural convection. In addition, some assumptions are considered for the simulation. The most important assumptions are that all the hydrogen released is taken from the system and that there is a local thermal equilibrium between the hydrogen gas and the hydride bed. The expansion of the metal hydride is also not taken into account and the hydride bed is assumed to be isotropic.

As design variables for the optimization, three different options were considered. The calculated number of fins were 4, 8, 12, and 16. The thickness of the fins was changed between 1.5 mm and 4 mm. The length of the fins was evaluated between 45 mm and 65 mm. The outer diameter remained the same as did the wall thickness of the tank shell. In addition, the length of the vessel was adjusted accordingly to the change of the internal geometry, in order to keep the amount of alloy inside of the tank constant.

RESULTS AND DISCUSSION

Figure 1 shows 2D geometry sketches of the temperature profiles at different concentrations and desorption kinetic curves for different lengths of fins with a thickness of 2 mm and a total number of 12 fins. The dehydrogenation kinetic curves show the hydrogen weight percent (wt.%) over the simulation time (wt.%: mass of hydrogen released upon desorption over the maximum mass of hydrogen released).

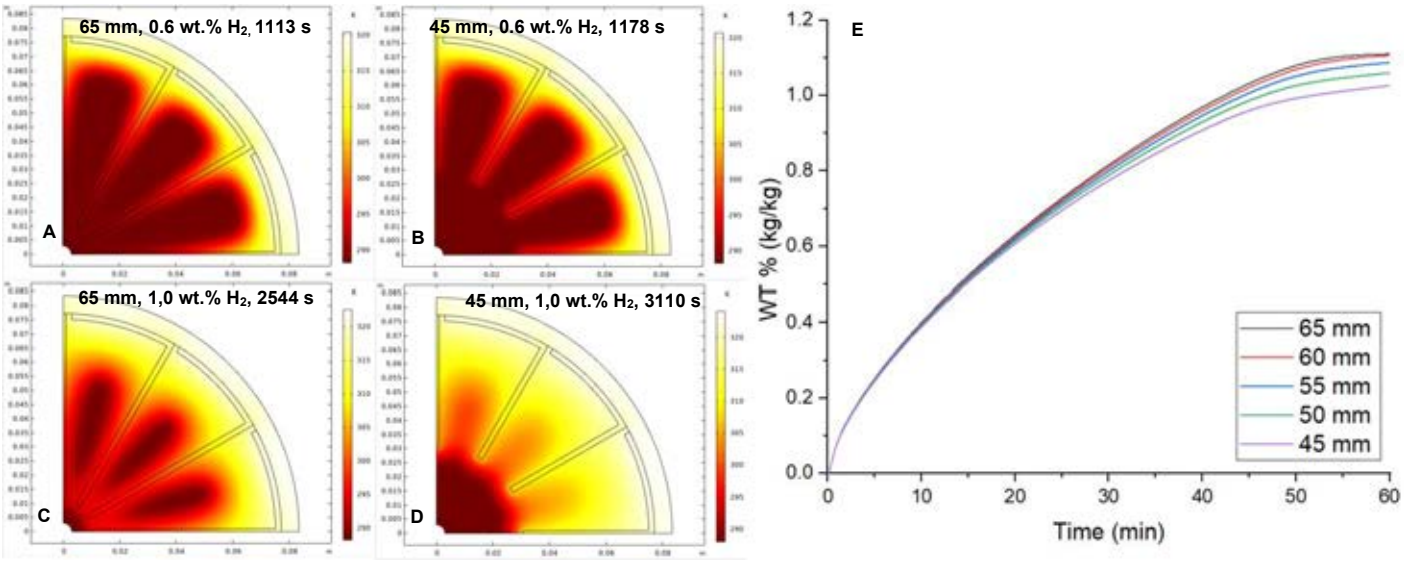

Figure 1: Example of the temperature evolution in a 2D tank geometry for 45 and 65 mm fins at 0.6 wt.% and 1.0 wt.% of the hydrogen capacity released (left) and example of the desorption kinetics for the released hydrogen (right).

In Figure 1, it can be seen that longer fins lead to slightly faster desorption kinetics. Lengths between 65 and 55 mm show almost no difference in terms of kinetic behavior. For lengths shorter than 55 mm, the kinetic behavior slows down more notably. Considering that the tank is heated up on the external shell, the dehydrogenation process starts from the hydride bed in contact with the internal part of the shell and fins. Up to about 0.6 wt.% H_2, the curves do not show almost any difference because all the fins' lengths cover the radial hydride bed portion. This fact is clearly seen by the temperature distribution at 0.6 wt.% H_2 by comparing 65 and 45 mm lengths of the fins (Figure 1A and B). As the fins' lengths are short, the heat transfer to the center of the tank becomes less efficient. Therefore, the differences are more notable for lengths shorter than 55 mm and after a dehydrogenation stage of about 0.6 wt.% H_2. In Figure 1C and 1D, the temperature profile between 45 and 65 mm fin's length at 1.0 wt.% H_2 is quite different. The reaction proceeds more slowly and, in the case of the 45 mm long fins, is practically terminated at 1.0 wt% H2, while in the case of the 65 mm long fins it proceeds more rapidly until about 1.1 wt%.

Figure 2 presents the hydrogen release rate and hydrogen supply time for different configurations. It is important to mention that the design is developed to provide 670 g/h. This rate is calculated with the amount of alloy in one tank (62.5 kg of Hydralloy C5®; wt.% max: 1.1). Figure 2A shows the hydrogen flow provided by tanks with 12 fins and with different thicknesses as a function of time. As seen, a thicker fin leads to the faster release of hydrogen. This behavior results in a faster response, though it does not provide hydrogen to the fuel cell for a long time. In Figures 2B and 2C, it is possible to observe that thicker or longer fins usually lead to better system performance. This is due to the better distribution of heat inside of the tank due to the enhanced thermal conductivity of the hydride bed due to the fins.

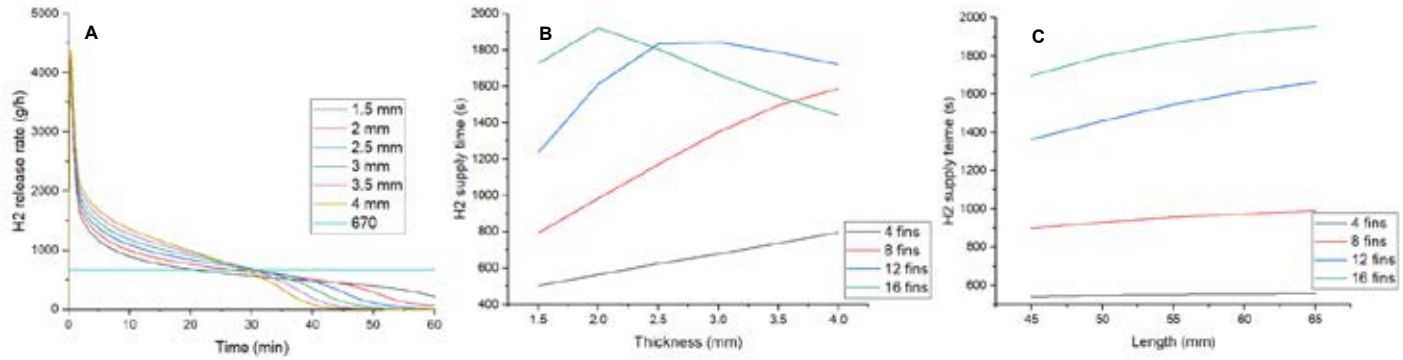

Figure 2: hydrogen release rate for different fin thicknesses (left), time until the tank cannot supply 670 g/h of hydrogen as a function of the thickness (middle) and the length (right) of the fins.

CONCLUSIONS

The limiting factor for metal hydride tanks is the heat transfer inside the pressure vessel in a scaled-up system. An efficient approach to improving the internal heat management of a scale-up metal hydride-based hydrogen storage reservoir is the addition of an internal structure that can provide a better heat distribution and enhanced heat conduction. This study shows that the system can be efficiently improved by adding fins inside of the tank. An optimal tank design configuration is found. A metal hydride-based tank with 16 aluminium inner fins of 2 mm thickness and 65 mm length is the most efficiant configuration, as it can provide the 670 g/h of hydrogen for more than 1900 seconds.

ABSTRACT

To cope with the tight timeframe of the global transformation from fossil to renewable energy sources, efficient methods and tools such as process and system simulation are essential for rapid development, cost-efficient design and scale-up validation of new energy systems. This numerical analysis investigates the coupling of a stationary metal hydride (MH) hydrogen storage system with a low-temperature 10 kW proton exchange membrane (PEM) electrolyzer as a fast-responding and well-controllable hydrogen source. The heat management of the solid-state storage tank is improved through additional aluminium fins and an external cooling jacket. For modeling and process simulation, Aspen Custom Modeler® is used to study the mass and heat transfer phenomena in the hydrogen storage tank, as well as the interaction with the electrolyzer. The hydrogen tank is designed to store a total capacity of 700 g of H_2 using 62.5 kg commercial room temperature AB_2-alloy, Hydralloy C5®. The operating pressure varies from 5 to 38 bar H_2, while the coolant temperature varies from 20 to 60°C depending on the exothermic absorption or endothermic desorption processes.

Keywords: Simulation, Hydrogen Storage, Room Temperature Hydrides, PEM Electrolyzer, Emergency Power Supply

INTRODUCTION

The efficient storage and transport of hydrogen in stationary and mobile applications is considered the central technological challenge of the global energy transition [1–4]. Due to hydrogen's low volumetric energy density at ambient temperature and pressure, it is necessary to develop improved storage methods and strategies to store hydrogen economically, practicably and safely [1,5]. While physically-based hydrogen storage systems such as compressed gas, cold/cryo-compressions and liquid hydrogen technologies are already utilized in many industrial applications, the group of material-based hydrogen storage systems such as adsorbents, liquid organic, interstitial and complex hydrides as well as chemical hydrides are still under development or used in niche applications, respectively [1,4]. However, since the low gravimetric energy density of MH-based hydrogen storage systems usually limits the mobile application, MH provides more promising properties for stationary storage solutions due to their relatively high volumetric storage capacity, intrinsic safety and long-term stability with low requirements in terms of operating pressure and temperature [4–6]. Since the use of renewable energies such as wind turbines and photovoltaics naturally leads to an unsteady power supply, a particular focus remains on the investigation of suitable stationary energy storage systems based on MH in combination with electrolyzers and fuel cells for demand-side management to balance the power grid and emergency power supply [7–9]. By developing process simulation models, the performance of a stationary MH storage system in interaction with a PEM electrolyzer and its performance for supplying hydrogen to a PEM fuel cell is investigated here.

MODELING AND SIMULATION

In the first approach, the MH tank was modelled with Aspen Custom Modeler® V11 as a dynamic 0D simulation that considered the equations for mass and energy conservation, the chemical reaction kinetics, and the thermodynamic properties - hydrogen pressure and temperature. The van't Hoff law: $ln\left(\frac{p_{eq}}{p_0}\right) = \frac{\triangle H}{RT} + \frac{\triangle S}{R}$ Eq. (1) was used to describe the equilibrium pressure of the AB_2-alloy as a function of the temperature of the MH bed [5]. As Hydralloy C5® is a commercial and well-characterized MH forming alloy, the material properties for the reaction kinetics were taken from the literature [10,11]. The modeling of the MH intrinsic reaction kinetic was expressed according to the equation (2): $d\alpha/dt = k(T)f(p_{op}, p_{eq})g(\alpha)$ Eq. (2) with $d\alpha/dt$ as the hydrogenation reaction rate, $k(T)$ for the Arrhenius rate term as a function of T, $f(p_{op}, p_{eq})$ as a function of the tank operating and equilibrium pressures and $g(\alpha)$ as a function of the reacted hydrogenation fraction to describe the intrinsic gas-solid reaction behavior [10,12]. The tank was designed with inner fins to enhance the effective thermal conductivity of the hydride bed. Thus, the effective thermal conductivity of the inner part of the tank, including the MH, the hydrogen gas phase and the aluminium fins was calculated as a weighted value considering the mass of hydride forming alloy and the mass of aluminium. In this

regard, the thermal conductivity of the hydride phase was taken as κ_{Alloy} = 1 W/m*K [13] and the aluminium alloy as κ_{Al} = 215 W/m*K [14]. Forced convection was considered on the outer wall of the tank with a convective heat coefficient of h_{wall} = 500 W/m²*K and a coolant reservoir of 1 m³ with an initial temperature of 20 °C. For the first simulation step, the model of the 10 kW PEM electrolyzer was simplified to an independent hydrogen source with a constant mass flow of 170 g H_2/h and without connection to the energy balances of the hydrogen tank. The filling of the MH tank was simulated at a constant inlet pressure of 38 bar H_2 and a relatively low coolant flow of 10 NL/min (pure water) at an inlet temperature of 20 °C. The dehydrogenation, in turn, took place with a constant hydrogen discharge of 670 g H_2/h at 5 bar and a coolant flow of 60 NL/min at 60 °C. Radiation heat losses and pressure losses due to friction were neglected. In addition, uniform distribution and temperature of the hydrogen gas phase, AB_2-alloy, and MH, respectively, was assumed. The simulation was done as a closed loop of charging and discharging the tank. Therefore, the final values of the hydrogenation process were defined as the initial values of dehydrogenation and vice versa in terms of masses and the internal tank pressure.

RESULTS AND DISCUSSION

The left side in Fig. 1 shows the cumulative masses of AB_2-alloy, hydride, and absorbed H_2 (Fig. 1a), and the center shows the inner tank plus coolant inlet and outlet temperatures (Fig. 1b) as a plot against absorption time. In addition, the right side shows the tank operating, the van't Hoff equilibrium and the PEM electrolyzer H_2 feed pressures (Fig. 1c).

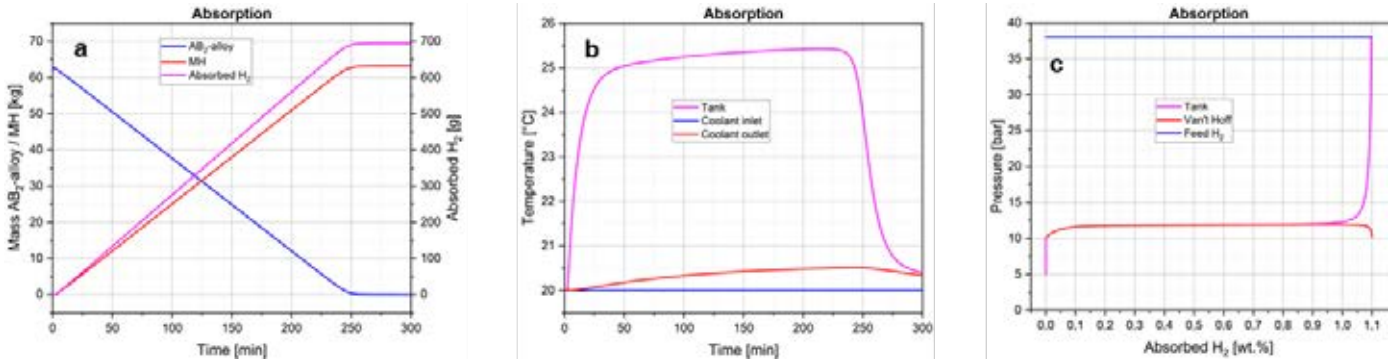

Figure 1: Masses vs. time (1a), temperature vs. time (1b) and pressure vs. wt.% of H_2 (1c) during the absorption.

The hydrogenation process is exothermic, and it results in the release of thermal energy to the environment. For this reason, the internal temperature profile of the tank (Fig. 1b) increases as soon as the hydrogenation reaction starts and reaches a maximum temperature of about 25.5 °C after 220 min. In contrast, the coolant temperature does not change significantly due to the forced convection conditions for the heat exchanger. The initial internal tank pressure is given as 5 bar, since it is the required minimum operating pressure for the PEM fuel cell virtually connected to the hydrogen tank. In Fig. 1c, it is possible to notice that the hydrogenation process does not start immediately, but only after approx. 2.5 min, because the initial internal tank pressure is lower than the equilibrium pressure of the AB_2-alloy-MH hydride system of about 10 bar at the initial operating temperature of 20 ºC. While the mass rates of hydride and hydrogen absorption increase due to the provided feed rate of 170 g H_2/h, the mass rate of AB_2-alloy decreases since it is consumed (Fig. 1a). As seen in Fig. 1a, the charging rate is relatively slow, and the entire hydrogenation process takes about 250 min to reach the total storage capacity of the tank. Under this low flow condition and proper heat release, the pressure evolution of the tank follows the equilibrium pressure of the solid phase between 20 and 25.5 ºC as shown in Fig. 1b. After about 1 wt.% of hydrogen is absorbed, the reaction rate slows down to zero and the tank pressure eventually rises to the hydrogen inlet pressure of the PEM electrolyzer of 38 bar (Fig. 1c).

The desorption characteristics in terms of mass balances and temperatures as a function of time, as well as the pressures vs. wt.% of hydrogen, are shown in Fig. 2. Taking into consideration that, at the beginning of the dehydrogenation process, the tank is in the hydrogenated state under 38 bar, the desorption from the solid phase does not start until reaching an operating pressure below the equilibrium pressure of about 6 bar at 20 °C (Fig. 2a and c). For nearby 3 min hydrogen is released from the gas phase with a mass flow rate of 670 g H_2/h, and then the MH starts to release hydrogen (Fig. 2c). In contrast to the absorption, the desorption of hydrogen from hydrides is an endothermic process that requires energy and results in cooling of the inner tank bed. The tank temperature initially decreases with the onset of dehydrogenation and reaches a minimal temperature of about 15.5 °C. Then, due to the heat provided by the coolant and the slower reaction rate as the residual amount of hydride decreases, temperature increases again (Fig. 2b). After about 60 min, most of the hydrogen bond in the hydride is desorbed, leading to a stagnation of the mass rates of desorbed hydrogen and formation of the AB2-alloy (Fig. 2a). In addition, the temperature curve's slope of the tank increases and the operating tank pressure drops to the given PEM fuel cell

operating pressure of 5 bar. The tank and thermal management configuration shows that the MH storage system is capable of providing 670 g H_2/h for about 1 h, which is approx. equivalent to providing 10 kW of power for 1 h.

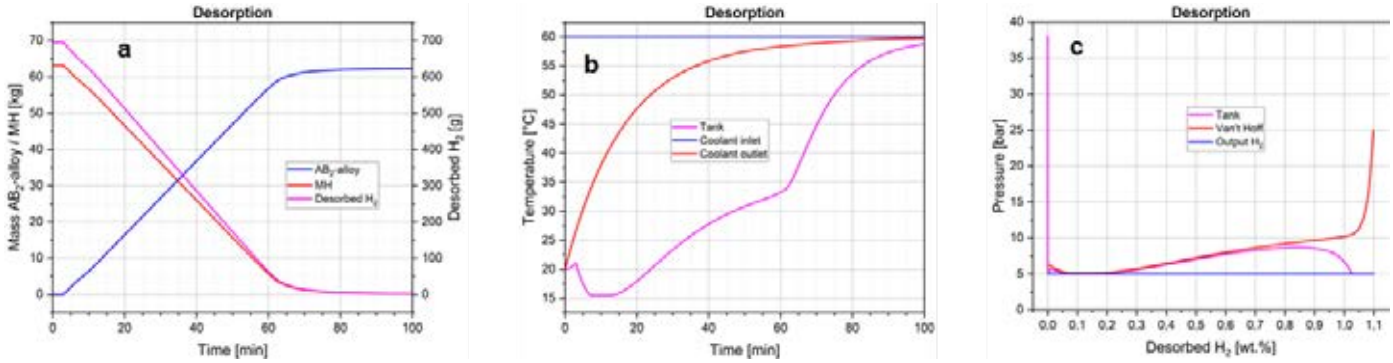

Figure 2: Masses vs. time (2a) and temperature vs. time (2b) and pressure vs. wt.% of H_2 (2c) during the desorption.

CONCLUSIONS

This research work deals with the process simulation of a hydrogen storage system based on a room temperature hydride coupled with a PEM electrolyzer. The developed MH storage-fuel cell-electrolyzer system is able to store about 700 g of hydrogen in approx. 250 min and provide about 10 kW of electrical energy for 1 h considering the hydrogen mass flow of 670 g/h. Aspen Custom Modeler® is used to create and investigate a numerical model of the hydrogen storage tank, taking into account mass and energy conservation, chemical reaction kinetics, pressures and temperatures. A model is presented that enables the simulation of MH hydrogen storage systems as a basis for further investigations on charging and discharging strategies of storage systems connected in parallel and series, respectively. Furthermore, in terms of system simulation and evaluation, this model also allows the coupling of heat exchangers, electrolyzers and fuel cells.

ABSTRACT

Hydrogen adsorption capacity of Ni(II) and Co(II)- exchanged ZSM-5 and US-Y were investigated at 298 K and 10 bar. Mesopore added zeolites that have a total pore volume value reaching 0.5 cm^3/g, showed a gravimetric H_2 storage capacity of 0.14wt.% and a volumetric storage capacity of 4.2 g/L at 298 K and 10 bar. The calculated isosteric heat of H_2 adsorption values ranged from 16 and 32 kJ/mol with the highest values observed on Ni(II)-ZSM-5. Theoretical heat of H_2 adsorption values were also calculated using density functional theory utilizing both cluster and periodic models for Co(II)- or Ni(II)- exchanged ZSM-5. The theoretical heat of adsorption values were calculated between 11 and 38 kJ/mol, in consistence with the experimental values.

Keywords: Cobalt, Nickel, Zeolite, Isosteric Heat of Adsorption, Density Functional Theory

INTRODUCTION

Fuel cell electrical vehicles (FCEVs) that use hydrogen as an energy carrier, are one of the fastest growing transportation areas. However, lack of a safe and efficient H_2 storage system is still an essential concern in the practical usage of hydrogen. Operating targets for the year of 2025 for a storage system set by US DOE (Department of Energy) are a gravimetric capacity of 5.5 wt % and volumetric capacity of 40 g/L that operates within the temperature range of 233 K and 333 K under a maximum storage pressure of 100 bar. Among the various H_2 storage systems, physisorption using porous materials (carbon-based materials, metal organic frameworks (MOF), covalent organic framework (COF), and zeolites) is a candidate application considering fully reversible and fast hydrogen uptake due to weak Van der Waals forces. Among the MOFs, the reported highest storage capacity in ambient conditions belongs to Ni_2(m-dobdc) and Co_2(m-dobdc) MOFs 11 g/L or 0.9 wt.% at 298 K and 100 bar [1] with reported heat of H_2 adsorption value of ~12 kJ/mole [2]. According to theoretical studies, adsorption enthalpy of porous materials at ambient temperature should be between 15–25 kJ/mole to ensure maximum adsorption capacity as well as reversibility [3]. H_2 storage capacity values of zeolites containing protons or alkali metal cations are reported to be between 1 and 2 percent by weight (77 K at 1 atm) [4]. In addition to the low heat of H_2 adsorption values on alkali metal exchanged zeolites, low micropore volumes (maximum 0.33 cm^3/g) cause limited H_2 uptake amounts (maximum 2.86 wt.% on FAU framework [5]). Although some of transition metal cations were investigated on zeolites (such as Cu(I)), there is only one study associated with Ni(II) cations [6]. One density functional theory study for Ni(I)-ZSM-5 reported the heat of adsorption as 67 kJ/mole when one hydrogen molecule binds to cation [7]. In current study, hydrogen adsorption capacities of Ni(II) or Co(II)-exchanged ZSM-5 and US-Y were investigated up to 10 bar at 298 K. To overcome micropore volume restriction, mesopore addition was performed using desilication (top-down method) to ZSM-5. Hydrogen binding energy on Ni(II)- and Co(II)-ZSM-5 was also studied theoretically.

MATERIALS AND METHODS

NH_4^+-USY (US-Y,ultra-stable Y is steam treated form of zeolite Y, Alpha Aesar, Si/Al=6, CAS:1318-02-0.1) was obtained commercially. ZSM-5 having Si/Al ratios of 33 and 20 were prepared hydrothermally at 423 K for 72 h following the procedure reported by Schmith et al. [8] using molar gel formulas of $1SiO_2{:}0.01Al_2O_3{:}0.125Na_2O{:}0.051TPABr{:}36H_2O$. and $1SiO_2{:}0.02Al_2O_3{:}0.125Na_2O{:}0.051TPABr{:}36H_2O$, respectively. Desilication at 0.2 M NaOH (Merck, >%99) solution at 358 K was performed on Na-ZSM-5 as reported by Groen et al. [9] to create mesopores. Ion-exchange of ZSM-5 and mesoporous ZSM-5 (Meso-ZSM-5) were performed using 0.2 M cobalt-(II)nitrate hexahydrate (Merck, 98%) or nickel-(II)nitrate hexahydrate (Merck, 98%) solutions for 24 h at 333 K two or three times. 1g NH_4^+-US-Y (Si/Al=6) was also ion-exchanged twice using 75 ml of 0.5 M cobalt-(II)nitrate hexahydrate (Merck, 98%) or nickel-(II)nitrate hexahydrate (Merck, 98%) for 24 h at 298 K.

The crystallinity of prepared zeolites were tested in METU Central Laboratory using Rigaku Ultima-IV X-Ray Diffraction Device (Cu Kα source, λ = 1.54 Å). Scanning electron microscope pictures of zeolites were obtained with QUANTA 400F Field Emission electron microscope. The elementary analysis was performed using inductively coupled plasma-optical emission spectrometer (Perkin Elmer Optime 4300DV). Surface area and pore volumes of zeolites were calculated using N_2 adsorption experiments conducted at 77 K by Micromeritics Tristar II 3020.

The periodic DFT simulations were performed using the Quantum Espresso package [10]. PBE functional was used along with PAW basis sets The Brillouin zone sampling was done using a single K-point (gamma point) The cut-off energies used for the wavefunctions and the charge densities were 76 Ry and 476 Ry, respectively. All the results presented were obtained by relaxing the whole structures until the net force acting on the ions was Fnet < 0.001 Ry/Bohr. Cluster model optimizations were performed using Gaussian09 [11] package with B3LYP functional and 6-31G(d,p) basis set.

H_2 Adsorption Measurements

Hydrogen adsorption isotherms for pressures in the range 0–10 bar were determined with volumetric method using a home-made high pressure volumetric adsorption system. Primarily, 0.3–0.5 grams of prepared zeolites were degassed under vacuum for 1 hour at 653 K using a scroll vacuum pump (Agilent Technologies, Model IDP3) for dehydration and pore cleaning processes. Afterwards, free space was determined using volumetric calculations with He (Hatgaz, %99.999), then the sample was degassed at 653 K for one more hour. H_2 adsorption experiments were carried out at room temperature using incremental doses of hydrogen gas (Hatgaz, 99.999%) up to 10 bar (0.5 bar increments). Hydrogen adsorption experiments were performed at three different temperatures to implement Clasius-Clapeyron equation (Equation.1) for isosteric heat determination.

$$\ln\left(\frac{P_2}{P_1}\right) = -\frac{Q_{st}}{R}\left(\frac{1}{T_2}-\frac{1}{T_1}\right) \quad (1)$$

RESULTS AND DISCUSSION

Hydrogen adsorption experiments were performed at 298 K up to 10 bar. The highest storage capacity belongs to Meso-Ni(II)-ZSM-5 with 0.14 wt% gravimetric capacity (3 g/L volumetric capacity at 298 K and 10 bar, see Figure 1.a) that is higher than Ni_2(m-dobdc) which shows 0.13 wt.% at 10 bar [1]. The volumetric capacity reaches 4.2 g/L on Ni(II)-ZSM-5 at 298 K and 10 bar, which is nearly double of the value observed for Ni_2(m-dobdc) [1]. The dominant parameter controlling the adsorption capacity is suggested to be the heat of H_2 adsorption at room temperature adsorption experiments. Calculated H_2/Metal ratios lower than 2 (see Figure 1.b) indicate adsorption of H_2 molecules on metal cation sites at room temperature at pressures lower than 10 bar. Similar H_2/Metal ratios observed on Meso-ZSM-5 and ZSM-5 samples, indicating that existence of mesopores is not changing the adsorption capacity under 10 bar pressure. Also, the order of zeolites from higher to lower H_2/Metal ratios (Meso-Ni(II)-ZSM-5~Ni(II)-ZSM-5>Meso-Co(II)-ZSM-5~Co(II)-ZSM-5~Ni(II)-USY>Co(II)-USY) is consistent with the order of the zeolites having higher heat of H_2 adsorption values (see Figure 1.c). The highest isosteric heat is achieved on Meso-Ni(II)-ZSM-5 with 32 kJ/mole. Heat of adsorption results of all zeolites are in the optimum range (15–25 kJ/mole). Ni(II)-US-Y and Co(II)-USY showed lower gravimetric H_2 adsorption capacity values when compared to Ni(II)-ZSM-5 (0.22 mmol Ni/g) even though they have a higher metal content (0.35 mmol Ni/g and 0.42 mmol Co/g). This is due to the lower heat of adsorption values observed on these zeolites as well as potential distribution of the cation sites in FAU, where the majority of the cations could be at the window of the 6MRs that are not accessible to H_2 molecules.

Theoretical calculations predicted heat of H_2 adsorption values between 11 and 38 kJ/mol, which is close to the experimentally calculated isosteric heat of adsorption values. Both techniques predicted higher heat of adsorption values for Co(II)- and Ni(II)- cations located at the α-sites.

Table.1 Heat of H_2 adsorption results calculated experimentally, cluster and periodic of DFT computations.

Zeolite	Experimental ($-Q_{st}$ kJ/mole)	DFT Gaussian ($-E_{ads}$ kJ/mole)	DFT ab-initio ($-E_{ads}$ kJ/mole)
Ni(II)-ZSM-5(α)	22–32	17–37	25–33
Ni(II)-ZSM-5(γ)		25–32	12–27
Co(II)-ZSM-5(α)	13–20	11–30	18–38
Co(II)-ZSM-5(γ)		4–16	1–34

CONCLUSION

Hydrogen adsorption capacity of Ni(II) and Co(II)- exchanged ZSM-5 and US-Y are investigated at 298 K and 10 bar. Mesopore added zeolites showed a maximum volumetric storage capacity of 4.2 g/L at 298 K and 10 bar. Ni(II)-exchanged zeolites show higher storage capacity than Co(II)-exchanged ones up to 10 bar, due to the high binding energy between nickel cation and hydrogen molecule. The calculated isosteric heat of H_2 adsorption values ranged from 16 and 32 kJ/mol with the highest values observed on Ni(II)-ZSM-5. Heat of adsorption results of all zeolites are in the optimum range (15–25 kJ/mole). According to theoretical calculations, the alpha site is preferable for both cations.

ABSTRACT

Ti-V-Nb-Cr multicomponent alloys are promising materials for hydrogen storage. In this work, we investigated in detail the hydrogen absorption/desorption reactions of the $(TiVNb)_{85}Cr_{15}$ alloy. The alloy was produced via electric arc melting and characterized by X-ray diffraction (XRD), Scanning Electron Microscopy (SEM) and Energy Dispersive X-ray Spectroscopy (EDS) analyses. The alloy presented single-phase BCC structure and dendritic morphology with small segregation of Ti and Cr to the interdendritic regions. Samples of the alloy were hydrogenated at different H/M (number of hydrogen atoms per metal atoms) ratio. XRD and Thermo Desorption Spectroscopy (TDS) analyses showed multi-step processes of hydrogenation/dehydrogenation. XRD analyses suggest that the alloy initially absorbs hydrogen via solid solution and subsequently forms an intermediate BCC hydride up to low levels of H/M absorbed (0.83 H/M). Afterwards, the intermediate hydride also absorbs hydrogen via solid solution leading to the formation of a FCC hydride, which absorbs hydrogen up to 2 H/M. TDS results showed multi-step desorption reactions which were associated to the desorption of the FCC and BCC hydrides. Moreover, Pressure Composition Isotherms (PCI) measurements indicated the existence of two plateaus of absorption and desorption, which also were associated to the BCC and FCC hydrides.

Keywords: Hydrogen storage, Multicomponent alloy, BCC alloy, Metal hydrides

1. INTRODUCTION

Metal hydrides are considered as an option to store hydrogen in a relatively safer and compact way in comparison to high pressure vessels [1,2]. However, most conventional metal hydrides present limitations such as poor cyclability, slow kinetics of hydrogen absorption/desorption, low gravimetric storage and/or undesirable thermodynamic properties [3,4]. Therefore, there is a demand for new materials that can potentially avoid these issues. Recently, a new group of alloys generically known as multicomponent alloys have been investigated for hydrogen storage applications [5–9]. These alloys present at least 3 elements in their chemical composition with substantial atom fractions and often form complex solid solution phases [10]. The versatility of combining elements with different characteristics in the complex solid solution phases might be the key factor to optimize hydrogen storage properties in multicomponent alloys. For example, a few works have been attempting to improve the thermodynamic behavior of hydrides from multicomponent alloys by combining elements with different hydrogen affinity such as Ti, V, Co, Ni, Cr, etc [6,8,9,11]. In this context, Ti-V-Nb-Cr alloys have been showing promising properties for hydrogen storage applications [6,8,11]. Strozi et al.[11] showed that changing the Cr content from 15 to 35 at.% on $(TiVNb)_{100-x}Cr_x$ alloys resulted in a change of the hydrogen equilibrium pressures at room temperature from 0.01 bar to 1-1.5 bar. However, the understanding of the hydrogenation reactions in multicomponent alloys is still in the early stages. Hydride structures of multicomponent alloys have been investigated and several differences are already reported. For example, a few alloys are reported to present single-step absorption reaction forming FCC/BCT hydrides [5,12], whereas other alloys present multi-step reactions forming intermediate hydrides [13–15]. Ti-V-Nb-Cr alloys have been suggested to form intermediate hydrides [6,8,11,14]. However, the complete hydrogenation reactions of these alloys are still unclear. In the present work we investigate in detail the absorption/desorption reactions of the $(TiVNb)_{85}Cr_{15}$ multicomponent alloy.

2. MATERIALS AND METHODS

2.1. Alloy synthesis and hydrogen storage measurements

The alloy was synthesized in an electric arc melting furnace under argon atmosphere using Ti, V, Nb and Cr pieces with purity level higher than 99.5%. A Ti getter piece was melted prior to the alloy synthesis to minimize the oxygen content in the sample. The alloy was remelted five times to improve chemical homogenization. Small pieces of the alloy were loaded into Sieverts-type apparatus and subjected to an activation procedure to facilitate hydrogen

absorption (heat treatment at 390 ºC under dynamic vacuum for 12 hours). PCI measurements were performed at room temperature and three other temperatures between 100 ºC and 200 ºC. Partially hydrogenated samples were produced at different levels of H/M absorbed to investigate the absorption reactions. Before hydrogenating the samples with the desired amount of hydrogen, the samples were subjected to a complete cycle of hydrogen absorption/desorption to ensure complete pulverization. This procedure was paramount for structural characterization.

2.2. Structural characterization and desorption analyses

Structure characterization analyses were performed using XRD, SEM and EDS techniques. XRD analyses were carried out in a D8 Advance Brucker diffractometer using Cu-Kα radiation ($\lambda_{K\alpha1}$ = 1.5406 Å, $\lambda_{K\alpha2}$ = 1.5444 Å). Phase structure identification and Rietveld refinement analyses were performed in the software General Structure Analysis System II (GSAS-II) [16]. SEM and EDS analyses were done in a Zeiss Merlin microscope. Desorption behavior was analyzed via TDS curves, which were obtained in a homemade apparatus with a Quadrupole Mass Spectrometer (QMS) detector. The apparatus measured hydrogen partial pressures from samples that were heated up to 450 ºC (heating rate of 5 ºC/min). The equipment was attached to a vacuum pump that provided pressures of 10^{-6} mbar. Moreover, temperatures were recorded via a K-type thermocouple in direct contact with the samples analyzed.

3. RESULTS AND DISCUSSION

Figure 1 (a) and (b) shows that the alloy presented a dendritic microstructure morphology with interdendritic regions richer in Ti and Cr. EDS assessments of the overall, dendritic and interdendritic regions are displayed in Table 1. The overall chemical composition was similar to the nominal composition. The measurements in the interdendritic region confirmed the segregation of Ti and Cr. XRD analyses of the as-cast sample in Figure 1 (c) shows the alloy formed a single-phase BCC structure. Upon hydrogenation, the alloy showed several structural changes as presented in the XRD patterns of the partially and fully hydrogenated samples (Figure 1(c)). It seems that for low levels of hydrogen absorption (0.5 H/M) there is a miscibility gap for the formation of an intermediate hydride which resulted in the co-existence of two BCC phases at this condition. Figure 1 (d) shows the (220) diffraction reflection exhibiting the splitting of this peak and the deconvolution of the two BCC phases. A similar miscibility gap has already been reported in Ti-Cr-V BCC alloys [17]. The sample with 0.83 H/M presented only one BCC phase with larger lattice parameters than the BCC phases of the previous samples. We believe this pattern is associated only to the intermediate hydride, which increased its lattice parameters due to further absorption via solid solution. In higher levels of hydrogen absorption (1.6 H/M) the alloy presented the co-existence of the BCC hydride and an FCC hydride. It is important to notice that the lattice parameters of the BCC hydride are very similar in the samples with 0.83 and 1.6 H/M. This indicates that the intermediate hydride attained its hydrogen solubility limit around 0.83 H/M. Lastly, the fully hydrogenated sample (2 H/M) showed the presence of the FCC hydride solely indicating that the absorption process was completed. The formation of FCC hydrides are often reported in TiVNbCr alloys and other multicomponent alloys [6–8,18]. Figure 1 (d) shows the TDS measurements of the partially and fully hydrogenated samples. One can see that the desorption profiles of the samples with 0.5 and 0.83 H/M were very similar. Single desorption peaks at high temperature conditions were observed for both samples. This desorption event can be related to the intermediate hydride desorption. The deviations on the onset temperatures were probably caused due to different fractions of BCC hydrides in the samples. Multi-step reactions of hydrogen desorption were observed in the samples with 1.6 and 2 H/M. Both samples presented two main desorption peaks that might be associated to the desorption reactions of the BCC and FCC hydrides. However, it is unclear the reasons for the different desorption profile and onset temperatures observed. Lastly, Figure 1 (e) shows the PCI measurements in absorption and desorption of the $(TiVNb)_{85}Cr_{15}$. The PCI curves suggest the existence of two plateaus, the first plateau presents low equilibrium pressures up to 0.8 H/M even at 200 ºC, whereas the second plateau present high equilibrium pressures that could be reasonable measured even at room temperature. The existence of these two plateaus is also consistent to the proposed reactions of BCC and FCC hydride formation. Therefore, we propose the following sequence of hydrogenation/dehydrogenation in the $(TiVNb)_{85}Cr_{15}$ alloy: BCC alloy ↔ solid solution absorption in the BCC alloy ↔ BCC hydride ↔ increase/decrease of H content in the BCC hydride ↔ FCC hydride. Summarizing, in this work we showed a detailed investigation of the hydrogen absorption/desorption reactions of the $(TiVNb)_{85}Cr_{15}$ alloy.

4. CONCLUSIONS

The $(TiVNb)_{85}Cr_{15}$ was successfully produced by arc melting and presented single-phase BCC structure with dendritic morphology. Segregation levels of Ti and Cr at the interdendritic regions were found. By means of several analyses, the absorption and desorption reactions of $(TiVNb)_{85}Cr_{15}$ alloy were proposed as follows: BCC alloy ↔ solid solution absorption in the BCC alloy ↔ BCC hydride ↔ increase/decrease of H content in the BCC hydride ↔ FCC hydride.

Table 1: Chemical composition of the overall, dendritic and interdendritic regions of the $(TiVNb)_{85}Cr_{15}$ alloy measured by EDS.

Region	Area	Ti (at.%)	V (at.%)	Nb (at.%)	Cr (at.%)

ABSTRACT

Methods to increase the heat conductivity and reduce the expansion stress of metal alloys during hydrogen absorption are investigated. The applied approach focuses on strategies, which are time-efficient and can be up-scaled for larger batches of metal alloy. The properties of the commercial available room-temperature metal alloy HydralloyC5 ($Ti_{0.95}Zr_{0.05}Mn_{1.46}V_{0.45}Fe_{0.09}$) are successfully improved by applying wash-coating techniques. By adding 10 wt.% ENG (expanded natural graphite) or aluminium-powder onto the metal surface prior to hydrogen absorption, the heat conductivity of the samples is improved. Furthermore, the overall expansion stress of the metal alloy during hydrogen absorption is reduced by 20% by adding only small amounts of Aerosil as a glidant agent (0.2 wt.%) to the coating mixture.

Keywords: hydrides, hydrogen storage, swelling, heat transfer, wash coating

INTRODUCTION

In a time of increasing global temperatures and the still significant dependency on fossil fuels, there is a more and more pressing demand for a sustainable alternative. Green hydrogen is one of the most promising candidates because its use does not release any CO_2 and has further the advantage of acting as a universal energy carrier. The most common hydrogen storage systems are high-pressure vessels (up to 700 bar) or the storage as liquid hydrogen. The high-pressure storage has the disadvantage of low volumetric capacity and expensive tank design, while the liquid hydrogen storage is problematic due to the high-energy penalty to condense the hydrogen and boil-off effects. The storage as hydride in the solid-state (e.g. in various metal alloys) is a promising alternative, but comes with its own challenges.

One of the challenges is to reduce the inevitable stress caused by swelling of the material during the hydrogen absorption (up to 20% [1]). This phenomenon occurs due to the larger lattice parameters of the hydride phase in comparison to the hydride forming alloy and the precipitation caused by the hydrogen cycling process. In order to maintain the mechanical stability of the tank, the stress caused by the swelling of the metal hydrides must be considered during the design of a solid-state hydrogen storage vessel. Free space is left in the storage tanks, which reduces the overall stress, but also the volumetric capacity. However, some reports show that adding a glidant material such as Aerosil might be a possibility to reduce this expansion stress [1].

Another challenge is the improvement of the low thermal conductivity of the hydride, which results in a challenging heat management. Regardless of the initial particle size, the metal alloy disintegrates into powders in the size range of microns after several hydrogen absorption and desorption cycles, which leads to a very low thermal conductivity (~1 $Wm^{-1}K^{-1}$). As a result of the exothermic hydrogen uptake, heat is accumulated in the metal alloy bed during hydrogen absorption, leading to hot-spots with decreasing kinetic performance. The heat transfer becomes the predominant effect within larger storage systems and represents the bottle-neck for its practical application [2].

Different methods to increase this heat conductivity have been investigated. While some methods try to improve the tank systems, e.g., adding aluminium fins [3] to have a large surface with high conductivity, it is also possible to directly improve the properties of the metal alloy, e.g. by coating with materials of high thermal conductivity [4]. Aluminium powder, which has high thermal conductivity and is inert in hydrogen atmosphere [5], and expanded natural graphite (ENG), a graphite modification with increased thermal conductivity, are some of the most commonly used compounds. These materials are added by simply mixing in a protective atmosphere (to prevent oxidation of the metal alloy) or compressed with the metal alloy to form pellets [6].

In our research, we have focused on using “room-temperature” metal hydrides, which have several advantages, such as fast kinetics and moderate working pressure and temperature conditions. Further, they can be handled without a protective atmosphere before the cycling, which makes loading of tanks and modifying the material much more

effortless. Room temperature hydrides have a low gravimetric capacity ranging ~2 wt.% of hydrogen, but a proper volumetric capacity of about 100 kg of H_2/m^3. In the case of stationary applications, room temperature metal hydrides are quite suitable. In such systems, the gravimetric capacity is a less critical parameter, and the lower operating temperatures make thermal management system much more simple to design. However, for larger systems, several hundreds of kg or even tons of material are needed, and the methods, as mentioned above, to improve the material's properties are expensive or not practical.

Therefore, we have investigated methods to add conductive material and glidant agent to the metal alloy surface, which are both time-efficient and can be scaled-up with relative ease.

MATERIALS AND METHODS

The metal alloy HydralloyC5 (AB_2-metal alloy; $Ti_{0.95}Zr_{0.05}Mn_{1.46}V_{0.45}Fe_{0.09}$) was brought from GfE (Gesellschaft für Elektrometallurgie) and the size was reduced to ~3 mm in a jaw crusher before use. ENG (particle size 5 µm; SGL-Carbon), polyvinylacetate (PVAct) (Arcos Organics), aluminium powder (particle size 11 µm, Alfa Aesar), Aerosil R805 (Evonik Operations) and acetone (Merck) were used as received. In a typical experiment, 10 g of HydralloyC5 was coated with a dispersion of PVAct as binder (0.5 g; 5 wt.%), ENG or Al-powder (1 g, 10 wt.%), and optionally Aerosil R805 (0.02 g; 0.2 wt.%) in acetone as solvent (80 ml). The solvent was evaporated during movement (60 RPM) in a rotation evaporator. The water bath was set to 60 °C and the pressure kept at ambient conditions. To remove excess binder after coating, the sample was heated in a furnace at 400 °C for 4 h. SEM images were done with a FEI Quanta 650. The hydrogen absorption-desorption behaviour was measured with an in-house produced Sieverts apparatus. The temperature and strain was measured in-situ, where a strain gauge and a thermocouple were attached directly onto the sample holder.

RESULTS AND DISCUSSION

The SEM images of the samples (Fig.1 a-d) show that for a good distribution of conductive material in the hydride bed during cycling, good coverage on the metal alloy particles before the disintegration to powder was necessary.

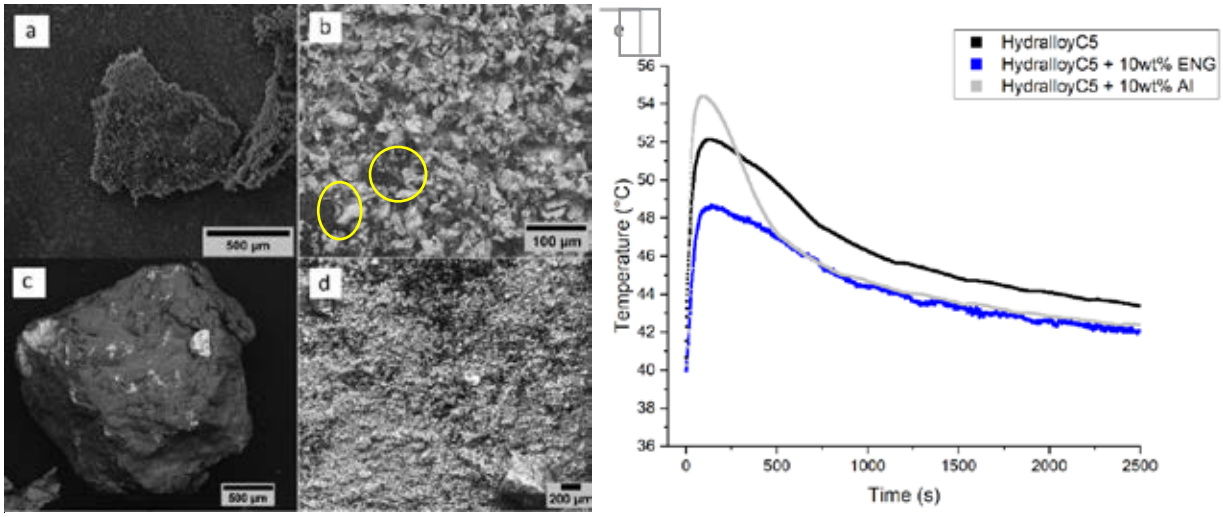

Fig. 1: (a) SEM-images of HydralloyC5 coated with ENG before and (b) after cycling in hydrogen atmosphere; (c) SEM-images of HydralloyC5 coated with Al-powder before and (d) after cycling in hydrogen atmosphere; (e) Measured temperature during hydrogen absorption of the pristine HydralloyC5 (black), ENG-coated sample (blue) and the aluminium-coated sample (grey)

With a modified version of the wash-coating process, the HydralloyC5 could be successfully coated with a layer of ENG (Fig.1a). For aluminium, the image shows also good coverage with a mostly closed coated surface (Fig.1c). After the hydrogen cycling, the particle size of the HydralloyC5 is reduced to ~20 µm, and small clusters of ENG are distributed between the particles (Fig.1b, yellow circles). In the case of aluminium powder, it has agglomerated to larger particles between the disintegrated HydralloyC5 (Fig.1d). However, in both cases, heat management is improved. Fig.1e shows a comparison of the measured temperature profiles during hydrogen absorption (at 40 °C and 40 bar H_2-pressure). For the ENG-coated sample, the peak temperature is reduced to 48.6 °C (blue line) compared to 52.2 °C (black line) in the uncoated sample. In contrast, it shows for the aluminium-coated sample a higher peak temperature (54.1 °C; grey line), but the heat is dispersed much faster.

The results of Fig. 2 show the strain measurement for pristine HydralloyC5 and a sample with added small amounts (0.2 wt.%) of Aerosil as glidant agent. According to Fig.2, during 12 hydrogen absorption-desorption cycles, the strain

to the sample holder increses with every cycle. The same trend is also noted when Aerosil is added. However, the maximum strain was reduced by 20% over the same number of cycles.

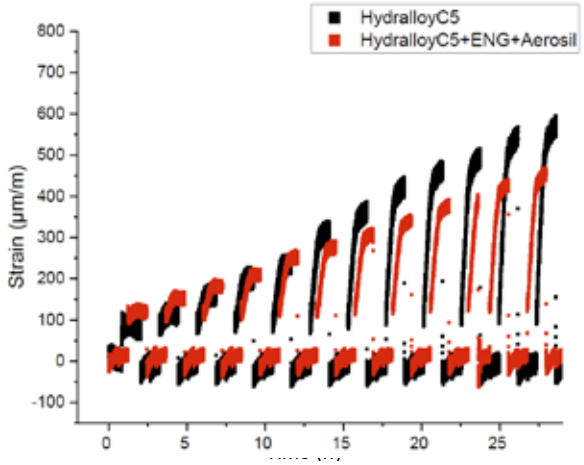

Fig. 2: Strain measurement on a completely filled sample holder was tested for 12 cycles of hydrogen absorption and desorption. Even with low concentrations of 0.2 wt.% of the Aerosil (red), a reduction of the expansion stress was observed in comparison with the unmodified metal alloy (black).

CONCLUSIONS

To the best of our knowledge, this is the first time where a straightforward method is applied for the coating of hydrogen storage material with 10 wt.% of a conductive material (aluminium powder and ENG). In both cases, the heat management could be improved compared to the unmodified metal alloy. For ENG, the temperature peak during hydrogen absorption was reduced, while the heat could be faster dispersed for aluminium powder. It could be further shown that by adding even a tiny amount of glidant material to the coating mixture, the expansion stress during hydrogen absorption could be significantly reduced.

ABSTRACT

The goal of the HyCARE project is to store renewable energy using hydrogen as energy carrier by means of a metal hydride (MH), coupling a phase change material (PCM) for the heat management. The feasibility of the concept has been investigated thanks to the realization of a prototype including a MH-tank and a PCM module storing about 0.5 kg of H_2. The innovation of the use of PCM in the heat management of MH system is linked to the reduction of external heat intake, and during the tests the optimal conditions of hydrogen flow, thermal fluid flow, starting temperature have been evaluated, in order to minimize the external power contribution. It was highlighted that, in the optimal conditions, the PCM was able to collect and supply the heat generated/required by the MH storage system, with the external power source contributing only to compensate the heat losses.

Keywords: Hydrogen storage, Heat storage, Metal hydride, Phase change material

INTRODUCTION

In the use of H_2 as widespread energy vector, its storage in the solid state with metal hydrides (MH) has the advantage of requiring low pressures and temperatures, when using intermetallic compounds (IMCs), reaching a high volumetric capacity. A MH storage system needs a suitable heat management to operate, so that a thermal fluid is usually used to remove/supply heat, since hydride formation implies the production of heat, while hydrogen release requires it. Generally, heat is released in the environment during charging, and therefore a quite low thermal efficiency is achieved, of the order of a few tens of percentage points. An interesting strategy, to increase the efficiency and thus to reduce the amount of requested external power for discharging hydrogen, is to store the heat generated during the exothermic absorption, to be reused during the endothermic desorption. In this regard, the use of phase change material (PCM) has been suggested to be an efficient solution [1] and the coupling of PCM- and MH-tanks is a novel concept, that could increase the efficiency above 70% [2–5]. The coupled system implies that, during MH absorption, the PCM consumes heat to melt, and then, in the desorption phase, the solidification of the PCM releases almost the same amount of energy.

In the framework of the EU-project HyCARE, a prototype of hydrogen and heat storage coupled system, based on MH and PCM, respectively, has been developed and tested [6]. The goal of the HyCARE project is to store renewables using H_2 as energy vector, developing an integrated system composed by an electrolyzer (EL), the mentioned hydrogen - heat storage system, and a Fuel Cell (FC), for the storage of energy for smart grid applications. The plant will be installed at ENGIE Crigen lab near Paris in 2022 and involves European industries, research institutes and universities. About 40 - 45 kg of H_2 will be stored directly form the EL at ~ 55°C, at a pressure between 25-30 bar, and it will be released at 1-2 bar to directly supply the FC. As MH, the IMC $TiFe_{0.85}Mn_{0.05}$ has been selected [7] and it has been produced at industrial scale, showing suitable properties for hydrogen storage in the plant conditions [8]. Whereas, for the heat storage a sustainably sourced and bio-based material has been selected as PCM. The feasibility of the HyCARE concept was proven through a prototype composed by a PCM module and MH-tank. This work reports the results of the tests performed to understand how the two modules can operate together in the best operative conditions, reducing the amount of external heat supplied.

MATERIALS AND METHODS

The set-up of the MH-PCM system is depicted in Fig. 1. An external power source (EPS) is used to circulate the thermal vector fluid (TVF), controlling its temperature, with both heating and cooling contributions. The TVF flows from the EPS to the MH-tank, to the PCM-module to finally return to the EPS. The flow is controlled by setting the pressure level in

the EPS, resulting in different flowrates, depending on the pressure drop of the circuit, and it is measured by a liquid flowmeter placed between the EPS and the MH unit. Thermocouples are located inside the MH-bed, the PCM-volume and at the inlet and outlet of the thermal fluid of each system. Also, hydrogen pressure and flow are monitored thanks to suitable sensors. The prototype has about 1/5 of the size of a final module; in the final HyCARE demonstrator 12 modules each for PCM and MH are planned. The MH prototype tank consists of a tube of 6 inch of diameter and about 1 m long, capable of storing ~ 0.5 kg of H_2.

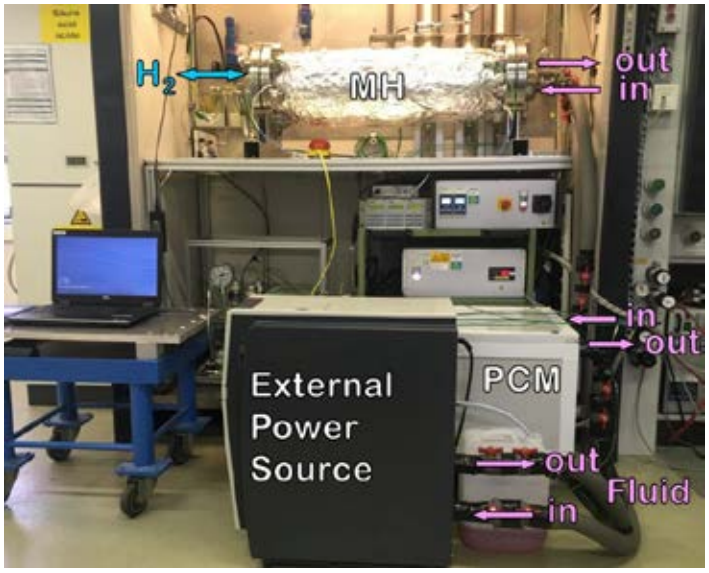

Fig. 1. Set-up of the coupled PCM-MH system with the EPS

RESULTS AND DISCUSSION

In order to find the best operative conditions, to minimize the amount of external power required, different parameters were evaluated during the tests, *i.e.,* external power contribution, started working temperature, as well as H_2 and thermal fluid flowrates. In all experiments, the hydrogen loading (absorption) occurs up to 30 bar, while the hydrogen unloading (desorption) takes place at about 2 bar, according to the plant operative conditions, defined for the selected alloy [8], that represent the integration of the system with an electrolyser upstream and a fuel cell downstream. Different H_2 flowrates have been considered:

- 160 Nl/min, *i.e.* the maximum available flow from the electrolyzer in the final HyCARE demonstrator,
- 80 Nl/min, corresponding to half of the maximum flow,
- 32 Nl/min, that is 1/5 of the maximum flow, since the prototype size is about 1/5 of the final module.

According to the selected H_2 flowrate, the flow of the thermal fluid is calculated and adjusted to manage properly the maximum power developed/required, in order to keep a temperature difference of approximately 7 °C between MH and PCM tanks. These boundary conditions imply that, for an H_2 flow of 160 Nl/min, a TVF flow of about 6 l/min is necessary; similarly, for an H_2 flow of 80 Nl/min, about 3 l/min of TVF flow are needed, while for an H_2 flow of 32 Nl/min, the TVF flow must be about 1 l/min. The influence of the EPS on the thermal management of the coupled system has been evaluated, considering the effect of its energy intake with heating/cooling both active, or completely deactivated, or only providing heat. The latter setup represents the scenario most similar to the contribution of solar panels in the final demonstrator. Different starting temperatures were also considered, to maximize the PCM contributions in the heat management of the coupled system, starting the absorption with the PCM totally solid, or partially liquid.

Finally, in some tests, the absorption occurred only when the pressure in the tank allowed a constant H_2 flowrate, resulting in an intermittent process. After several trials, the optimal working conditions were established. It was proven that the two modules are able to work nicely together, limiting contributions from the EPS, which mainly acted during the early stages of the reactions, just to overcome the heat losses. Then, in the final part of the reactions, its contribution increased again, because of the lower amount of H_2 absorbed/desorbed that implied a lower amount of heat exchanged between the two modules. Due to this reason, the best strategy includes the use of only constant hydrogen flow.

CONCLUSIONS

The feasibility of a coupled system for hydrogen-heat storage, based on metal hydride and phase change material, has been successfully proven through the realization and test of a prototype system that involves a $TiFe_{0.85}Mn_{0.05}$ as MH

and a bio-based materials as PCM. By varying the parameters, like the hydrogen and thermal fluid flowrates and the starting working temperature, it was possible to develop a strategy that allows a minimal contribution of an external power source. Indeed, the external power intake has been found to be necessary just to compensate the heat losses, while the PCM is able to successfully manage the heat for the MH processing. In particular for the final system, it has been evaluated to proceed starting the absorption with the PCM partially melted, *i.e.,* close to 53°C, performing reaction by applying only a constant hydrogen flow, in order to avoid that the external power source needs to contribute in the final part of reaction, because of the lower amount of hydrogen that can be processed.

ABSTRACT

Power systems using renewable energy sources have emerged as a sustainable solution for decarbonizing the energy sector. Implementing such systems requires integrating them with an efficient storage medium to improve their reliability and flexibility. This work explores the modeling and parameterization of a fuel cell system, with the purpose of coupling it with a metal hydride-based hydrogen storage reservoir. An electrical and thermal 0D simulation model for a 1.6 kW air-cooled proton exchange fuel cell stack is developed to investigate its performance, heat transfer and temperature development. The model validation and simulation are done by testing it with four different steady-state power demand scenarios. Experimental results show an efficient thermal coupling between the fuel cell stack and the metal-hydride system. Simulations and experimental results show an excellent agreement. The developed modeling approach is also appliccable to the design of different gas-to-power configurations and sizes, for the design of fuel cell–metal hydride storage systems.

Keywords: PEM fuel cell, 0D-modelling, Matlab-Simulink-Simscape, system integration, gas-to-power

INTRODUCTION

In view of the increasing energy consumption of the world's population, the search for reliable and sustainable fuels and energy sources is becoming increasingly important to decarbonize the energy sector. Efficient and flexible energy storage systems are essential to compensate for insufficient energy generation periods and temporarily store excess energy production. One promising way of storing electrical energy from renewable sources is to use hydrogen as an energy carrier, due to its large gravimetric energy density of 142 MJ/kg [1]. Hydrogen production *via* electrolysis and its combination with different kinds of hydrogen storage systems has been increasingly investigated as a potential solution for large-scale applications to cover the rising energy demand [2]. Among the explored power-to-gas configurations, using a solid-state hydrogen storage system offers an efficient and safe solution for long-term storage. In this way, hydrogen can be provided to a fuel cell for electrical power generation as required [3-5].

This work presents the design of a simulation model for a 1.6 kW air-cooled proton exchange membrane fuel cell (PEMFC) developed using Matlab/Simulink/Simscape. In the frame of the MH2-Powerbank [6] and Digi-Hypro projects, the developed simulation model is validated *via* experiments carried out in an integrated backup fuel cell and a metal hydride storage system composed of TiFeMn hydride forming alloy.

MODEL CONCEPTUALIZATION AND EXPERIMENTAL SETUP

The working principle of a PEMFC is governed by a redox reaction where hydrogen and oxygen react to produce electrical power (P_{el}) as the main product, water, and heat (Q) as a by-product. In this way, the electrical power and heat generation are connected.

$$2H_2+O_2 \rightarrow 2H_2O+P_{el}+Q \quad (1)$$

Fig.1 a) shows a diagram of the entire PEMFC simulation model concept. For the determination of the electrical power (V_{fc}), the electrical model takes into consideration the thermodynamic output voltage (E) minus the activation and ohmic losses ($R_{ohm} \cdot i_{fc}$) from the fuel cell by applying equation (2):

$$V_{fc} = E - R_{ohm} \cdot i_{fc} \quad (2)$$

The thermal model calculates the temperature of the cooling air at the exhaust area of the fuel cell (T_{out}) and the fuel cell temperature (T_{fc}) using the generated heat from the fuel cell ($\dot{Q}_{gen}$) in the description of the total heat flow of the fuel cell stack as described by equation (3):

$$\Delta\dot{Q} = -\dot{Q}_{gen} - \dot{Q}_{diss} \quad (3)$$

where the heat losses are due to forced convection ($\dot{Q}_{conv}$) and conduction ($\dot{Q}_{cond}$)

$$\dot{Q}_{diss} = \dot{Q}_{conv} + \dot{Q}_{cond} \quad (4)$$

$$\dot{Q}_{conv} = h \cdot A_{stack} \cdot (T_{FC} - T_{amb}) \quad (5)$$

The heat transfer coefficient (h) calculation was done using three non-dimensional numbers, Prandtl, Reynolds and Nusselt, assuming for the case of Nusselt number a stream length surrounding a flat plate.

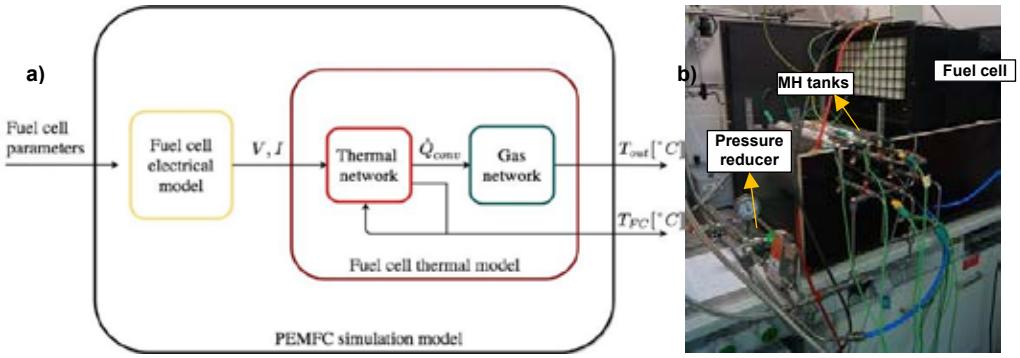

Fig 1. Diagram of the PEMFC simulation model (a) and the experimental setup used in MH2 Powerbank (b)

The general assumptions for the thermal model are that:

- The fuel cell stack is enclosed in a adiabatic casing.
- The fuel cell stack is a rectangular-shaped solid block uniformly heated and gets cooled by external flow of air.
- The radiation losses are neglected.

The experimental setup is shown in Fig. 1 b) and it was operated at standard temperature (25 °C). The fuel cell was tested with an external electrical load in a dynamic state and pressurized tanks to obtain the polarization curve. The operative pressure of the fuel cell is 1.4 bar and it was regulated with a pressure reducing valve. To test the thermal coupling of MH2 Powerbank (metal hydride tanks and fuel cell) the electric load was used for four different power scenarios (60.8 W, 121.4 W, 240.3 W, and 467.4 W) at a steady state for 1 hour. The experimental setup was equipped with an anemometer to measure the exhaust air velocity coming from the fuel cell to calculate the thermal behavior.

RESULTS AND DISCUSSION

Figure 2 shows the experimental and simulated results of the compensated polarization curves and the temperature profile of the exhaust air of the fuel cell (T_{out}) for 240.3 W as an example of all carried out experiments. As seen in Figure 2 a), the validation for the electrical model is done by comparing the compensated polarization curve and the simulated data in a range between 0 A and 34.24 A where the linear voltage drops from 49.5 V to 47.95 V. The voltage compensation installed in the FC (green line in Figure 2 a)) after 34.24 A does not work properly anymore. Thus, the voltage starts to fluctuate and then decreases until it reaches a value of 14.15 V. The simulated data (red line) defines the useful work range of the fuel cell. The results provided by the electrical model exhibit an excellent agreement with the experimental results with a correlation coefficient 0.9223.
The validation for the thermal model has been done under four different power demand scenarios by comparing the experimental data of the exhaust air temperature (T_{out}) of the fuel cell and the simulated data. Figure 2. b) shows an example of the results for a power demand of 240.3 W under steady-state. Measured data shows a significant drop in temperature of about 10 °C at 1.6 min. This drop is due to a misreading in the anemometer located at the exit of the fuel cell case. The model is in perfect agreement with the measured (correlation coefficient 0.9808). The simulated fuel cell temperature is also obtained (T_{fc}) and applied as a reference parameter for the accuracy of the thermal model.

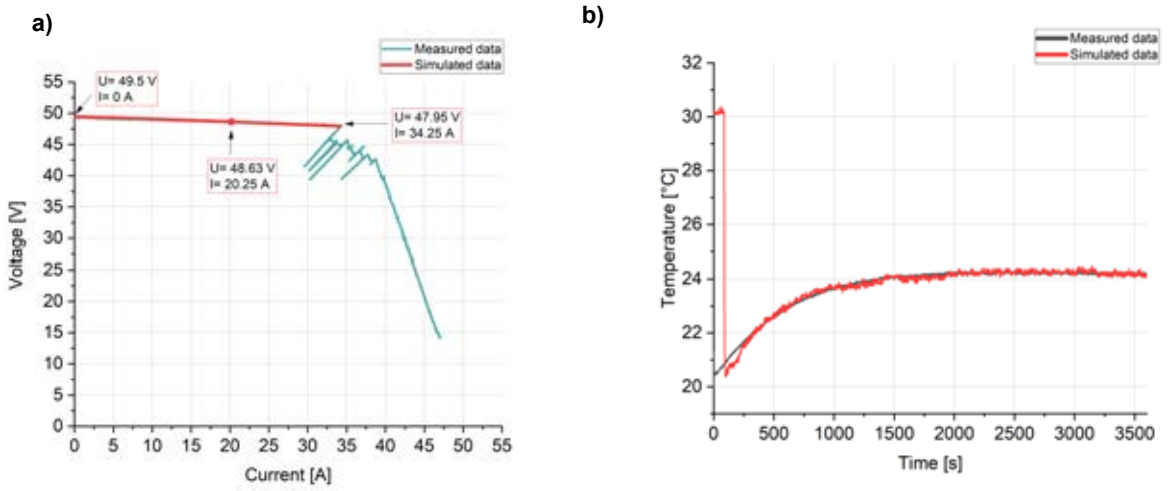

Fig 2. Simulation and experimental results for the electrical a) and the thermal b) behavior of the PEMFC for an experiment carried out at 240.3 W. The correlation coefficient for the electrical model validation is 0.9223 and for the thermal model 0.9808.

CONCLUSIONS

The integrated system (MH2 Powerbank) can provide constant electrical power from 60.8 W to 467.4 W at steady-state conditions. The experimental outcomes show that the output voltage of the fuel cell is compensated for delivering a constant voltage of about 48 V in the case of an emergency power supply. Despite this, the developed electrical and thermal system models allow defining an operative work range of the fuel cell and show an excellent agreement with the experimental results having correlation coefficients of 0.9223 and 0.9808, respectively. The developed fuel cell system model can be applied for system integration into a fuel cell-metal hydride storage system, to test it under dynamic power demand scenarios.

ABSTRACT

Sustainable resource and energy management are essential considerations in designing hybrid energy systems. Finding an optimal framework that combines the requirements for a reliable design and satisfaction of continuous operation at minimal costs in all operating conditions is essential to clients and investors. This study emphasizes the size optimization of grid-connected hybrid photovoltaic, wind, and hydrogen storage systems. In this regard, by adopting the Hybrid Optimization Model for Electric Renewable (HOMER) energy-balance methods, the optimal design architecture is established. Additionally, the system's technical and economic aspects were examined in this study. Analysis of hourly simulations was performed to decide the optimal size, cost, and performance of the hybrid system. The optimum design configuration consists of a 2 kW PV array, 1 wind turbine, 1.33 kW converter, 2 kW electrolyzer, 5 kg hydrogen tank, 2.5 kW fuel cell, and 100 kW grid. Levelized Cost of Energy (COE) and Net Present Cost (NPC) are 0.169 $/kWh and $ 25,879.11 respectively, for different renewable energy fraction (RF) values of 91.5%.

Keywords: Renewable energy, Optimum sizing, Solar energy, Wind energy, Hydrogen

INTRODUCTION

Population growth and rapid technological advancements have led to a significant rise in energy demand and energy consumption worldwide. Globally, fossil fuels are a prominent source of electricity which increasing utilizing of them, increases global warming and greenhouse effect risks [1]. An important and reliable alternative energy source is solar energy; however, its storage is essential to utilize this resource [2]. In addition to batteries, hydrogen increases interest in storing renewable energy sources such as solar energy and wind energy. Hydrogen is the lightest, simplest, and most abundant element of the universe and has the biggest energy content per unit mass of any other fuel [3]. In addition to being a fuel, hydrogen can also be an energy carrier that can store and transport energy [4]. Practical hydrogen storage is still a big challenge which implementing hydrogen in our daily life still has many problems [5]. Several studies are being carried out on hydrogen to store energy longer than batteries[6-8].

The water electrolyzer, fuel cell, and hydrogen tank are considered as alternative storage systems. In this system, the generated power through solar power covers the load demand, and the excess energy runs through the water electrolyzer to produce hydrogen. The hydrogen tank is considered for storing the hydrogen for later use.

Based on an analytical model, Yunez-Cano et al. [9] proposed a hybrid photovoltaic/hydrogen (PV/H_2) system consisting of electrolyzer, hydride metal alloy tanks, and polymeric fuel cells system as a safe, small, and reliable electricity backup system that can meet the electricity of an isolated mobile home in Mexico. In another study, D. Maclay et al. [10] developed and tested an experimental solar-hydrogen-powered residence simulator. The system consisted of an electrolyzer powered by a solar photovoltaic array that produced hydrogen to serve as a storage device for energy. Fuel cells generated electricity from hydrogen in parallel with batteries to meet the dynamic power demands of residential applications. In order to compete with conventional energy storage systems, such systems would need to be significantly less expensive. Taking into account the climatic conditions of Saudi Arabia, Rahman et al. [11] examined the energy storage systems to store electricity generated by renewable sources. As a result of their findings, they concluded that no one storage system could satisfy all the requirements for an ideal electrical energy storage system.

This paper aims to optimize the size of a hydrogen fuel cell/photovoltaic/wind grid-connected hybrid system using the Hybrid Optimization of Multiple Energy Resources (HOMER) algorithm. The hybrid system is expected to satisfy daily and yearly load requirements of a typical single house in Toronto, Canada, at a low energy cost and a high renewable energy contribution and reduce excess power and harmful emissions. Previous studies have made a few efforts to apply hybrid systems (wind and solar energy) in cold climate countries to evaluate an on-grid connected system.

MATERIALS AND METHODS

As part of a feasibility study, load profiles, climate data of solar radiation (average solar radiation intensity of 3.53 kWh/m^2/day), and wind speed (average wind speed of 6.88 m/s) at the selected area are collected. Then a computer-aided renewable energy simulation tool was used to estimate the optimum design configuration and the cost of implementing the solution. The system modeling includes photovoltaic panels, wind turbines, electrolyzer, fuel cell, hydrogen tank, and converter systems (Figure 1).

This study uses HOMER software to design, simulate, analyze, and determine the economic feasibility of the system. The total Net Present Cost is calculated for evaluating the life-cycle cost in HOMER. NPC comprises set-up, replacement, operations, maintenance, and mixing costs associated with emissions. In designing a system in HOMER, the cost of energy (COE) is another crucial factor to consider.

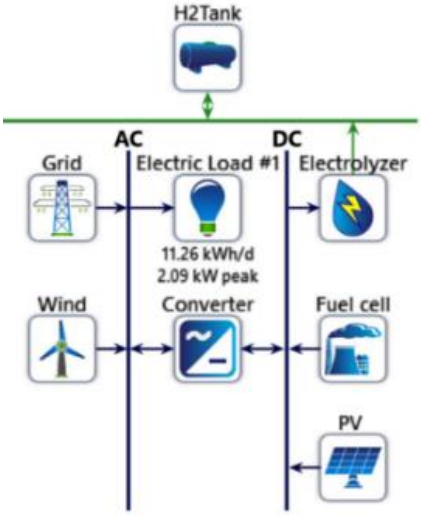

Figure 1. Schematic diagram of the system.

RESULTS AND DISCUSSION

According to the previous results, renewable energy systems with solar modules, wind turbines, and any storage system have the lowest cost of production due to the availability of resources [13,14]. It is impossible to generate solar power at night and wind power when the local wind speed at the hub height is less than the wind turbine's cut-in wind speed. In this study, the system integrates solar and wind energy to make up for the weaknesses of the other. As a result, the levelized and total energy costs would be decreased. The PV array and wind turbine provide load demand, while the stored hydrogen in the tank produces electrical energy through the fuel cell. The results showed that wind turbines have the crucial role in electrical energy production than fuel cell and photovoltaic panels.

During the simulations, many configurations are designed to find the optimum one. The size of the PV array varies from 1 to 5 kW; the number of the wind turbines varies from 1 to 3; the size of the electrolyzer varies from 1 to 10 kW; the size of the hydrogen tank varies from 1 to 20 kg. Table 1 shows the optimum size and cost of the system components. The optimum design configuration consists of a 2 kW PV array, 1 wind turbine, 1.33 kW converter, 2 kW electrolyzer, 5 kg hydrogen tank, 2.5 kW fuel cell, and 100 kW grid with COE of 0.169 $/kWh and NPC of $ 25,879.11. Figure 2 shows the cost summary for each of the components in the simulated system. By deducting the cost of the system, which includes the cost of purchase, repair, and replacement of equipment, the colored bars below the zero line represent the income of hybrid systems and as negative costs to calculate the total net cost of the hybrid system. The wind turbine has the highest capital cost ($22,831), followed by PV ($5,259).

This simulated hybrid power plant is connected to the grid, and simulations have been conducted using the grid. Table 2 provides information about the grid for the simulated hybrid power plant. As shown, 7,521 kWh of energy is sold compared to 987 kWh of it is purchased annually. Based on these results, a hybrid system consisting of both solar and wind power can meet the load demand all over the year with a minimum cost.

CONCLUSIONS

This paper develops and investigates a grid-connected renewable energy-based system in Toronto, Canada, consisting of a photovoltaic array, wind turbine, electrolyzer, hydrogen tank, and fuel cell. The system's solar and wind energy combination leads to 100% renewable energy contribution in around a year. For example, During the night where no solar radiation is available, wind energy supplies energy, and the storage system meets the load requirements if the wind speed is less than the wind turbine's cut-in wind speed. HOMER software is used to find the

optimum configuration with ideal components size and minimum COE and NPC. According to the results, the optimum design configuration consists of a 2 kW PV array, 1 wind turbine, 1.33 kW converter, 2 kW electrolyzer, 5 kg hydrogen tank, 2.5 kW fuel cell, and 100 kW grid which leads to a minimum COE of 0.169 $/kWh and NPC of $ 25,879.11. The production of hydrogen using renewable energy resources allows the use of an environmentally friendly fuel. Study results demonstrate that the proposed flexible design can meet the loads, support continuous operation, and reduce harmful environmental emissions.

ABSTRACT

Molecular dynamics simulations were performed in order to analyze the hydrogen sorption kinetics between α-MgH_2 and hcp Mg structures under different temperatures and pressures. Results showed that hydrogen desorption from magnesium hydride and absorption by hcp magnesium increase at the higher temperatures. During the hydrogen desorption from magnesium hydride and absorption into hcp magnesium, crystallographic orientation change in the magnesium atoms was observed. At 400 °C, the pressure was found to have a negative impact during the hydrogen desorption from magnesium hydride due to the prevention of recrystallization.

Keywords: Magnesium hydride, Hcp magnesium, Molecular dynamics, Hydrogen sorption kinetics

INTRODUCTION

Increasing demand for alternative energy sources and the harmful effects of fossil fuel usage gradually draw attention to hydrogen energy [1,2]. However, in order to use hydrogen in practical applications, several obstacles still need to be overcome. One of the most important challenges in this regard is the storage of hydrogen [3,4]. Conventional storage techniques such as storing the hydrogen as a liquid at cryogenic temperatures or in the form of pressurized gas are quite inefficient way in terms of the small gravimetric and volumetric capacity and also for the high cost of operation [5]. However, new materials and methodologies are being developed in recent years for solid storage of hydrogen that has significant advantages compared to the conventional methods. Within these solid storage materials, magnesium hydride structures constitute a promising solution for the storage of hydrogen in high capacities [6,7]. Besides, for a better understanding of the hydrogen uptake and release kinetics and also for developing new Mg-based hydrogen storage structures, atomistic modelling of the hydrogen sorption mechanisms is crucial. In this study, hydrogen diffusion in the interface of Mg/MgH_2 was investigated under the effect of different temperatures and pressures by Molecular Dynamics (MD).

METHODOLOGY

Molecular dynamics simulations were performed by LAMMPS [8] (Large-scale Atomic/Molecular Massively Parallel Simulator) software. A bicrystal was constructed that is composed of alpha magnesium hydride and hcp magnesium where the two structures were merged along one direction (figure 1). Temperature and pressure equilibration was performed on the bicrystal by NPT ensemble at room temperature and 0 isobaric pressure for 0.25 ns. Simulations for the diffusion of hydrogen were performed under 3 different temperatures (200 °C, 300 °C, 400 °C) and 3 different isobaric pressures (0 GPa, 0.5 G, 1 GPa), i.e. 9 simulations were performed in total, by NPT ensemble for 1.5 ns. Periodic boundary conditions were utilized in all three directions. In order to evaluate the hydrogen absorption of the hcp magnesium and desorption from magnesium hydride, total diffused hydrogen number in the half bottom part of the simulation cell along y direction (N_d) was tracked during the NPT ensemble, and normalization was applied with respect to total hydrogen content in the simulation cell (N_t) where the normalized hydrogen content is:

$$N_n = \frac{2N_d}{N_t} \quad (1)$$

For the interatomic interactions, angular dependent potential (ADP) was utilized [9]. Visualization, common neighbor analysis (CNA), and determination of the atomic positions were performed by OVITO software [10].

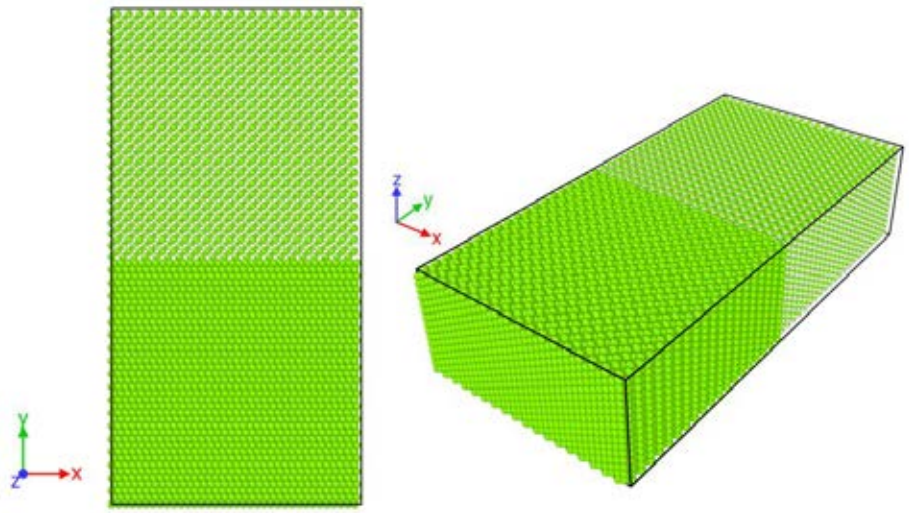

Fig. 1. Initial configuration of simulation cell; green balls represent the magnesium atoms and white balls represents the hydrogen atoms.

RESULTS AND DISCUSSION

Figure 2 shows the normalized diffused hydrogen content under different temperatures and pressures during the NPT ensemble. Results indicate that diffusion of the hydrogen increases when increasing the temperature. The most diffusion takes place under 400 °C for all pressure values. On the other hand, at both 200 °C and 300 °C, it was observed that normalized concentration does not exceed 0.1 and the concentration was equilibrated before 0.2 ns. Distinctive desorption of hydrogen from MgH_2 and absorption by the Mg was observed under 400 °C temperature and 0 isobaric pressure. Although the hydrogen uptake rate is equal under all pressures values at 400 °C until 1 ns, an earlier decrease in the rate was observed at pressurized simulations.

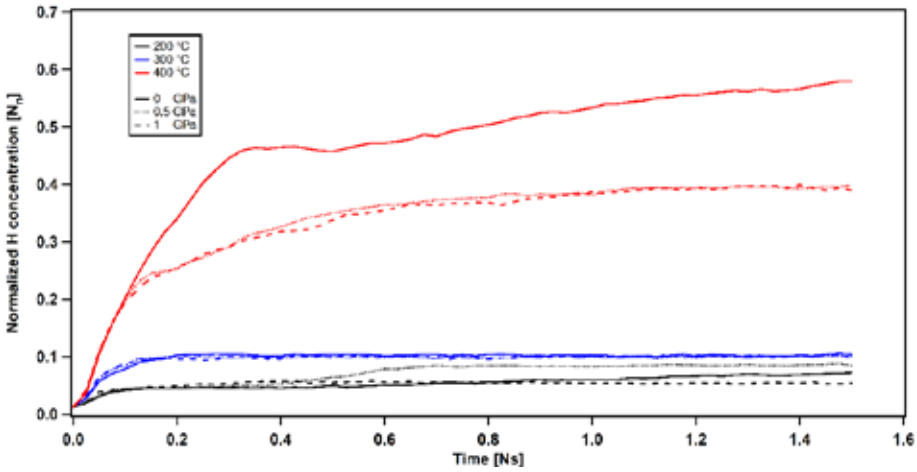

Fig. 2. Absorbed hydrogen content by initial hcp magnesium region (half bottom part along y axis) under different temperatures and pressures.

Crystallographic structure types according to common neighbour analysis (CNA) were shown in figure 3. In the initial case, evaluating the positions of only Mg atoms provides a crystal structure similar to BCC at the upper half part of the simulation cell (α-MgH_2) where the bottom part consists of hcp Mg (figure 3a). Similarly, figure 3b, 3c, 3d, and 3e show the structure types of the Mg atoms after the sorption of hydrogen. It was found that hydrogen desorption from α-MgH_2 and absorption by the hcp magnesium crystals lead to a transformation to fcc type structure during the temperature and pressure simulations starting from the Mg/MgH_2 interface. In both 200 °C and 300 °C, transformation from bcc to fcc and hcp to fcc structure takes place at the interface in a very limited region. However, at 400 °C for each pressure value, bcc type crystallographic structure of the Mg atoms in MgH_2 completely transforms to fcc type structure at the end of the simulations. Only in the 400 °C and 0 GPa (figure 3e), a different crystallographic orientation in the fcc structure was observed after recrystallization. On the other hand, in

pressurized simulation cells under the same temperature (figure 3d), the formation of the fcc structures is in the same orientation with the lower temperature simulations and no recrystallization was observed.

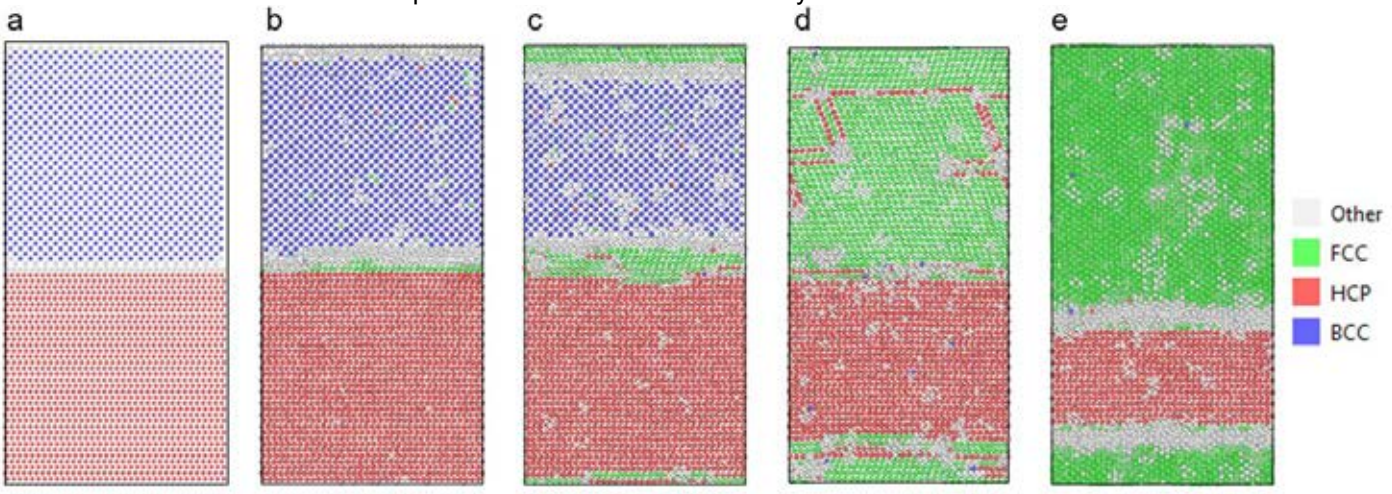

Fig. 3. Crystallographic structure types of only magnesium atoms for a) initial relaxed simulation cell and b), c), d), and, e) after the hydrogen diffusion simulations at 200 °C 0 GPa, 300 °C 0 GPa, 400 °C 1 GPa and, 400 °C 0 GPa respectively.

CONCLUSIONS

In conclusion, the effect of the temperature and pressure on the sorption of hydrogen in magnesium and magnesium hydride was investigated by molecular dynamics simulations. It was observed that higher temperatures lead to an increased uptake and release rate for all pressures values. Additionally, during the hydrogen desorption from magnesium hydride phase at elevated temperature, recrystallization of the magnesium atoms was observed under 0 GPa pressure which enhanced the hydrogen desorption.

ABSTRACT

To ensure the safety of hydrogen refueling systems and fuel cell vehicles under different conditions, the filling parameters are usually set very conservatively and lead to waste energy consumption and investment. The lumped parameter hydrogen gas model and one-dimension tank wall model of the hydrogen filling process previously proposed by our team are improved by considering the Joule Thomson effect and kinetic energy and using a more accurate model of the heat transfer coefficients between hydrogen gas and inner tank wall and between ambient and outer tank wall. Based on our validated model, the effects of constant and two-stage average pressure rise rate (APRR) and inlet temperature on refueling performance were investigated, respectively. Compared with the optimal filling strategies of the reference papers, the current strategies with two-stage APRRs and inlet temperatures can further reduce the cooling power by 23.8% and 16.3%, respectively, without increasing the cooling consumption. It is beneficial to reduce the equipment cost of the refrigeration system.

Keywords: Hydrogen refueling, Precooling, Average pressure rise rate, Filling strategies, Refueling performance

INTRODUCTION

SAE J2601 protocol stipulates that during the hydrogen refueling, the temperature inside the onboard tank should not exceed 85 ℃, the pressure should not exceed 125% of the nominal working pressure, and the refueling time required to be within 3-5 min. The look-up table method and the MC method meet the above requirements. However, to ensure the safety of the hydrogen refueling systems and fuel cell vehicles under different conditions, the filling parameters are usually set very conservatively. The filling parameters that affect the refueling performance should be studied and adjusted according to the specific situation to obtain a higher state of charge (SOC), less energy consumption and investment. The filling parameters such as ambient temperature, initial temperature and initial pressure in different regions or vehicles are not easily controlled manually, so this paper only studies the precooling/inlet temperature, filling rate (APRR) and filling time. Our team has built three lumped parameter models of hydrogen storage tanks: single-zone (hydrogen), dual-zone (hydrogen and tank wall) and triple-zone (hydrogen, tank wall liner and shell) models. These models are well-validated and used to predict filling time, final hydrogen temperature, and mass and inlet temperature based on experimental data and references. This paper further improves our previous model by considering the Joule Thomson effect and kinetic energy and using a more accurate model of the heat transfer coefficients between hydrogen gas and the inner tank wall and between the ambient and outer tank wall. Based on our validated model, the effects of constant and two-stage APRRs and inlet temperatures on refueling performance were investigated, respectively.

2 THERMODYNAMICS MODEL

Fig. 1 shows the thermodynamic model of a hydrogen refueling system, improved from our previous model [1]. The Joule Thomson effect and the kinetic energy are expressed in Eq. (1-2). The accurate formula for the heat transfer coefficients between hydrogen and the inner tank wall and between ambient outer tank wall and ambient are expressed in Eq. (3-4) [2].

$$\mu_{JT} = \left(\frac{\partial T}{\partial p}\right)_h \tag{1}$$

$$\dot{E}_k = \frac{\partial}{\partial t}\left[\int_{CV}\left(\frac{1}{2}v^2\right)\rho dV\right] = \frac{8\dot{m}^3}{\pi^2\rho^2 d_{\text{in}}^4} \tag{2}$$

$$\text{Nu}_{D_{\text{in}}} = \frac{a_{\text{in}} D_{\text{in}}}{\lambda_{\text{gas}}} = a\text{Ra}_{D_{\text{in}}}^{b} + c\,\text{Re}_{d_{\text{in}}}^{d}\ ,\ \ \text{Ra}_{D_{\text{in}}} = \frac{g\beta|T - T_w|c_p\rho^2 D_{\text{in}}^3}{\mu\lambda}\ ,\ \ \text{Re}_{d_{\text{in}}} = \frac{\rho v d_{\text{in}}}{\mu} = \frac{4\dot{m}}{\pi\mu d_{\text{in}}} \tag{3}$$

$$\text{Nu}_{D_{\text{out}}} = \frac{a_{\text{out}} D_{\text{out}}}{\lambda_{\text{air}}} = \left(0.4\text{Re}_{D_{\text{out}}}^{0.5} + 0.06\text{Re}_{D_{\text{out}}}^{2/3}\right)\text{Pr}_{\text{air}}^{0.4}\ ,\ \ \text{Re}_{D_{\text{out}}} = \frac{\rho_{\text{air}} v_{\text{air}} D_{\text{out}}}{\mu_{\text{air}}}\ ,\ \ \text{Pr}_{\text{air}} = \frac{\mu_{\text{air}} c_{p_{\text{air}}}}{\lambda_{\text{air}}} \tag{4}$$

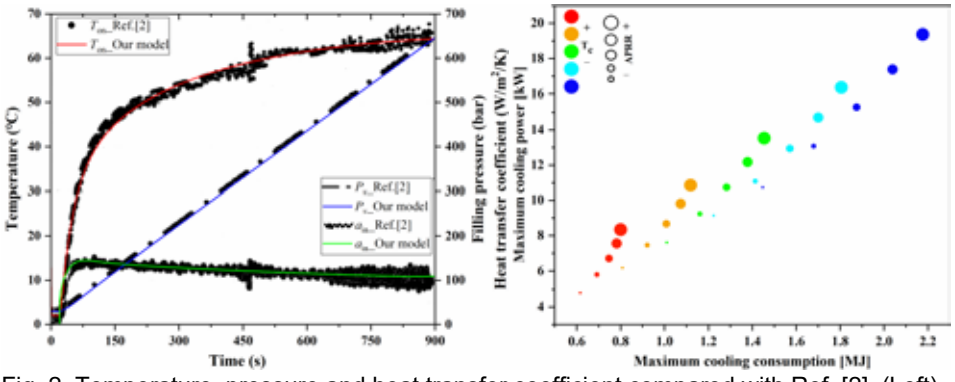
3 MODEL IMPLEMENTATION, VALIDATION

3.1 Model implementation

The model is implemented on Matlab/Simulink platform. Table 1 shows the parameters of onboard tank in current study.

Table 1. Parameters of the onboard tank in the current study.



Tank geometry [2]		Tank characteristics [3]	
Volume of the tank, L	90.5	Thermal conductivity for Liner, W/(m·K)	0.4
Nominal working pressure, MPa	70	Specific heat capacity for Liner, J/(kg·K)	1917
Internal length, m	0.58	Density for Liner, kg/m³	954
Internal diameter, m	0.434	Thermal conductivity for CFRP, W/(m·K)	0.53
Outer diameter, m	0.484	Specific heat capacity for CFRP, J/(kg·K)	942
Diameter of the injector, m	0.006	Density for CFRP, kg/m³	1442

Table 2. Initial and boundary conditions for model validation [2].

Initial pressure, MPa	3
Initial temperature, ℃	1.9
Ambient temperature, ℃	1.9
Inlet temperature, ℃	7.9
APRR, MPa/s	0.07

3.2 Model validation

Table 2 shows initial and boundary conditions for model validation. Fig. 2 shows the model verification results. The simulation values are consistent with reference data [2].

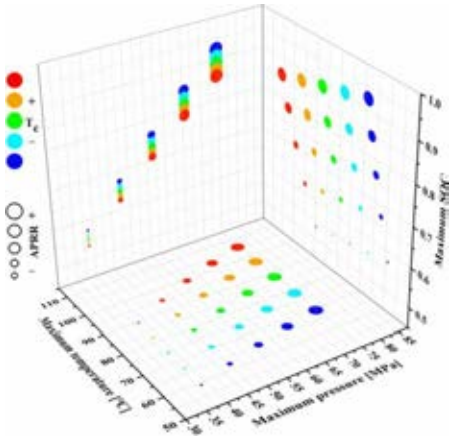


Fig. 2. Temperature, pressure and heat transfer coefficient compared with Ref. [2]. (Left)
Fig. 3. Effects of constant APRRs and inlet temperatures on maximum cooling consumption and power. (Middle)
Fig. 4. Effects of constant APRRs and inlet temperatures on maximum temperature, pressure and SOC in the onboard tank. (Right)

4 PARAMETRIC STUDY

4.1 Constant APRR and inlet temperature

We investigated the refueling performance of different constant APRRs and inlet temperatures. The parameters are shown in Table 3. There are 5 sets of parameters for APRR and inlet temperature, respectively, so there are 25 kinds of results. As shown in Fig. 3, maximum cooling consumption and power increase almost linearly when APRR increases or inlet temperature decreases. Fig. 4 shows the projection of the 25 results on three faces. The inlet temperature has little effect on the pressure, has a large effect on the SOC, and has the greatest effect on the temperature. The APRR has a small effect on the temperature and a large effect on the SOC and pressure.

Table 3. Value of parameters.

Time [s]	APRR [MPa/s]	Tc [℃]
180	0.2	−20
180	0.25	−10
180	0.3	0
180	0.35	10
180	0.4	20

Table 4- Maximum results of typical cases and relative rate of change.

Case		Temperature [℃]	SOC	Cooling consumption [MJ]	Cooling power [kW]
Inlet temperature = −20 ℃	**Case1**	**69.988**	**0.966**	**2.124**	**19.999**
	Case4	70.379 (+0.5%)	0.959 (−0.7%)	2.118 (−0.3%)	15.246 (−23.8%)
APRR = 0.428 MPa/s	Case1	79.987	0.947	1.697 (−1.7%)	14.846 (−11.3%)
	Case2	**79.983**	**0.947**	**1.727**	**16.730**
	Case4	80.001	0.947	1.687 (−2.3%)	16.199 (−3.2%)
	Case5	79.929	0.947	1.709 (−1.0%)	15.854 (−5.2%)
	Case6	79.937	0.947	1.693 (−2.0%)	13.999 (−16.3%)

4.2 Two-Stage APRR and inlet temperature

We investigated the refueling performance of different two-stage APRRs at inlet temperatures of -20, -10, 0, 10 and 20 °C. Since the pattern is similar at each inlet temperature, only the one at −20 °C is shown in Fig. 5. Cases 2, 3 and 5 are significantly worse in temperature, pressure and SOC, so we can compare only cases 1 and 4, as shown in Table 4. Case 4 is significantly better than case 1. We also investigated the refueling performance of different two-stage inlet temperatures at APRR of 0.428. Case 6 is significantly the best, as shown in Table 4.

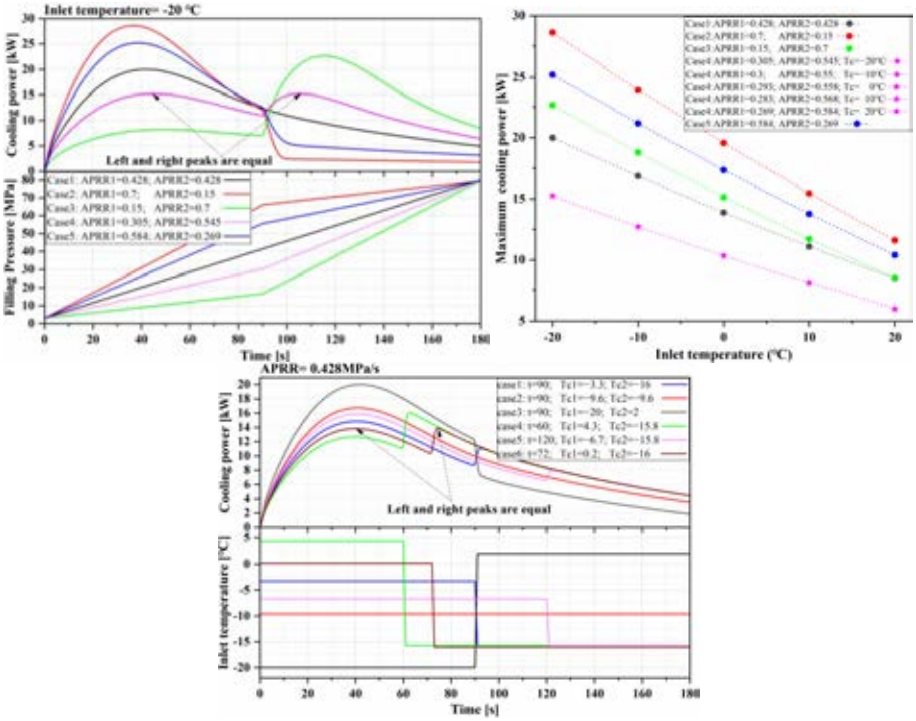

Fig. 5. Effect of different two-stage APRR strategies on cooling power at an inlet temperature of -20°C. (Left)
Fig. 6. Effect of different two-stage APRR strategies on maximum cooling power at different inlet temperatures. (Middle)
Fig. 7. Effect of different two-stage inlet temperature strategies on cooling power at APRR of 0.428. (Right)

5 CONCLUSIONS

We improved the lumped parameter hydrogen gas and one-dimension tank wall model of the hydrogen filling process previously proposed by our team, mainly including adding the Joule Thomson effect, the conversion of kinetic energy to internal energy, and the accurate modeling of the heat transfer coefficients between hydrogen and inner tank wall and between ambient and outer tank wall. The effects of constant and two-stage APRRs and inlet temperatures on hydrogen refueling performances are studied based on our validated model. The specific conclusions are as follows:

- Compared with the previous research results where the best filling strategy is linear APRR [4], we can always find two-stage APRR1 and APRR2 at different inlet temperatures, which can further reduce the cooling power by 23.8% without increasing the cooling consumption.
- Compared with the previous results obtained using a constant precooling/inlet temperature solved by the analytical solution, we can always find two-stage precooling/inlet temperatures Tc1 and Tc2 to further reduce the cooling power by 16.3% without increasing the cooling consumption.

ABSTRACT

In the current work, we present an investigation about modeling the lithium reactive hydride composite (Li-RHC) under desorption conditions. Such modeling is fundamental to enable finite element simulations (FEM) to design optimized hydrogen storage systems. In order to obtain the kinetic data for the study, the dynamic behavior of ball-milled Li-RHC powder is characterized in a Sievert apparatus. Different combinations of pressure and temperature are assessed and the reaction mechanisms of both MgH_2 and $LiBH_4$ are individually identified. The MgH_2 decomposition follows a JMAEK with n = 1 reaction mechanism, while the Prout-Tompkins (PT) model describes the reaction mechanism of $LiBH_4$ very well. However, the PT model involves a new parameter, t_0, associated with the vertical translation of the fitted curve. In order to make the equation applicable for FEM simulations, a novel method is here developed to represent t_0 as a function of the system's parameters, namely, temperature and pressure. This study provides new capabilities of using the PT model to predict the behavior of the desorption of $LiBH_4$ within a wide range of temperature and pressure conditions.

Keywords: Hydrogen Storage, Kinetic Modeling, Reactive Hydride Composite, Desorption, Borohydrides

INTRODUCTION

The need for new energy storage systems has led to the development of different hydrogen storage systems. One of these systems, the Lithium Reactive Hydride Composite (Li-RHC), shows great promise for applications in which a high gravimetric capacity is critical for practical application. However, for the application of hydride systems, the tank's design plays a critical role in the overall performance and the technical and economic feasibility of the system. For this reason, simulation, such as finite element simulation (FEM), has been used to design optimized systems. For that, descriptions of the heat flow, mass transfer and reaction kinetics are necessary. While the absorption kinetics of the Li-RHC system has been described elsewhere in detail [1], the desorption kinetics of the Li-RHC has not been the subject of a comprehensive study.

The desorption of the Li-RHC system usually follows two steps, of which the desorption of the MgH_2 is the first one.

$$MgH_2 \rightarrow Mg + \frac{1}{2} H_2 \quad (1)$$

This reaction proceeds rapidly in the usual temperatures (T) for Li-RHC desorption.

For the T and pressure (P) ranges in which the material in this work is investigated, the reaction is expected to follow

$$2\ LiBH_4 + Mg \rightarrow 2\ LiH + MgB_2 + 3\ H_2 \quad (2)$$

While the complete kinetic description of the absorption has been previously done [1], the two-step desorption reaction is yet to be described comprehensively. In the work of Puszkiel et al. [2], the authors have used the Prout-Tompkins (PT) model to describe the $LiBH_4$ decomposition. However, this requires the use of a new variable, t_0. This variable can be determined empirically with relative ease, as this is a parameter for the non-linear fitting of the kinetic curve. However, up to this day, and to the best of our knowledge, there is no description of how to predict or model the value of t_0 as a function of the system's parameters. Such modeling is necessary in order to be able to use the integrated kinetic equation to perform simulations that account for changes in both T and P. In this work, we present the kinetic modeling of Li-RHC under desorption conditions, including a novel, empirical approach for the determination of t_0 as a function of the system's variables, developing a method that can be applied to different systems which depend on this variable for a complete description of the reaction kinetics.

EXPERIMENTAL PROCEDURE AND MODELING

In this work, a high-energy ball milling was used to prepare the Li-RHC powders. The experimental parameters were described elsewhere [1]. The prepared powders were put inside a sample holder to investigate the material's desorption

kinetics. All the experiments were carried out using ca. 150 mg of powder in a Sievert-type Apparatus (HERA, Canada, Canadian Patent). The material was cycled at least 7 times to ensure the reproducibility of the material's kinetic behavior. Then, a series of experiments under different T and P were carried out to investigate the kinetic behavior of the material under desorption conditions (green circles, in Fig. 1). All the absorption reactions were carried out with the same conditions (400 °C, 30 bar initial H_2-pressure). As seen, several conditions of P and T were investigated to increase the reliability and the range of applicability of the developed kinetic model.

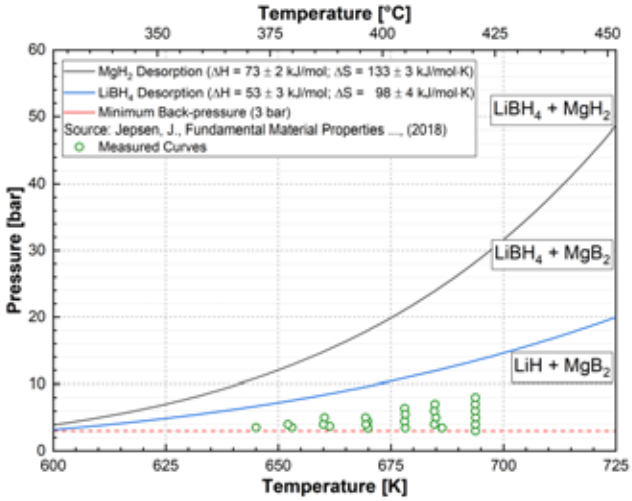

Fig. 1. Thermodynamic equilibrium lines and P-T pairs for the kinetic curves measured for the assessment. The red dotted line represents the minimum overpressure used.

MODELING APPROACH

For all the considered calculations, the variable reacted fraction α can be used to follow the progress of the desorption reaction. α varies from 0 to 1. The modeling approach is described by the separable variable method as described by equation (3):

$$\frac{d\alpha}{dt} = K(T) \cdot F(P) \cdot G(\alpha) \quad (3)$$

, in which α is the reacted fraction, t is time, K(T) is related to the temperature dependency (Arrhenius term), F(P) is related to the pressure dependency, and G(α) is related to the reaction mechanism. A detailed description of the equations, methods, and application of the method is out of the scope of this work and can be seen in ref. [1,3,4].

RESULTS AND DISCUSSION

The dehydrogenation process occurs in two series reaction: First, MgH_2 decomposition (Eq. 1) and then, the desorption reaction of $LiBH_4$ (Eq. 2). Therefore, a model should account for the different reaction mechanisms. The G(α) expression has been identified for each desorption reaction. The found reactions coincide with the ones found by Puszkiel et al. [2]. The best models have been found: for Eq. 1, the JMAEK with n = 1, and Eq. 2, the PT model. The integrated model is as shown in equation (4):

$$\alpha = A_1 \cdot (1 - exp[-(k_1 \cdot t)]) + A_2 \cdot \left(1 + \exp\left(-k_2 + (t - t_0)\right)\right)^{-1} + adj \quad (4)$$

, in which α is the reacted fraction, the indices 1 and 2 refer, respectively, to reactions shown in Eq. 1 and Eq. 2, k is the kinetic constant (in s^{-1}) and depends on the system's T and P, t_0 is a PT model variable (in seconds) and t is the time in seconds. The variables A_1 and A_2 approximately represent each reaction's contribution to the total system H_2-capacity and are nearly constant across different T and P ranges. For all the fitted curves, the mean values of 0.37 and 0.80 are used for, respectively, A_1 and A_2. An excess of 0.17 is observed, and it is a product of the mathematical expression that defines the PT model. This excess comes from the values of the PT model at t = 0 s. In this particular case, by assuming "adj" as -0.17, it is possible to compensate for this behavior. Finally, the t_0 variable can be understood as the vertical translation in the x-axis. This vertical translation can be interpreted graphically as an inflection point in the second desorption reaction (as shown in the blue arrow in Fig. 2.a)).

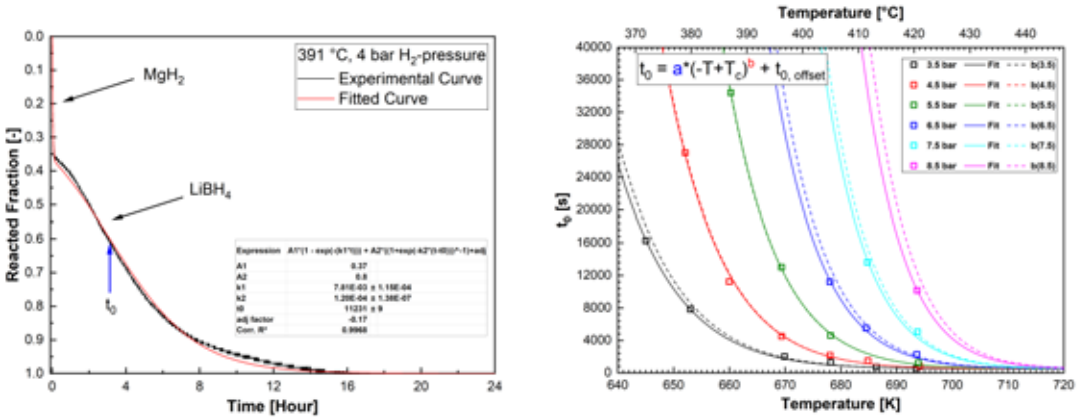

Fig. 2. – a) Experimental and fitted Desorption curves of the Li-RHC under 391 °C and 4 bar of initial H_2-pressure. b) Plot of the t_0 variable as a function of T for several pressures. The squares are the points obtained from the experiments as shown in Fig. 2 a), the full curves are the best fit obtained from the used expression and the dotted lines are the back-calculated values after performing a fit to obtain an expression b(P) (b as a function of P).

The plot of t_0 against T shows that by grouping the values in pressure ranges and using an appropriate equation, it is possible to find mathematical expressions that can successfully describe the variation of t_0 as a function of T and P. In this equation, a is a constant (concerning T and P), and b is a function of P.

CONCLUSIONS

In this work, the desorption kinetic behavior of the Li-RHC under a wide range of different combinations of pressure and temperature is investigated. A combined approach for the reaction kinetics is employed, and a novel method for modeling the t_0 parameter (from the Prout-Tompkins model) is proposed. The proposed equation accounts for the system conditions such as temperature and pressure. This novel approach allows performing simulations with systems that follow the Prout-Tompkins model despite the additional parameter being necessary for the complete description of the kinetic behavior.

ACKNOWLEDGEMENT

The authors would like to thankfully acknowledge the Karl-Vossloh-Stiftung for the financial support provided for this project (Project Number S047/10043/2017). Also, thanks to Carolin Fritsch for all the support with some of the experimental work.

HYDROGEN PRODUCTION FROM THE CATALYTIC DEHYDROGENATION OF HYDRAZINE BORANE OVER Pd-Ni-B CATALYST

[1] Merve Rabia Gürlük, [1] Göksel Özkan*
[1]Gazi University, Faculty of Engineering, Department of Chemical Engineering, Maltepe, Ankara, Turkey

ABSTRACT

This study aimed to investigate the hydrogen generation from the hydrazine borane. Efficient and reversible hydrogen release can be achieved from the boron based materials such as M_xBH_4 (M: Li, Na, Ca, Mg), B-N-H (amine boranes) through catalytic and non-catalytic dehydrogenation. Particularly, hydrazine borane ($N_2H_4BH_3$) has been taken into account as a chemical hydrogen storage material due to its high hydrogen content (15.4%). Hydrogen production was carried out by catalytic dehydrogenation of as-synthesized hydrazine borane. Therefore, palladium-nickel (Pd-Ni) bimetallic catalyst supported on Ni-B-O (boride and oxide mixtures) was successfully prepared by co-precipitation method, and its catalytic properties and performance were assessed (SEM, XPS and XRD analyses) for catalytic dehydrogenation. The results showed that 3.58 moles of (H_2+N_2) gas were produced in the presence of Pd-Ni-B catalyst by the hydrolysis of hydrazine borane.

Keywords: Hydrogen, Hydrazine borane, Catalytic dehydrogenation

INTRODUCTION

Hydrogen is regarded as one of the best alternative energy carriers in the increasing demand for an efficient and clean energy source because of its abundance, high energy density and environmentally friendly [1, 2]. Recently, boranes and boron–nitrogen–hydrogen (BNH) compounds have been proposed as hydrogen storage materials in the last decade. Among these boron containing materials, hydrazine borane is an attractive hydrogen carrier owing to its theoretically high hydrogen storage capacity (15.4% by mass) and its stability at optimum conditions. Although hydrazine borane (HB) has a high hydrogen storage capacity with its protic ($4H^{\delta+}$) and hydridic hydrogens ($3\ H^{\delta-}$), it is difficult to release all the hydrogen in the borane complex [2, 3].

The first synthesis and thermal decomposition of hydrazine borane were described by Goubeau and Ricker in the beginning of 1960s. They demonstrated that the most efficient method to produce hydrazine borane was the reaction of sodium borohydride and hydrazine hemisulfate salt in 1,4-dioxane [4]. Generally, hydrogen stored in HB can be generated through hydrolysis in the presence of selective catalysts according to the following equation (Eq. (1)) [5, 6]:

$$N_2H_4BH_3\,(aq) + 3H_2O \rightarrow B(OH)_3 + 5H_2 + N_2 \quad (1)$$

The dehydrogenation mechanism of hydrazine borane depends on both the hydrolysis of BH_3 group and the decomposition of N_2H_4 moiety in the presence of metal catalysts. In the first step, 3 moles of H_2 are released with the hydrolysis of the BH_3 group, and in the second step, 6 moles of gas (5 moles of H_2 and 1 mole of N_2) are generated by the hydrolysis of both the N_2H_4 and BH_3 groups in the hydrazine borane. The catalysts studied for the dehydrogenation reaction are divided into 3 categories [2, 3]:

- Fe and Re-based catalysts, incomplete conversion in the hydrolysis of the BH_3 group (< 3 moles of H_2)

- Co, Ni, Pd, Pt and Au-based catalysts, active only in the hydrolysis of the BH_3 group (3 moles of H_2/1 mole of BH_3)

- Ru, Rh and Ir based catalysts, active in the hydrolysis of both the BH_3 and N_2H_4 group.

Different catalysts have been tested for hydrogen generation from the dehydrogenation of HB including reduced noble metal catalysts, bimetallic catalysts. Indeed, it has been discussed that monometallic catalysts (Fe, Re, Ni, Cu, Co, Pt) are effective in hydrolysis of BH_3 group, whereas Ru-, Rh-, and Ir-based catalysts are active in the decomposition of N_2H_4 moiety [6, 7]. Karahan et al. have proved that $RhCl_3$ catalyst was used to release approximately 3 equivalents of H_2 [6]. In addition, Yao et al. have found that NiPd nanoparticles modified with MoO_x catalyst was an active catalyst for the dehydrogenation of HB [8].

Gurluk and Ozkan studied the synthesis of the Zr-Ni-B supported Rh-based catalyst for the hydrogen generation from the hydrazine borane. Rh based ternary catalyst was prepared from simultaneous reduction of zirconium,

nickel and rhodium salts by using sodium borohydride as a reducing agent. They found that approximately 3 equivalents of H_2 was released from the dehydrogenation of hydrazine borane [9].

MATERIALS AND METHODS

The Synthesis of Pd-Ni-B Catalyst

Pd-Ni-B catalyst (containing 5% Pd by mass) was synthesized by co-precipitation method. Firstly, dilute solutions were prepared by weighing 3.85 g nickel chloride hexahydrate ($NiCl_2.6H_2O$) and 0.083 g $PdCl_2$. After that, the diluted solutions were taken into a beaker in an ice water bath and mixed in a magnetic stirrer. In order to reduce palladium and nickel, 0.2 M $NaBH_4$ solution was added slowly to the aqueous solutions. Later, the sample was washed 3-4 times with hot distilled water, and the resulting product was dried in a vacuum dryer.

The Catalytic Dehydrogenation Experiments

Experimental studies have been carried out for hydrogen production from as-synthesized hydrazine borane by catalytic hydrolysis. Firstly, the aqueous solution of the synthesized catalyst was added to the reactor. After that, 20 mL of HB solution (0.1% by mass) was placed in the feeding apparatus. The temperature of the water bath was kept in the working temperature. The gas burette system in the experimental setup was filled with water and checked for any leakage. When the temperature of the reactor reached the desired temperature, the fresh aqueous solution of HB was injected into the reactor and the chronometer was started with the reaction. The time corresponding to the volume change in the gas burette system was recorded and the experiments were completed in which the water level in the gas burette system stabilized.

RESULTS AND DISCUSSION

Hydrogen production by catalytic dehydrogenation from boron-based compounds was carried out using an aqueous solution in the presence of a catalyst. One of the main drawbacks in the hydrolysis of hydrazine borane is the slow reaction rate and the formation of unwanted by-products such as hydrazine [5, 6]. Therefore, different catalytic systems have been developed and used for the dehydrogenation of hydrazine borane.

After the synthesis of hydrazine borane, Pd based catalyst was synthesized and its catalytic performance in hydrogen release was investigated. According to the literature, it has been revealed that bimetallic/trimetallic catalysts with noble metals (especially Ru, Rh and Pt) showed high catalytic activity in the hydrolysis of hydrazine borane because adding a second element to the monometallic catalysts increased the catalytic activity [2, 5-7]. Consequently, Pd-Ni/B bimetallic catalyst was used for the catalytic hydrolysis of hydrazine borane. In the dehydrogenation of the hydrazine moiety, the presence of a second metal such as nickel made the catalyst more active and selective [5]. The prepared Pd-Ni-B catalyst was characterized by Scanning Electron Microscopy (SEM) with Energy Dispersive X-Ray Analysis (EDX), X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS).

The plots of mol (H_2+N_2)/mol $N_2H_4BH_3$ (n (H_2+N_2)/n HB) against time for the hydrolysis of HB aqueous solution by Pd-Ni-B catalyst at different temperatures (30-60°C) are shown in Figure 1. The hydrogen release started immediately and proceeded until the complete hydrolysis of HB. From the Fig. 1, the hydrogen production went up with the increase in the temperature. As a result, the maximum hydrogen generation was acquired as nearly 3.5 moles of (H_2+N_2) gas at 60°C.

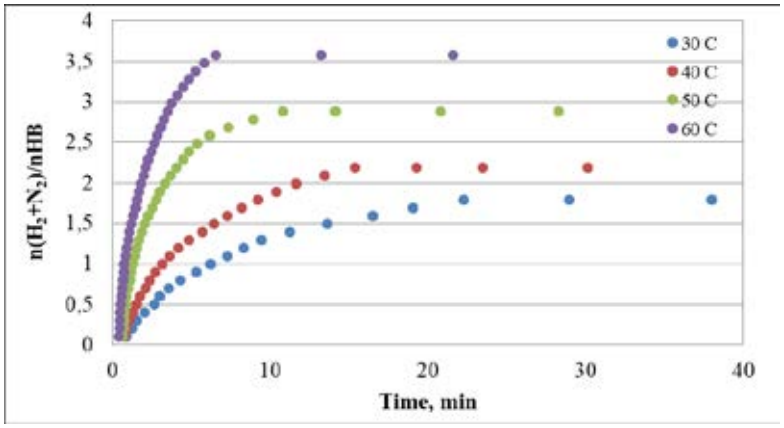

Fig. 1. The catalytic dehydrogenation of HB at different temperatures

CONCLUSIONS

In this study, Pd-Ni bimetallic catalyst supported on Ni-B-O (boride and oxide mixtures) was prepared by co-precipitation method for the catalytic hydrolysis of hydrazine borane. Furhermore, the catalyst was characterized by SEM-EDX, XRD and XPS. Pd-Ni-B catalyst exhibited good catalytic activity and stability for the dehydrogenation of hydrazine borane. Accordingly, 3.58 moles of (H_2+N_2) gas were generated in the presence of Pd-Ni-B catalyst

ABSTRACT

This study focuses on the catalytic dehydrogenation of ethylene diamine bisborane (EDABB). For this goal, Pd-Ni-Zr-B catalyst was prepared in two steps by using co-precipitation method with $NaBH_4$ and impregnation method. The catalyst was characterized with XRD, XPS, SEM-EDX and multi-point BET analysis. The effect of temperature (90°C-120°C) was investigated on dehydrogenation of EDABB. The hydrogen production yield significantly increased at the temperature increases and also the reaction time reduced as well. Highest yield of equivalent hydrogen has reached 5.94 moles at 120°C. Reusability test of the catalyst was also carried out and average HGR result was obtained.

Keywords: Catalytic dehydrogenation, Ethylene diamine bisborane, Ethan 1, 2-diamine borane

INTRODUCTION

Reducing fossil-based fuels and environmental issues have led to rise of a number of alternative energy sources. Hydrogen that has a zero carbon emissions and high capacity of energy is well-known material and it can be used as energy storage material. Hydrogen can be played an important role for sustainable and eco-friendly solution. At this point, hydrogen storage is one of the key roles. A part of the hydrogen storage is using chemicals as a storage material. In this area borane based chemical material has significantly investigated in literature [1].

The most well known amine borane is ammonia borane used as hydrogen storage material because of being high hydrogen capacity (19.6% by mass) and non-toxicity material. It is important on fuel cell applications that the most amine borane groups like mono- and di-alkyl amine boranes release hydrogen as high purities at the mild conditions [2].

It has recently started to attract attention as a hydrogen storage material in the class of amine boranes in the literature. Ethylenediamine bisborane (EDABB, $C_2H_{14}B_2N_2$) also known as ethane 1,2-diamine borane is an alkyl diamine borane in amine borane derivatives, which makes EDABB interesting because it is faster in thermolysis than ammonia borane and does not contain gaseous impurities such as borazine as a by-product. During solvolysis, 3 moles of equivalent hydrogen can be taken from 1 mole ammonia borane, while 4-6 moles of equivalent hydrogen can be taken from 1 mole EDABB. It is a stable compound and containing 11.49% hydrogen as a mass [3].

In this work, EDABB dehydrogenation in ethylenediamine (EDA) media has been focused. For this purpose, EDABB was synthesized, and Pd-Ni-Zr-B catalyst was prepared. Catalytic reaction was carried out at different temperatures.

MATERIALS AND METHODS

Materials

Ethylenediamine dihydrochloride (Sigma-Aldrich), tetrahydrofuran (Sigma- Aldrich), nickel (II) chloride hexahydrate ($NiCl_2.6H_2O$, Aldrich), zirconium (IV) chloride ($ZrCl_4$, Merck-Schuchardt), palladium (II) chloride ($PdCl_2$, Merck), sodium borohydride ($NaBH_4$, Fluka) and deionized water were used.

EDABB Synthesis

EDABB was prepared according to literature with minor modifications [4]. For the synthesis, ethylenediamine dihydrochloride salt (11.39 mmol) and sodium borohydride (22.78 mmol) were added in THF. The reaction mixture was stirred at room temperature for 4 h under the reflux. After reaction, the mixture was filtered, and then the solvent was removed under vacuum evaporation. The solid washed with hexane and then filtrated. Filtrate cake was dried under vacuum at room temperature (White solid, 85% efficiency, 90% purity). Purity of EDABB was analyzed with hydrolysis reaction using with $RuCl_3$. Also, FTIR and ^{11}B NMR analysis was applied.

Catalyst preparation and characterization

Briefly, 0.059M nickel chloride hexahydrate and 0.065M zirconium chloride was mixed for 1 g of Ni-Zr-B catalyst. 0.18 M sodium borohydride was added drop wise to the mixture under intense stirring at 5°C. The precipitate was separated by centrifuge, washed 4 times using deionized hot water to separate from impurities and finally left to dry at 105ºC. 5% by mass of Pd active substance was added to the Ni-Zr-B sample by the impregnation method. PdCl2 solution (0.281mmol for 1 g sample) was added to the Ni-Zr-B catalyst sample and impregnated at 110°C by mixing until dryness in a stirred vessel. The sample was activated by using hydrogen and helium gas mixture for 1 hour. Catalyst was characterized with XRD, XPS, SEM-EDX and multi-point BET.

Dehydrogenation of EDABB

Dehydrogenetion of 0.5% by weight EDA solution of EDABB was performed at 90 ºC, 100 ºC 110 ºC and 120 ºC having with 0.02 g catalyst. The reaction system contains 50 ml volume 2 neck glass reactor, 50 ml volume pressure stabilizing liquid feeding apparatus and washing bottle having 0.1M H_2SO_4 solution. The produced hydrogen was measured as function of time in a gas burette system.

RESULTS AND DISCUSSION

Non-catalytic and catalytic dehydrogenation of 0.5% by mass of EDABB in the presence of ethylenediamine solvent were studied. In the experimental studies, ethylenediamine was chosen as the solvent and worked around 120°C, which is close to the boiling point of ethylenediamine (116 - 118°C). The non-catalytic dehydrogenation experiment was carried out only at 120 °C. Catalytic dehydrogenation experiment was carried out at 90°C, 100°C, 110°C and 120°C with 0.02 g Pd-Ni-Zr-B catalyst. In Fig. 1, nH_2/nEDABB versus the reaction time curves for both cases are given comparatively.

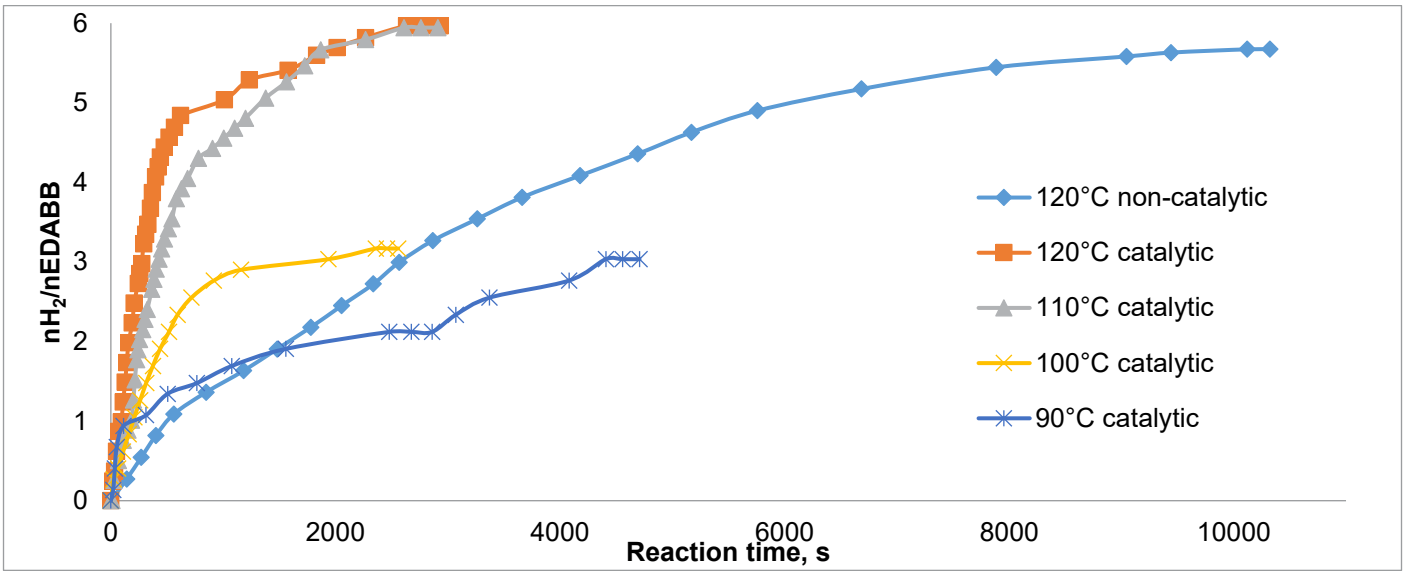

Fig. 1. Dehydrogenation of EDABB with EDA (0.02 g Pd-Ni-Zr-B)

In the non-catalytic dehydrogenation of EDABB at 120°C, 5.67 moles of hydrogen per mole of EDABB (94.5% molar production yield) were released in approximately 3 hours [5]. It has been shown that 6 moles of hydrogen can be produced per 1 mole of EDABB. When the results of dehydrogenation in the catalyst environment were examined, it was observed that 5.96 moles of hydrogen were released at 120°C in 2633 s, that is, in approximately 44 min. In addition, at temperatures of 90°C, 100°C and 110°C, it was determined that 3.03 mole of hydrogen was released in 4408 s, 3.16 mole in 2358 s and 5.94 mole in 2611 s, respectively. It has been determined that around 6 moles of hydrogen (99% molar hydrogen production efficiency) can be taken catalytically within 40-45 min at 110°C and 120°C temperatures. However, when the temperature drops to 100°C and below, it has been observed that the amount of hydrogen production decreases by about half. Although it can be operated at 120°C without catalysis, it has been understood that hydrogen can be released effectively by shortening the reaction time at 110°C and 120°C with catalyst. Reusability test was also carried out with 5th cycle as shown in Fig. 2 and the average HGR result of Pd-Ni-Zr-B was found 66.64 $ml.min^{-1}.g^{-1}$.

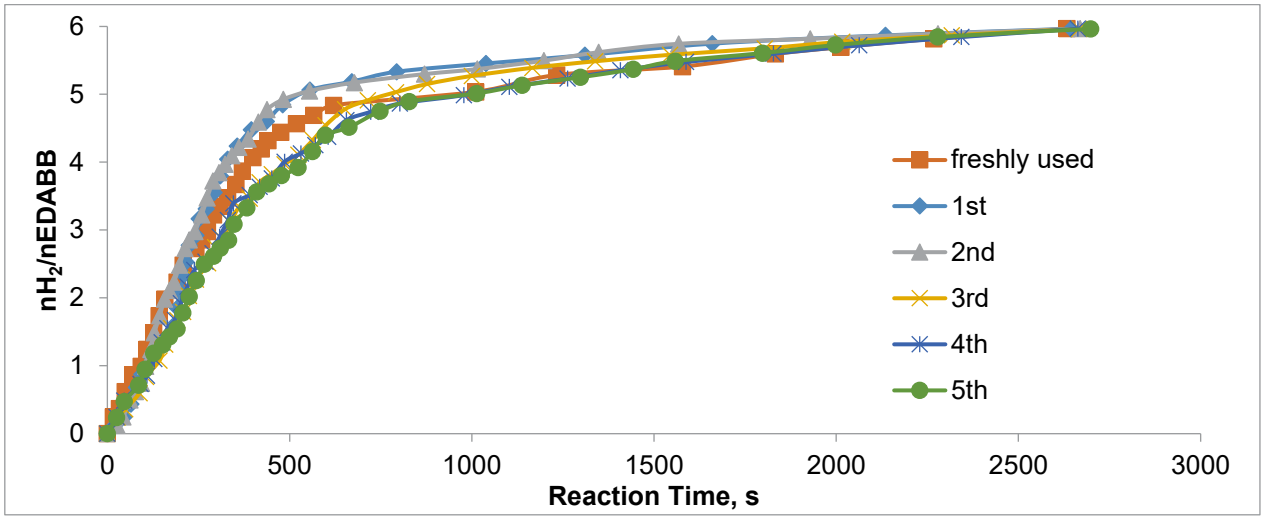

Fig. 2. Reusability of Pd-Ni-Zr-B

CONCLUSIONS

In this work, EDABB successfully synthesized at high yield and purity. After then catalytic dehydrogenation of EDABB was investigated at different temperature. For dehydrogenation reaction, Pd-Ni-Zr-B catalyst was prepared with reduction and impregnation methods respectively. The effect of temperature was examined. Hydrogen production yield was increased by increasing the temperature. Also, the reaction time was reduced. Nearly, 6 per equivalent mole of pure hydrogen were taken from 1 per equivalent mole of EDABB.

ABSTRACT

Polymeric grades play a vital role with their unique properties in many components realizing the "Hydrogen Economy". The elastomeric grades in sealing applications are exposed to high-pressure hydrogen (H_2) gas and a wide range of temperatures, therefore, the development of novel materials is an ongoing process in order to fulfill the future requirements. This study focuses on the development of novel elastomeric grades, introducing novel filler strategies to improve the transport and mechanical properties, and subsequently minimizing possible degradation/damage. The proposed grades were initially tested for identifying the fulfillment of required properties, the resistance to rapid gas decompression (RGD), and deviations in high-pressure H_2 conditions. The used filler modification methods provided promising results on 2D filler functionalization and hydrogen exposure tests revealed dissolution of gas into the material and subsequent possible alterations of properties.

Keywords: Hydrogen gas storage, Sealing, Elastomers, Filler modification, Rapid gas decompression

INTRODUCTION

In a response to the climate crisis the world is facing, the European Union presented a Green Deal in 2019/20 to reduce the net emissions of greenhouse gases at least 55% by 2030 compared to 1990 levels, and to reach a climate-neutral continent by 2050 [1]. These ambitious targets encourage all the stakeholders to reach viable alternative resources. Therefore, hydrogen receives great attention as a clean energy carrier as well as a feasible and cost-effective renewable energy storage solution [2]. However, this emphasizes the importance of improvement of technologies and materials involved in these systems. Fig.1 shows an illustration of vital roles played by polymeric materials in a typical hydrogen gas system in the transportation sector. These systems demand materials to work up to ~100 MPa in gas storage tanks and wide temperature ranges (-40 to 85 °C) fulfilling the near future requirements [2,3].

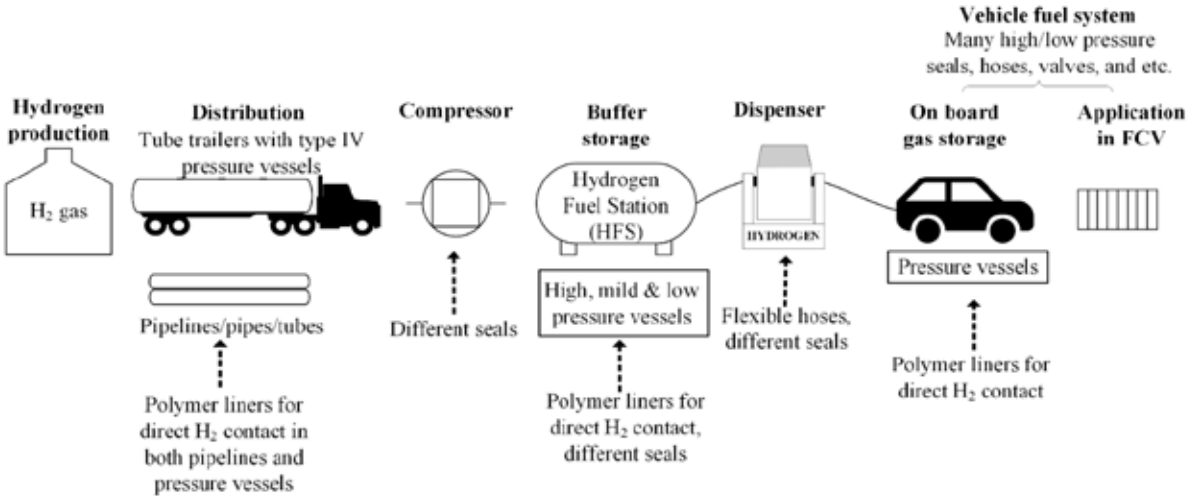

Fig. 1. Illustration of applications of polymeric grades as vital components in a typical hydrogen energy system [2]

Especially, leaking through sealings as a result of permeation and possible mechanical damage in prevailing harsh conditions is a major concern in economical and safety point of view. RGD is a well-known damage expected in sealing applications due to gas dissolution under exposure and subsequent sudden release in loading-unloading routines [4]. As a part of the Polymers4Hydrogen project, which is an Austrian Research Promotion Agency (FFG)-funded project to develop novel polymeric material grades, experimental methods, and simulation tools to facilitate the H_2 economy, this study presents an approach to develop elastomeric grades and novel filler strategies with intended properties, for

example, possibility to use in wide temperature range and transport properties which is an important parameter in terms of permeation and RGD. Further, literature mentions the possibility of adding two-dimensional (2D) fillers for improvement of barrier properties due to the possible tortuous path [5]. Therefore, this study intends to eliminate the possible drawbacks in 2D filler incorporation to elastomer by exfoliation and filler functionalization.

MATERIALS AND METHODS

Arlanxeo Deutschland GmbH, Dormagen, Germany, provided four cross-linked elastomer grades, which can be used as sealing materials, as shown in Table 1. The benchmark characterization of these grades was conducted identifying the material properties and relevance of different compositions. Therefore, mechanical, thermo-mechanical, hardness, and compression set measurements were conducted according to the respective standards. The RGD properties of the proposed grades were tested at the facility of SKF Sealing Solutions Austria GmbH, Judenburg, Austria, based on the NORSOK standard [6]. The hydrogen exposure tests were performed at the facility of "Bundesanstalt für Materialforschung und -prüfung" (BAM), Berlin, Germany, at different pressures (up to 100 MPa) at different temperatures (up to 120 °C) for a period of 7 and 21 days.

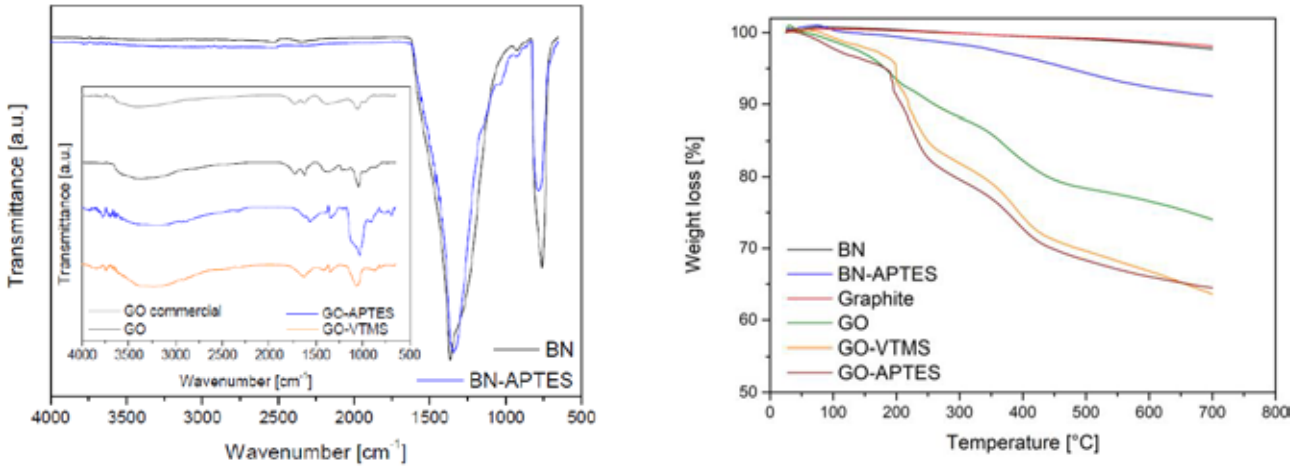

Table 1. Proposed elastomer grades and composition

Material	Composition
HNBR 1	Carbon black (CB) N 550: 75phr, Acrylonitrile (ACN) content: 21%
HNBR 2	CB N 550: 67phr, Polyamide (PA): 10phr, ACN content: 21%
NBR 1	CB N 550: 75phr, ACN content: 18%, Peroxide cured
NBR 2	CB N 550: 75phr, ACN content: 18%, Sulfur cured

The step of development of novel filler strategies considered two types of layered 2D fillers (hexagonal boron nitride (BN) and oxidized graphite flakes (GO)) for improvement of transport properties. The surface was activated prior to modification steps and silane coupling agents (SCA) with suitable functional groups, for example, aminopropyltriethoxysilane (APTES) and vinyltrimethoxysilane (VTMS), which could be useful for different matrix materials, were attached to the activated surface. The modified fillers were characterized using infrared spectroscopy (FT-IR), thermogravimetric analysis (TGA), X-ray photoelectron spectroscopy (XPS), and zeta potential measurements (ZP).

RESULTS AND DISCUSSION

The proposed elastomeric grades showed relatively higher hardness ~80 ShA, tensile strength in a range of ~25-30MPa, above 10 MPa of stress at 100% strain, and positive results on the resistance to rapid gas decompression based on NORSOK ranking. Based on mechanical properties, the addition of PA in HNBR2 and sulfur curing step in NBR2 provided improvements compared with their counterparts. Considering the low-temperature properties, which is important in these conditions, NBR grades (T_g ~ -45 °C) showed an edge over the HNBR grades (T_g ~ -30 °C). Exposure to high-pressure H_2 gas showed slight influence for the tests up to 20 MPa in visible dimensional changes, however, tests at 100 MPa exposure showed even visible blisters as a result of rapid gas release (< 5 sec) of pressure. After exposure, the weight and volume of the specimens were increased and density and hardness were decreased revealing the dissolution of gas. Tensile tests of these exposed specimens showed reduced mechanical properties indicating possible incurred micro damages inside the material.
FT-IR, TGA, XPS, and ZP results showed promising results of the 2D filler modification study and Fig. 2 summarizes the ATR-FT-IR spectra (Fig. 2a) and weight loss indications based on TGA measurements (Fig. 2b). According to Fig. 2a, BN indicates minor changes after the silanization process in the range of the Si-O stretching vibration at ~1000 cm^{-1}, however, GO reveals decreased intensities in C-O peaks as well as traces of the Si-O vibration and C-H vibrations at ~3000 cm^{-1}. As illustrated in Fig. 2b, the GO fillers show a better functionalization ability with significant weight loss in both VTMS and APTES, compared with BN-based methods.

(a) (b)

Fig. 2. FT-IR and TGA results of treated fillers [7]

CONCLUSIONS

The applicability of proposed elastomeric grades, novel filler strategies for improving intended properties, and possible degradation in high-pressure H_2 gas conditions were briefly discussed in this paper. The mechanical, thermo mechanical and RGD results showed the relevance of these grades in expected conditions. The 2D filler modification step provided good results on filler functionalization and possible incorporation in to relevant polymeric grades. Gas exposure tests revealed the dissolution of H_2 into the rubber grade and possible damage in subsequent sudden gas release. Therefore, the promising findings of this study provide a meaningful direction to reach the goals of intended material development.

DIFFERENT WAYS TO STORE MASSIVE QUANTITIES OF HYDROGEN

[1*] *Louis Londe*, [1] *Arnaud Réveillère*

*Corresponding author e-mail: louis.londe@geostock.fr

ABSTRACT

Hydrogen can be stored in underground caverns or geological structures in various ways. The easiest way to store hydrogen is in salt caverns. These are created by injecting water into a well down to a salt geological layer, with the extraction of salt-saturated brine. This type of storage is suitable for storing hydrogen at extremely high pressures.
The second way to store large quantities of hydrogen is to inject pure hydrogen or a hydrogen-methane mix into porous rock. The hydrogen content may vary from a few per cent to 100 per cent. Hydrogen can also be stored underground by converting it into a liquid carrier, such as ammonia, which can then be stored in a Lined Rock Cavern. A liner is often required to prevent contact between ammonia and water. Lastly, hydrogen can be stored underground by injecting it into a Lined Rock Cavern. This may take the form of compressed storage (gaseous hydrogen) or cryogenic storage (liquid hydrogen. A liner is required owing to extremely high pressures or extremely low temperatures. The present article exposes state of the art of all these techniques of hydrogen underground storage, outlines technical gaps and identifies main ongoing or required technology developments needed to bridge them.

Keywords: Underground, Storage, Salt, Cavern, Rock

INTRODUCTION

Underground storage is likely to be the best solution for fulfilling extensive storage needs (Jens, 2021 [1]) as it boasts numerous advantages in terms of environment protection, safety and, above all, CAPEX (for high storage capacity) and OPEX.

HYDROGEN STORAGE IN SALT CAVERNS

Salt caverns are a proven technology for storing hydrocarbons, including natural gas, liquid hydrocarbons such as crude oil or refined products, and liquefied hydrocarbons such as LPG. More than 1,900 salt caverns exist worldwide. Salt caverns are created by solution mining, i.e., by injecting fresh water or sea water into a deep well. Solution mining is also referred to as the “leaching” process. A large variety of sizes exist, ranging from 50,000 m3 to more than 1,000,000 m^3.

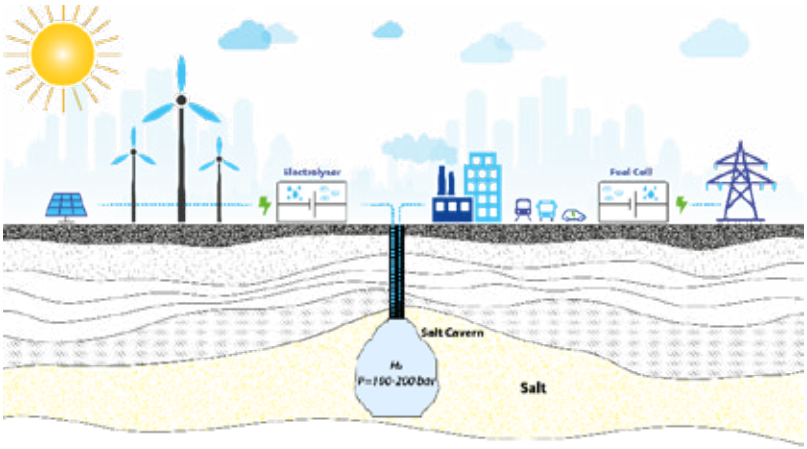

Figure 1: Hydrogen storage in salt cavern

Salt caverns were first used for hydrogen storage five decades ago in the UK, the first such cavern being commissioned near Teesside in 1972. Five decades later, only six salt caverns have been built for hydrogen storage. There is obviously no technical showstopper to create salt caverns for hydrogen. Nevertheless, a few specific items deserve attention and explain why some of the new ongoing projects are presented as demonstrators.

HYDROGEN STORAGE IN POROUS ROCK

Porous rocks, either in depleted fields or in aquifers, have been used for storing natural gas for over a century. Unlike salt caverns, porous rock storages use natural voids. Wells are drilled to inject and withdraw the gas. Pressures as high as 200 bar are common practice. Storing hydrogen into porous rock is considered today as a blending of natural gas (i.e., mainly methane) and hydrogen. The hydrogen-methane mix can be burnt as such to produce energy. Alternatively, hydrogen can be separated from methane at the well head, for example using pressure swing adsorption technology. Storing methane-hydrogen mix in porous rock has been done in the past. Town gas, often containing up to 50% hydrogen, has been stored in a dozen of European underground storage facilities, in depleted fields or aquifers (Marcogaz, 2017 [2]). The gas industry is currently launching research programs and pilot plants to provide scientific evidence that the town gas experience can be repeated as part of a controlled and documented approach. Various items are being investigated (Heinemann, 2021 [3]).

HYDROGEN STORAGE AFTER ITS TRANSFORMATION INTO A LIQUID CARRIER

It is likely that ships will be used for the intercontinental transportation of hydrogen. Hydrogen tankers could transport liquid hydrogen (LH2) at very low temperatures (-253°C). A promising alternative is to use molecules containing hydrogen, providing that the molecules are easy to liquefy. A popular hydrogen liquid carrier is ammonia (NH3). Ammonia is easy to liquefy for transport purposes. Underground storage of liquid hydrogen carriers is an option that could offer all the advantages of underground storage where salt is not available.
Ammonia could be stored in hard rock caverns in almost any kind of rock providing that it is strong enough to be excavated without heavy support.

However, the underground storage of ammonia is not straightforward, as ammonia has a high affinity with water. Consequently, ammonia often needs to be isolated from water with a steel liner.These “Lined Rock Caverns” (LRC) are feasible with a limited R&D effort. The LRC concept was demonstrated in 2004 in Sweden for natural gas with a pressure higher than 200 bar and for fast cycling conditions (Sydkraft AB, 2004). There should not be any significant difficulty for ammonia around a few tens of bars. Alternatives at lower pressure and lower temperature, say between 0°C and -40°C, are also feasible.

HYDROGEN STORAGE IN LINED ROCK CAVERNS

The fourth hydrogen storage technology is the Lined Rock Cavern, directly as hydrogen rather than as a transformed molecule such as ammonia. Two different options are to be considered:

- Option 1: For pipeline transport, hydrogen is to be stored as a gas.
- Option 2: For tanker transport, hydrogen is to be stored as a cryogenic liquid, at -253°C.

Options 1 and 2 generate different challenges. In both cases, these challenges are greater than for ammonia LRC, owing to high pressure (option 1) or very low temperature (option 2). But both options are advantageous in terms of environmental protection and safety, and may prove economically attractive for large capacities.

LPG and liquid hydrocarbons are stored around the world in unlined mined caverns. However, a pressure of 100 or 200 bar would require building an unlined rock cavern at a depth of 1,000 m to 2,000 m to fulfil the Hydrodynamic Containment Principle (Aberg, 1975 [4]; Van Hasselt, 2003 [5]). A shallower cavern with a liner is therefore highly recommended. The feasibility of such an LRC for pressurised hydrogen has been confirmed by the Skallen project, in which pressures of higher than 200 bar have been reached with success (Sydkraft AB, 2004 [6]).

Let us now consider a cryogenic cavern for LH2. A similar concept has been developed for liquefied natural gas (LNG) (Amantini, 2005 [7]). The principle of the cryogenic cavern combines two proven technologies: the rock cavern commonly used for LPG and liquid hydrocarbon storage, and the containment system used in LNG tankers and LNG tanks. Tightness is ensured by a steel membrane. Insulation layers are installed behind the steel membrane, protecting the rock mass against thermal shock. This insulation also reduces the initial boil-off rate. Adapting this LNG cryogenic cavern to hydrogen storage will require R&D studies as the temperature of LH2 (-253°C) is lower than that of LNG (-162°C).

CONCLUSION: UNDERGROUND HYDROGEN STORAGE IN THE COMING YEARS

Large-scale hydrogen storage is required to face future challenges in terms of energy and the environmental transition. Hydrogen will be used primarily for industrial decarbonisation, carbon-free mobility, and carbon-free power generation. It will be used initially to decarbonize industry and mobility, for which underground storage will be required within a couple of years. Underground pure hydrogen storage for power generation will also emerge, but large-scale

demand may come later, in all likelihood after 2040. Meanwhile, the gas and power generation industries will use a methane-hydrogen mix, well before 2040. The methane-hydrogen mix will gradually reach 20% hydrogen, and possibly more, and will be stored underground, mainly in porous rock reservoirs.

Salt caverns will probably account for the largest share of underground storage needs, followed by porous rock reservoirs, especially for methane-hydrogen mixes. When the technology is ready, mined caverns will find their place in the value chain for international trading (ammonia, liquid hydrogen) or where pure hydrogen is to be stored in places without salt.

R&D efforts vary for these various techniques. For pure hydrogen storage, salt caverns are ready for commercialisation, and porous media is nearly ready as well. Both are ready for storing blends of hydrogen and natural gas, which is actually authorized in many countries and can happen tomorrow, should the business model enable it. Current research is aiming aimed at furthering our knowledge and establishing standards.
Mined cavern techniques – for pressurised hydrogen, pressurised substitutes (such as ammonia) or liquefied hydrogen – will require a few years of technical developments. The corresponding caverns will be lined. Lined Rock Caverns (LRCs) for pressurised hydrogen or pressurised ammonia could be ready for commercialisation in the near future. LRCs for liquid hydrogen present greater challenges owing to the very low temperature involved (-253°C).
These mined cavern techniques will remain more expensive than salt caverns and porous rock reservoirs. However, owing to their geological adaptability, mined cavern solutions will be needed to complete the hydrogen storage portfolio.

ABSTRACT

Liquid organic hydrogen carrier systems (LOHC) are presented as an alternative for energy storage and transportation. Platinum group metals (PGM) have proven to be efficient in LOHC hydrogenation/dehydrogenation reactions for hydrogen storage cycles. However, their cost and the high Pt/LOHC ratio are their major drawbacks. In this work, the performance of low-PGM and/or PGM-free catalysts on LOHC dehydrogenation is studied. Bimetallic systems are good candidates to replace or to decrease the PGM content increasing also the dehydrogenation yield.

Keywords: Hydrogen storage, liquid-organic hydrogen carrier (LOHC), dehydrogenation, bimetallic catalyst.

INTRODUCTION

Liquid Organic Hydrogen Carrier (LOHC) systems have recently been considered as a promising candidate for hydrogen storage and transport. In this concept, aromatic compounds can be catalytically hydrogenated and dehydrogenated without changing their chemical properties (Figure 1). The LOHCs offer numerous advantages such as:

(i) moderate to high hydrogen storage capacities,
(ii) easily reversible hydrogenation/dehydrogenation reaction, and
(iii) no additional infrastructure is needed as the same distribution network of liquid fuels can be used [1].

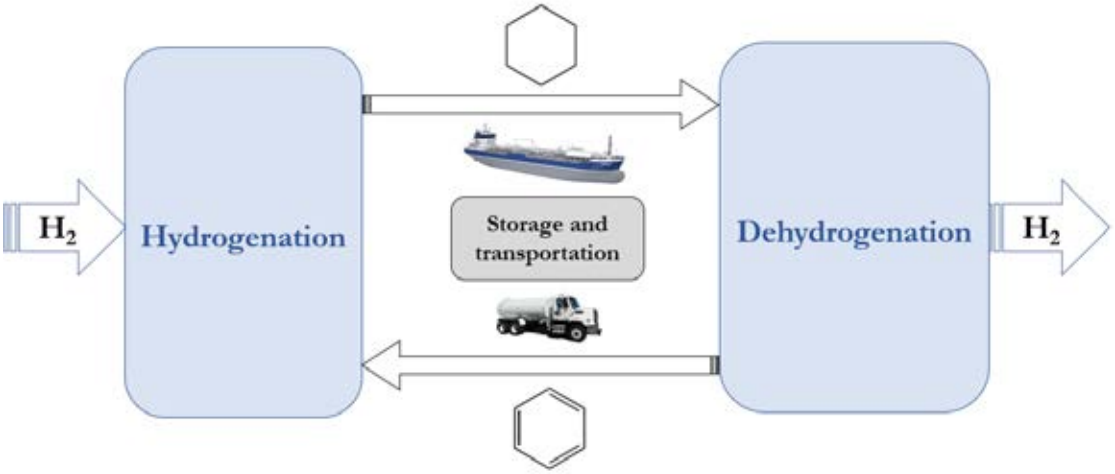

Figure 1. Schematic two-way LOHC cycle. Hydrogen lean benzene is hydrogenated into a hydrogen rich molecule cyclohexane.

The dehydrogenation process consists of an exothermic reaction thermodynamically favourable at low temperatures and pressures. In the dehydrogenation process, Pt-based catalysts have shown a high activity [2,3]. However, the performance of non-noble metal-based catalyst and their promoting effect on Pt has not yet been studied in detail. For these purpose, monometallic and bimetallic Pt-Ni and Pt-Co catalyst were prepared, characterized and tested.

MATERIALS AND METHODS

The dehydrogenation experiments were performed in a lab-scale reactor at 260ºC and atmospheric pressure with a molar ratio of 1/2000 (mol Pt/mol LOHC). The reactor outgoing gas phase was quantified using a flow indicator and monitored by a μ-GC. The reaction progress was evaluated analyzing liquid samples by GC-MS and H-NMR.

RESULTS AND DISCUSSION

Physicochemical characterization of catalytic samples by ICP, TPR, CO chemisorption, XPS and SEM showed differences in chemical state, metal-support interactions and average crystallite sizes, indicating the importance of the morphological and surface properties of metal phases in driving the dehydrogenation activity of the catalyst. The activity results revealed that the reaction takes place mainly in the first thirty minutes of the experiment. After that, the reaction rate slowed down due to the presence of partially hydrogenated compounds (Figure 2).

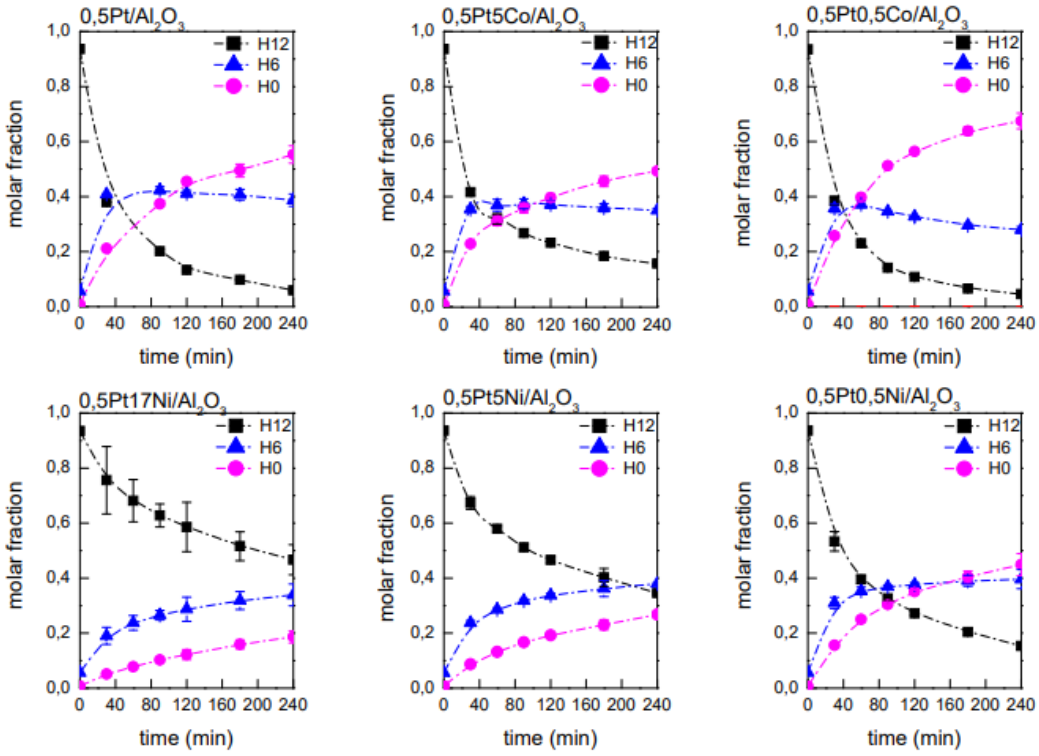

Figure 2. Composition profile for dehydrogenation experiments at lab scale reactor for Pt, Pt-Ni and Pt-Co catalysts (T=260 ºC; P=1 bar; n=1500 rpm; 1/2000 mol_{Pt}/mol_{LOHC}). H12 (full hydrogenated LOHC), H6 (partially hydrogenated LOHC) and H0 (full dehydrogenated LOHC).

The activity and selectivity of Pt-Ni bimetallic catalyst improved decreasing the Ni loading, however, they showed poorer performance than the monometallic Pt sample. On the opposite, the Pt-Co sample with the lower Co content enhanced high dehydrogenation activity and productivity with an increase of a 36% (Table 1). Regarding to the monometallic Ni and Co catalysts, they did not show significant conversion with a degree of dehydrogenation lower than a 3%.

Table 1. Productivity values in the LOHC dehydrogenation reaction.

Catalyst	Productivity, $g_{H2}/g_{Pt}/min$
$1Pt/Al_2O_3$	1,27
$0,5Pt/Al_2O_3$	1,80
$0,5Pt5Co/Al_2O_3$	1,98
$0,5Pt0,5Co/Al_2O_3$	2,45
$0,5Pt17Ni/Al_2O_3$	0,22
$0,5Pt5Ni/Al_2O_3$	0,60
$0,5Pt0,5Ni/Al_2O_3$	1,35

CONCLUSIONS

Bimetallic systems including a non-noble metal are a great alternative to reduce the Pt/LOHC ratio in the dehydrogenation reaction. It has been proved that small Co loadings improve the productivity compared to the bare sample with a higher platinum content. Thus, the overall catalytic performance is affected by the total number of active sites available and the metal-support interactions. Cobalt has demonstrated to act as a promoter, enhancing higher dehydrogenation conversion for hydrogen storage and transportation and decreasing the quantity of PGM used.

ABSTRACT

Cost-effective hydrogen storage at commercial scale is a limiting factor for the propagation of hydrogen energy. Physisorption enhanced hydrogen storage at low to moderate pressure may offer a possible solution. In this paper, we report the synthesis of zeolitic imidazolate frameworks (ZIF-8) and hybrid material of ZIF-8 and carboxylate functionalized carbon nanotubes (ZIF/*f*CNT) for hydrogen storage applications at room temperature and moderate pressures. Both materials were further characterized by various physicochemical characterization tools to investigate the morphology, crystallinity, thermal stability, and textural properties. ZIF-8 exhibits the highest specific surface area of 2023.6 m^2/g whereas 1576.9 m^2/g was obtained for the hybrid material. Both samples showed rhombic dodecahedron morphology with three-dimensional framework structures. Thermogravimetric analysis revealed that the hybrid material possesses higher thermal stability, of securing 53 wt. % of the structure, than pure ZIF-8 due to the addition of *f*CNT. The carboxylate functionalized carbon nanotubes stored 0.15 wt. % of hydrogen at room temperature and pressure up to 50 bar. The process was reversible at this temperature, indicating a physisorption based storage mechanism. The results of hydrogen storage measurements of ZIF-8 and ZIF/*f*CNT will also be presented and discussed.

Keywords: Zeolitic Imidazolate Frameworks, Hybrid material, Hydrogen storage

INTRODUCTION

Hydrogen is a clean fuel which has a long history in the energy sector since the 1800s. Given the rise of greenhouse gas emission originating from fossil fuels, it is noteworthy that abundant hydrogen could play a predominant role in developing alternative energy in the transportation sector and manufacturing industries [1,2]. Hydrogen can be stored through compressed gas method, and in liquid form, however, both methods are impeded by high cost due to high pressure and low cryogenic temperature, respectively [3,4]. Solid-state materials have emerged in the past decade as promising alternative materials for hydrogen storage [5–7] [8]. Particularly, physisorption based hydrogen storage materials show fast kinetics, reversibility, low dissociation temperature, moderate pressure, and acquired low enthalpy of adsorption which lessen the thermal management difficulties [8]. Generally, physisorption materials show high hydrogen uptake at 77 K, however, storage capacities must be improved at ambient conditions to meet the US Department of Energy (DOE) targets. A wide range of carbon-based materials, metal-organic frameworks (MOFs), and zeolites have been investigated as possible physisorption materials for hydrogen storage applications.

Among the MOFs, zeolitic imidazolate frameworks (ZIFs) possess favorable surface area, microporous structure, and thermal and chemical stabilities [10]. These advantages make ZIFs a promising material for H_2 storage applications. However, more research is needed on fundamental approaches to achieve higher hydrogen uptake and understand the nature of H_2 interaction to improve ZIF materials for commercial applications. On the other hand, carbon materials such as carbon nanotubes (CNTs) are one of the best options for hydrogen storage because of their unique properties – highly porous structure, better reversibility of hydrogen, and low mass density [11]. In the present work, we report the synthesis of ZIF-8 which was further added to carboxylate functionalized carbon nanotubes (ZIF/*f*CNT) as a hybrid material for hydrogen storage applications. It is to be noted that the synergistic effects arise from the mesopores and carboxylate groups of CNTs and highly microporous frameworks of ZIF which may create significant performance benefits for hydrogen adsorption. These nano-adsorbents were characterized by a range of physicochemical techniques and hydrogen storage measurements. The introduction of functionalized carbon nanotubes made the hybrid material a highly stable compound for the higher adsorption capacity of hydrogen.

MATERIALS AND METHODS

Chemicals: Zinc nitrate hexahydrate ($Zn(NO_3).6H_2O$, >99.0%), 2-methylimidazole ($C_4H_6N_2$ (HmIm), >98.0%), and Methanol (CH_3OH (MeOH), >99.5%) were obtained from Sigma Aldrich. Carboxylate functionalized carbon nanotubes (*f*CNT) were purchased from Nanostructured & Amorphous Materials, Inc. USA. All the chemicals were used directly without any further pre-treatments.

Synthesis methods of ZIF-8 and ZIF/*f*CNT: In a typical procedure, 2.971 g of $Zn(NO_3).6H_2O$ and 6.572 g of HmIm were dissolved, separately, in 20 ml MeOH and stirred for 10 minutes. Then HmIm solution was slowly poured into zinc

solution and continued stirring for 1 hr, at the speed of 250 rpm. The Zn^{2+}:HmIm:MeOH ratio were 1:8:100. After the reaction, the heterogeneous mixture was centrifuged at 4000 rpm speed for 30 minutes. After that the clear solution was decanted and 15 ml of MeOH was added to the solid product, for washing purpose, and centrifuged again at similar conditions. This washing step was repeated three times. Next, the product was dried in an air oven at 80 °C for 10 hr. Finally, the solid product was carefully grounded using mortar and pestle. The synthesis of ZIF/*f*CNT followed the same procedure except that the *f*CNTs were sonicated in 10 ml MeOH for 30 minutes before being added to the Zn and HmIm mixture.

RESULTS AND DISCUSSION

The morphological structures of ZIF-8 and ZIF/*f*CNT measured by scanning electron microscopy (SEM) are shown in Fig.1. ZIF-8 exhibited rhombic dodecahedron structures with 12 faces, with average particle size of 550 nm (Fig. 1a), similar to the reported literature [12]. Interestingly these structures did not collapse after adding *f*CNTs (Fig. 1b), which was attributed to the successful synthesis of hybrid material. The *f*CNTs were uniformly well dispersed among the ZIF-8 crystal particles. As shown in the images, no residual of zinc material was found which indicates that the zinc precursor was completely reacted with HmIm during the synthesis.

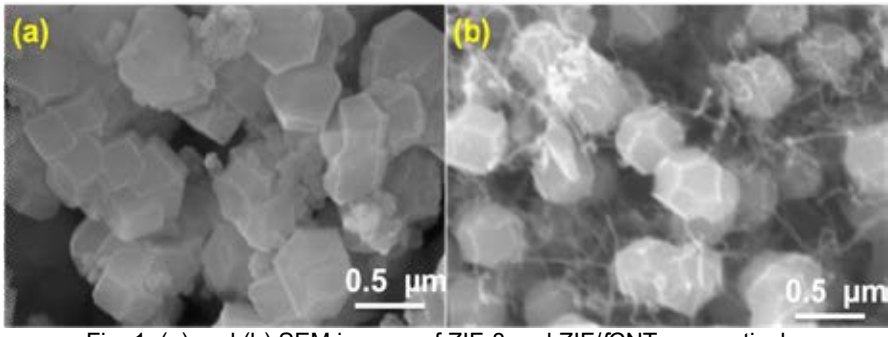

Fig. 1. (a) and (b) SEM images of ZIF-8 and ZIF/*f*CNT, respectively.

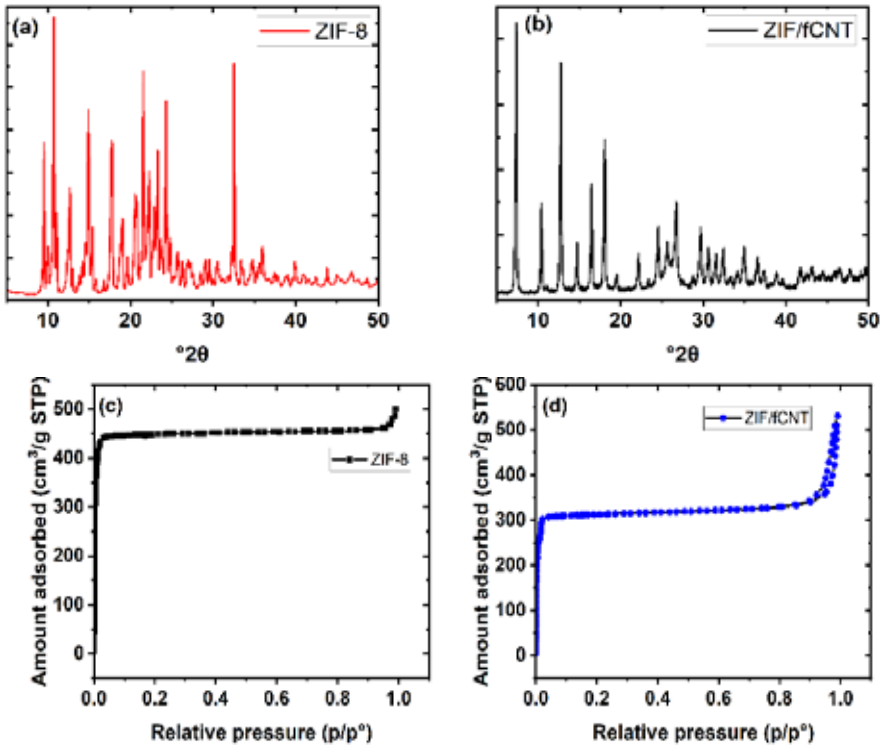

Fig. 2. (a-b) XRD profile of ZIF-8 and ZIF/*f*CNT; and (c-d) Nitrogen isotherms of ZIF-8 nanocrystals and ZIF/*f*CNT hybrid material.

The X-ray diffraction (XRD) profiles of the ZIF-8 base and hybrid materials are represented in Fig. 2a and b, respectively. The detection of strong peaks corresponds to the good crystallization of the ZIF-8 (Fig. 2a) sample and are in accordance with the published reports. Although the presence of CNTs makes broad peaks between 7° and

15° in Fig. 2b, the hybrid material obtained similar peaks as in the base material [13]. This shows that the incorporation of *f*CNTs did not have a detrimental effect on the growth and crystalline structure of ZIF-8.
Fig. 2c and d display the N_2 sorption analysis of ZIF-8 and ZIF/*f*CNT to determine the adsorption properties. The base material exhibited type-1 isotherm indicating that the material was microporous in nature. In contrast, the hybrid material showed type-4 isotherm along with hysteresis loop, which was attributed to the increase of mesopores, which could potentially aid the hydrogen transport and adsorption processes. The measured Brunauer–Emmett–Teller (BET) specific surface area of the two materials was high in both cases and of the same order of magnitude, being 2023.6 m^2/g for ZIF-8 and 1576.9 m^2/g for ZIF/*f*CNT. The reason behind the decrement in the latter sample could be surface coverage of ZIF by the *f*CNTs. The total pore volume increased from 0.77 cm^3/g for ZIF-8 to 0.81 cm^3/g obtained for ZIF/*f*CNT. The average pore size also increased when CNTs were added to ZIF-8 to 2.07 nm; whereas it was 1.52 nm for the base material. The increment in pore size corresponds to new pores created when carbon nanotubes were attached with ZIF-8 nanocrystals [14].

Thermal stability of as-synthesized samples was measured by thermogravimetric analysis (TGA), with obtained curves shown in Fig. 3a. As seen in the TG curves, both materials did not exhibit major change up to 400 °C; after that, the organic linkers in the ZIF-8 framework started decomposing where sudden weight loss was recorded, thus, the structure collapsed. Interestingly, the hybrid material curve shifted to higher temperature and secured 53.32 wt. % of the structure, whereas ZIF-8 holds back 46.7 wt.% of the sample. This quality indicates that the hybrid material has improved the thermal stability due to addition of more stable *f*CNTs. Moreover, *f*CNTs provide as nucleation sites for the growth of ZIF-8 structure [15]. Hydrogen storage measurements carried out on gravimetric apparatus at room temperature and pressure up to 50 bar. Outgassing was done 250 °C for 10 hours prior to the measurements. The H_2 storage results of *f*CNT reference sample are presented in Fig. 3b. Hydrogen uptake showed monotonous dependence on pressure meaning that the uptake increases proportionally to the pressure. As shown, *f*CNT achieved hydrogen storage capacity of 0.15 wt. % which is more than pristine CNTs reported elsewhere [16]. However, the sample desorbed merely 51% of stored hydrogen due to the kinetic changes, and functional groups that could impede hydrogen diffusion inside the cavities. The H_2 storage measurements of ZIF-8 and ZIF/*f*CNT will also be reported and discussed.

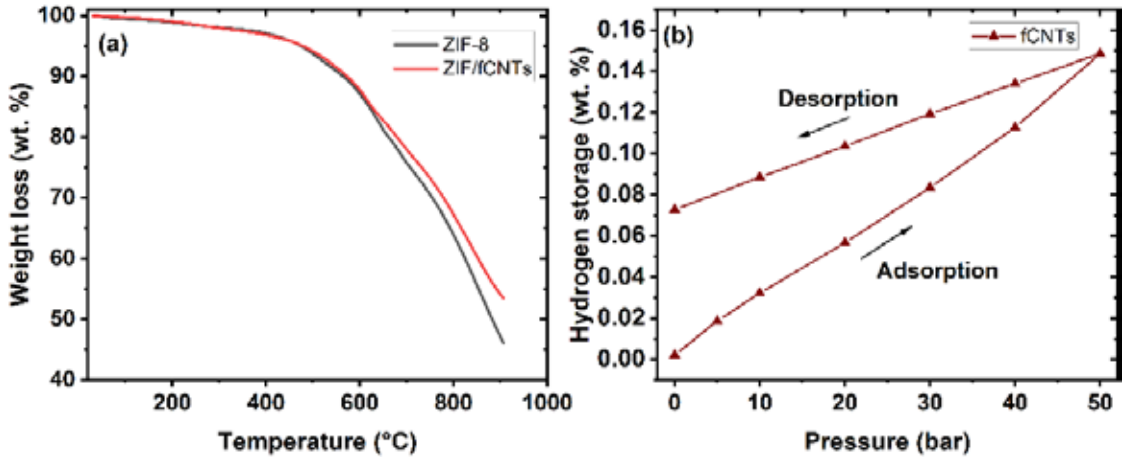

Fig. 3. (a) Thermogravimetric curves of ZIF-8 and ZIF/*f*CNT, and (b) Hydrogen adsorption/desorption isotherms of *f*CNTs.

CONCLUSIONS

Chemical synthesis of zeolitic imidazolate framework (ZIF-8) and hybrid material (ZIF/fCNT) was reported using methanol as solvent at room temperature and atmospheric conditions. A clear and complete crystalline structure of ZIFs are obtained from this method, and both materials showed rhombic dodecahedron morphology with three-dimensional frameworks. There was no detrimental effect seen on the ZIF-8 structure after adding the *f*CNTs. Further, the hybrid material sustained 53.32 wt. % of structure in thermal stability test due more stability of *f*CNT. However, ZIF-8 exhibited the highest surface area of 2023.6 m^2/g whereas 1576.9 m^2/g was obtained for ZIF-8/*f*CNT which is due to the surface coverage of nanotubes on the surface of ZIF-8. The carboxylate functionalized carbon nanotubes stored 0.15 wt. % of hydrogen at room temperature and pressure up to 50 bar which is higher than the pristine CNTs in the published literature.

ABSTRACT

Hydrogen solid state storage technology uses absorption and desorption of di-hydrogen gas at low pressure in metal alloys. In the tank the powder swells, shrinks and decrepitates leading to stress over the wall. The present study first deals with the mechanical characterization by three different methods at different scales, of a storage TiFe alloy. Compression tests of macroscopic samples, ultrasonic elastic characterization, and microscopic scale nano indentation give respectively: 50, 153 and 24 1~305 GPa. This discrepancy is directly linked to the scale and microstructural heterogeneities. An optimization process is proposed to identify a set of numerical parameters able to simulate with DEM the elastic brittle behaviour of our hydride under compression. These data are a first step to model the decrepitating phenomenon and to help design of solid storage tank of hydrogen.

Keywords: hydrogen solid state storage, discrete element modeling, multiscale mechanical characterization

INTRODUCTION

Some metallic compounds react in presence of hydrogen in a reversible way. Hydridation, a true phase transformation is associated to strong volume growth (up to 30%) [1]. During the lifetime of a tank, the storage material, crushed into powder, undergoes repeated swelling and shrinking. It leads to fracture and segregation of particles within the tank and fatigue of the container walls [2]. To better understand and control this phenomenon, identifying the mechanical behavior of these intermetallic compounds is a key challenge.

Indeed, designing hydrogen storage tank require an efficient numerical tool taking into account the decrepitation phenomenon at different scales, from particle size to whole container. In the DEM framework, we aim at identifying the elastic modulus. Here, we propose three experimental methods to assess the elastic modulus of an industrially used TiFe alloy: macroscopic compression test, ultrasonic measurement, nano indentation test. In parallel, a DEM simulation of the compression test is optimized to validate the representation of both elastic and brittle response of the material.

EXPERIMENTAL METHODS

Material and sample preparation

The TiFe ingot is produced in an induction furnace by melting the pure components into a cupper mold. This material can store 1.6 wt.% of hydrogen at 22 °C, at 25 bar. Thus, TiFe is a good candidate to store hydrogen due to absence of rare earth compounds. Usually, the ingot is then crushed to fill the tank. Here after, to perform mechanical characterizations, we deal with the as cast material. Cylindrical samples with a radius $r = 5\,mm$ and a height $h = 15\,mm$ are withdrawn with Electrical Discharged Machine. We obtain 15 samples for compression and ultrasonic tests. In parallel, millimetric particles, from the same ingot, are coated and polished for nano indentation.

Compression tests

Compression tests are carried out over the 15 samples to assess the elastic modulus. We use a 100 kN electromechanical Instron testing machine with two compression plates. The tests are displacement controlled with a velocity of 0.02 mm/s. We acquire the displacement of the crosshead and the resulting force. To correct the device compliance, a compression of the mounting alone is carried out: the displacement on the upper face of the sample is inferred. To get rid of the first contact transitory perturbation while remaining in the elastic domain, the data are processed for forces between 10 kN and 15 kN (~130 to 170 MPa).

Ultrasonic elastic characterization

The elastic modulus can be identified thanks to the velocity of elastic waves in the material. The modulus is related to the velocity by: $E = \rho V^2 A$ with ρ the density, V the velocity of the waves and A a constant. Here the elastic waves are propagated along the longitudinal direction of the compression cylinders (~15 mm long). The wave velocity is inferred from the reflected wave time delay. A parameter is related to the Poisson ratio through $(1-2\nu)(1+\nu)/(1-\nu)$. An error of 4% over ν (± 0.015) induces a variation of 4.5% on E. Here after, the used Poisson ratio is 0.32 (between the raw titanium and raw iron Poisson ratio).

Nano indentation measurement

Measurements have been performed on the surface of one polished particle (~1mm^3) with a CSM ultranano indentor device with a berkovitch indentor (F<50 mN). Two matrices of 10x10 indents spaced 4.5 µm apart, over two different areas on the particle surface have been tested (Fig 1). Each indentation generates a typical displacement-force curve from which an apparent elastic modulus is computed. From the 200 measurements, a clustering analysis is carried out to assess the heterogeneity and an average elastic modulus.

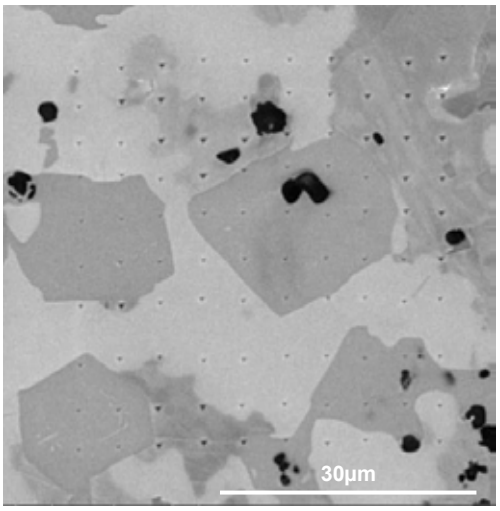

Fig 1. Backscattered SEM micrograph of one matrix of 100 nano indents

NUMERICAL METHODS

Discrete Element Modeling (DEM) data settings

Our final purpose (not discussed here) is to identify the optimal numerical parameters and simulate one hydriding particle response. The compression test is simulated in the framework of DEM, using YADE [3]. We aim to define a set of numerical parameters, at the element scale, which allows predicting the previously identified macroscopic elastic modulus and roughly the brittle fracture. The unknowns are the size of spherical elements, the numerical Young modulus E_N (stiffness between two elements), the admissible tensile strength between two elements σ_N and the cohesion factor C_N. The digital specimen is a cylinder discretized with spherical elements. Its aspect ratio is $r/h = 1/3$ as in experiments. Its volume is similar to one particle volume right after crushing in the tank. The numerical parameters are varied, each simulation return a macroscopic compression curve from which the elastic modulus and the ultimate compression strength are compared to target values.

Numerical parameters identification method

In the framework of DEM, the element size has a critical influence both on the calculus time and on the mechanical response (E_N does not directly correspond to macro rigidity, but only to inter-element interaction description). The trade-off between discretization and calculus time leads to 0.09 mm elements.

Once element size defined, the numerical parameters E_N, σ_N and C_N are varied to fit the macroscopic elastic modulus correlated to experimental compression test results. An optimization based only on the elastic modulus leads to unphysical ultimate compression strength. Thus, fracture limit must be considered in the parameters fitting process. A multi-parameter optimization with two objectives is introduced: E_{obj} (elastic modulus) and UCS_{obj}(ultimate compressive strength). For computation sake, a mono-objective formulation is obtained by defining the relative error average: $\varepsilon = \frac{1}{2}\left(\left|\frac{E_{mes}-E_{obj}}{E_{obj}}\right| + \left|\frac{UCS_{mes}-UCS_{obj}}{UCS_{obj}}\right|\right)$. For simplicity, optimization is based on a simplex method [4]. We perform the optimization method from several initial sets of parameters to analyse the impact of initial conditions on the convergence quality: occurrence of a global minimum or several local minima.

RESULTS AND DISCUSSION

Compression test

Most of the specimen collapse in a brittle way before a linear behaviour is settled down. Fig 2 shows the engineering stress-strain curves of the seven non-fractured samples. Elastic modulus is identified around 50 GPa with a standard deviation of 8 GPa. This value is surprisingly low, and we suspect an important effect of the casting defaults, mainly pre-existing cracks, inner shrinking and heterogeneity of the metallurgical microstructure. It appears that the macro scale is not well suited to characterize such a damaged material elasticity.

Ultrasonic elastic characterization

Three non-fractured samples are analysed. The wave velocity for all specimens is found at 5875 m/s. Consequently, the elastic modulus is assessed at 153 GPa $\pm$ 7 GPa, (4.5% on E). This value seems peculiarly satisfactory when considering elastic modulus of both Iron and Titanium. Nevertheless, the ultrasonic technic remains sensitive to damage, such as cracks, that might disturb wave propagation. Thus, additional characterization was needed to investigate the elastic property at a different scale.

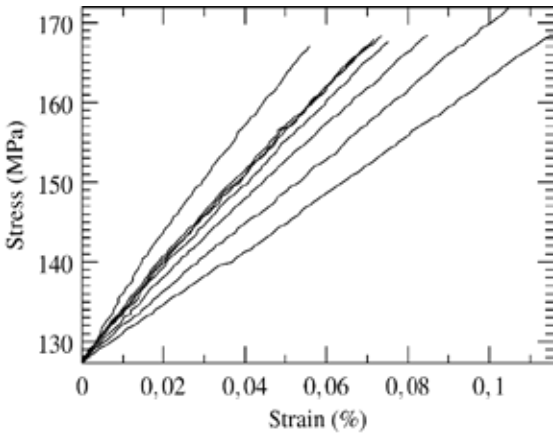

Fig 2. Stress-strain curves of the non-fractured samples

Nano indentation measurement

The SEM micrograph (Fig 1) shows one of the matrices of indents. The studied alloy exhibits strong heterogeneity at the microscale (domains radius ~15µm, numerous spheroidal inclusions…). A clustering analysis of the 200 concatenated measurements [5] reveals four co-existing populations, well correlated with microstructural domains, each characterized by one indentation elastic modulus (see Table 1). The hardest domain (area 4: E=350 ± 29 GPa) corresponding to precipitates. The rest of the sample is composed of similar metallurgical phases whose local elastic modulus is between 241 GPa and 305 GPa.

Table 1. Elastic modulus of the four populations measured by nano indentation

Area number	Indentation Elastic Modulus (GPa)	Corresponding color on SEM micrograph (Fig 3)
1	257 ± 14	Lightest grey
2	241 ± 7	Tabby grey
3	305 ± 12	Darkest grey
4	350 ± 29	Black dots

Even if the stiffness is revealed highly heterogeneous at micro scale, the different domains in the core material, with a typical size of 15 µm, are nested with each other. The use of a homogenized modulus at an upper scale seems relevant. It should also be noted that this very small-scale method tests the medium between structural defects (joints, cracks, shrinkage), so it is normal to obtain a rather high estimate of the stiffness.

Experimental summary

Table 2 summarises the identified elastic modulus. The values are significantly different from one method to another according to the working scale. Each technic is sensitive to specific heterogeneities or structural defects. Further numerical investigations deal with an intermediate scale: the millimetric particle. It stands on two scalar material parameters to give account rigidity and brittleness. We have arbitrary chosen E_{obj} = 200 GPa and UCS_{obj} = 400 MPa.

Table 2. Summary of the elastic modulus measurements

Nano Indentation	Compression Test	Ultrasonic method
241~300 GPa	50 GPa	150 GPa

Numerical parameters identification

Every optimisation converges in 5 hours on a desktop computer; results are summed up in Table 3 . Depending on the initialization, the simplex method converges toward a local minimum. In the DEM framework, a given macro behavior can potentially be simulated with several set of micro- numerical parameters. A suitable one set of parameter presents both small error (ε) and a good physical agreement. In our case, only one is suitable (bolted line on the Table 3).

Table 3. Results of the optimizations from different set of initial parameters

Initiation micro parameters			**Optimized micro parameters**			**Macroscopic elastic parameters**		
E_N	σ_N	C_N	E_N	σ_N	C_N	E (GPa)	UCS (MPa)	ε (%)
500	500	12	504	504	12.3	215	1100	1330%
430	670	13	417	703	13.2	176	14200	1730%
350	**102**	**3**	**451**	**736**	**2.16**	**191**	**449**	**5%**
100	200	15	100	203	15	0.43	4010	490%
800	200	3	945	843	2.67	241	288	24%

CONCLUSION

We paid attention on the mechanical behaviour of TiFe alloy to predict the breathing phenomenon during the lifetime of solid storage state tank. Experimental investigations using different methods permit to estimate the elastic modulus

at 50, 150 or 241~305 GPa: unfortunately, dependant on the considered scale of a highly heterogeneous and damaged material. A range of order (200 GPa) is nonetheless argued for simulation of millimetre particle. In parallel a DEM simulation of compression on a millimetric sample is optimized to link numerical inter-elements parameters to the macroscopic response. Several sets of optimum parameters regarding the elastic modulus and the ultimate compression strength are found. Among theses sets one is identified as suitable for further numerical investigation about the phenomenology of decrepitation or the design of storage tank

ABSTRACT

High-pressure hydrogen storage systems are indispensable for the widespread implementation of hydrogen technology, which is why there is a requirement for an efficient compressor. The most used method of hydrogen compression is via mechanical compressors, but lately, electrochemical hydrogen compressors (EHCs) are increasingly getting more attention due to their many advantages. However, in published articles, there is a limited number of mathematical models due to the intricate nature of the EHC operating mechanism. In this paper, a mathematical model of EHC made in MATLAB/Simulink Software is described through simple equations based on the fundamental physics laws and electrochemical relations, considering occurring overvoltages, including hydrogen back-diffusion. The results obtained as time functions are analysed for various operating temperatures to give more detailed insight on temperature influence on different parameters which affect EHC performance. The simulation indicates temperature effect on multiple inner processes, necessitating optimisation of parameters to balance adverse temperature impact according to required EHC features.

Keywords: Electrochemical hydrogen compressor, Proton exchange membrane, MATLAB/Simulink, Temperature

INTRODUCTION

To store gaseous hydrogen at higher pressures (350 bar or 700 bar, depending on the hydrogen storage type), a compressor is needed. Theoretically, compression could be possible in the process of hydrogen production with a proton exchange membrane (PEM) electrolyzer, if not for the hydrogen permeation to the oxygen side forming a potentially explosive mixture [1]. EHC has an analogous working principle, only without hydrogen back-diffusion presenting a critical safety issue but limiting the compressor's performance. Humidified hydrogen at low pressure is fed to the anode flow field plate and collected at the cathode flow field plate at higher pressure due to potential difference applied on the electrodes from the outside power source. The hydrogen molecule is divided into atoms and oxidized at anode catalyst layer into electron and proton, which transports through the selective PEM, reducing with electron to hydrogen molecule again at the cathode catalyst layer. Presently, the highest achieved EHC stack output pressure amounts to 1000 bar [2], while for the one EHC cell, the highest reached value is 168 bar [3]. The pressure limiting critical issues are membrane deformation and hydrogen back-diffusion due to significant pressure difference, both creating a requirement for further research to improve the EHC performance. Also, other limiting factors are present overvoltages, which are the reason why the total applied cell voltage must be increased. One of the enhancement approaches is the optimisation of EHC operation with parameter change, such as temperature, input pressure, or stoichiometric ratio, to increase the output pressure [4]. The easiest way to determine different parameters influence on the EHC performance can be achieved via mathematical modelling. Several authors have published their modelled results [5–8], but there is a literature gap for detailed models describing EHC dynamics, especially accounting for back-diffusion, as Durmus et al. [9] highlighted in review on the development of the EHCs.

MATHEMATICAL MODELLING OF ELECTROCHEMICAL HYDROGEN COMPRESSOR

Equations described in this chapter are implemented in the mathematical model of single-cell EHC made with MATLAB/Simulink, which was then validated with experimental results published by Chouchan et al. [10] at 275 K. The EHC operating temperature range analysed is stated according to optimal PEM temperature (295 – 355 K), i.e., Nafion – the most frequently used low-temperature membrane [11]. The maximum temperature is limited due to a decrease in membrane moisture level with high temperatures, which strongly reflects on the membrane proton conductivity [12]. Relevant input parameters for EHC mathematical model are listed in
Table 1.

The overall EHC efficiency (Eq. 1) is defined by voltage (Eq. 2) and current efficiency (Eq. 3), where voltage efficiency is the ratio of theoretical voltage and applied cell voltage and current efficiency as output and theoretical value of compressed hydrogen governed by Faraday's law.

$$\eta_{EHC} = \eta_{voltage} \times \eta_{current} \quad (1)$$

$$\eta_{voltage} = E_{Nernst} / E_{EHC} \quad (2)$$

$$\eta_{current} = q_{n,output} / q_{n,theoretical} \quad (3)$$

Table 1. Input parameters for EHC mathematical model

Input	Label	Amount	Unit	Reference
Membrane thickness	φ	0.0125	cm	Nafion 115 manufactured thickness
Temperature	*T*	295 – 355	K	Nafion temperature range
Active area	*A*	25	cm^2	Nafion 115 manufactured area
Anode pressure	p_{input}	101325	Pa	Constant atmosphere pressure
Total cell voltage	E_{EHC}	0.025 – 0.1	V	[10]
Membrane water content	λ	17	-	Hydrated Nafion membrane [13]
Charge transfer coefficient at anode and cathode	α	0.5	-	Equal to the symmetry factor for both electrodes
Permeability constant	*DH*	$8.61* 10^{-15}$	mol/(Pa*m*s)	Average value for Nafion 115 [10]
Cathode volume	V_c	24.14	cm^3	[10]

The voltage efficiency evaluates the irreversibility and resistance of EHC accounting for the activation overpotentials, ohmic overpotential, mass-transfer overpotential, and diffusion overpotential, as shown in Eq. 4, while the current efficiency describes EHC mechanical reliability and is affected by the possible leakage on the cathode side and hydrogen back-diffusion [10].

$$E_{EHC} = E_{Nernst} + \eta_{act} + \eta_{ohm} + \eta_{mass-transf} + \eta_{diff} \quad (4)$$

Nernst voltage is the theoretical minimum voltage that needs to be applied to achieve a relative pressure difference. The activation overpotentials describe the kinetics of electrochemical reactions occurring at anode and cathode, ohmic overpotential shows the resistance due to the EHC component's contact, as well as resistance to proton transfer through PEM, depending on membrane's dimensions, water content and the operating current. Mass-transfer overvoltage includes flow limitations that hydrogen encounters when approaching catalyst due to high current inserting faster pace. Diffusion overpotential accounts for the concentration difference due to hydrogen back-diffusion [14] and is calculated by reducing the total voltage by other overvoltages. All listed limitations are surmounted by increasing the applied potential difference (total cell voltage), which lowers the EHC efficiency as shown in Eq. 2.

RESULTS AND DISCUSSION

The polarization curve has been registered while changing the temperature from 295 K to 355 K and applied potential from 0.025 V to 0.1 V. The current density, as well as the hydrogen flux, increase with the temperature rise [7] at the start of a simulation due to the positive impact on the membrane proton conductivity. While reaching equilibrium (*i* = const., *p* = const., $q_{n,output}$ = 0), higher temperature EHCs current density drops faster, resulting in output pressure lower equilibrium values. Better hydrogen permeability through PEM also causes a decrease in ohmic resistance, which consequently heightens EHC voltage efficiency [4], hence, to pump the same amount of hydrogen (constant current density), at lower temperatures EHC requires more electric power than at higher temperatures [15]. However, the mass transfer and activation overpotentials are higher with temperature increase [16]. Furthermore, hydrogen back diffusion has higher rates [5], which lowers the EHC current efficiency. As can be seen in Fig. 1, by applying the higher potential difference, hydrogen is compressed to higher pressures with the consequence of lower efficiency. Also, for all simulated total voltages, with lower temperatures, higher output pressure can be achieved. However, for smaller pressure differences, increased temperature ensures improved EHC efficiency. Nonetheless, the energy needed for increasing the temperature should also be considered.

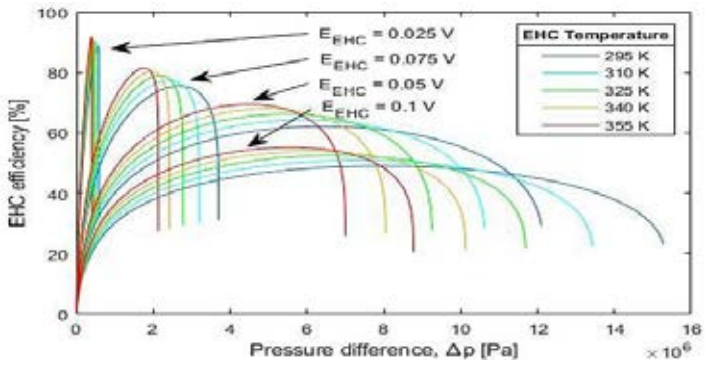

Fig. 1. Simulated temperature influence on EHC efficiency for different applied voltages regarding achieved output pressure

CONCLUSIONS

Simulation analysis has been conducted for the simplified mathematical model of EHC to better understand its performance, described with essential governing equations, under different operating temperatures. The model accounted for Nernst potential, activation overpotentials, ohmic overpotential, and hydrogen back-diffusion. Temperature change affects the EHC performance in multiple ways, principally, membrane proton conductivity, overvoltages, Nernst potential, and hydrogen back diffusion, all impacting the efficiency and output pressure. Taken all into account, the simulation indicates that the EHC should operate at the optimum operating temperature depending on the required output parameters. For further research, a comprising mathematical model accounting more detailed water management will be conducted with accompanying experiment validation.

EXPERIMENTAL PROOF OF CONCEPT OF A NOVEL HIGH DENSITY, LOW PRESSURE HYDROGEN STORAGE SYSTEM UTILIZING THERMOCHEMICAL HEAT STORAGE

[1*] *Michael Lutz,* [1] *Marc Linder,* [1] *Inga Bürger*

ABSTRACT

In the next decades the global energy system will shift towards renewable energy. Hydrogen technologies have the potential to play a major role in the future´s energy grid. With hydrogen becoming more and more important, safe and efficient hydrogen storage systems are required. Metal hydrides are able to chemically store hydrogen free of loss, at low pressures and potentially high storage densities. However, hydrides with exceptionally high storage densities, such as magnesium hydride, require high operation temperatures above 250 °C. Therefore, heat management is challenging, since heat at that temperature level has to be supplied and removed for hydrogen desorption and absorption, respectively. In this work, the experimental proof of concept of a novel hydrogen storage system using magnesium hydride and the thermochemical heat storage system $Mg(OH)_2$ / MgO is presented. Thereby, the heat of absorption is stored in the same reactor and – with the supply of water vapor - it is available for the hydrogen desorption again. Potentially, storage densities of 20.8 g_{H2} L^{-1} can be stored at a hydrogen pressure of 9 bar. A water vapor pressure of 9.75 bar is sufficient to reach 300 °C in the MgO compartment, which is sufficiently high to drive the H_2 desorption.

Keywords: Hydrogen storage, thermochemical heat storage, magnesium hydride, magnesium hydroxide

INTRODUCTION

With the shift of our global energy system from energy carriers based on fossil fuels towards renewable ones, new energy storage technologies have to be developed. One possibility to store excess electrical energy for later use is its conversion to chemically stored energy such as hydrogen. With hydrogen becoming more and more important, there is a need for safe and efficient hydrogen storage technologies. State of the art systems for that purpose are pressurized storage or liquefaction which have either low efficiency or their safety is questionable.

Metal hydrides represent one option to store hydrogen [1], reaching high volumetric storage densities at low pressures along with loss-free long-time storage. However, due to their chemical reaction, heat is being released and required during hydrogen absorption and desorption, respectively. This heat management is challenging, as e.g. for magnesium hydride showing an exceptionally high storage density of 7.7 w.t%, the temperature level is above 250 °C.

In this contribution we experimentally proof the concept of a novel stationary adiabatic hydrogen storage system, which utilizes magnesium hydride due to its high storage density at a pressure below 10 bar without requiring excessive external heat management. We incorporated a thermochemical heat storage system, namely the $Mg(OH)_2$ / MgO system, into the same reactor. The heat being released during the hydrogen absorption in the metal hydride is thermochemically stored via the dissociation of $Mg(OH)_2$ to MgO and water vapor. To reverse the reaction, water vapor is supplied to the MgO, the previously stored heat is released leading to the desired hydrogen release from the magnesium hydride. While this system has been investigated before analytically [2] and numerically [3] [4], this contribution provides the experimental proof of concept of the adiabatic storage system with high density at low pressure. Further results of this experimental proof have been published in [5].

EXPERIMENTAL

The adiabatic storage reactor was constructed and tested in laboratory scale. It was connected to a test bench which is able to provide hydrogen in the pressure range of 1 to 50 bar and water vapor in the pressure range of 50 mbar to 10 bar. Furthermore, constant pressure can be applied during the experiments. The reactor itself consists of a double walled tube with 234 g magnesium hydride in the inner tube and 400 g magnesium hydroxide in the outer tube, separated by a steel wall. Therefore, heat transfer between the materials is possible while mixing of the gases is prevented. An alloy of 90% magnesium and 10% nickel along with 10 wt.% expanded natural graphite was used as hydrogen storage material. These compounds were compressed to pellets with a diameter of 30 mm. For hydrogen supply and incorporation of thermocouples into a stack of pellets, a central hole was drilled. The pellets were manufactured at Fraunhofer Institute for Manufacturing Technology and Advanced Materials IFAM in Dresden,

Germany [6] The unmodified magnesium hydroxide was obtained from Sigma-Aldrich (Nr. 63081). Both materials and a section of the reactor are shown in Fig. 1.

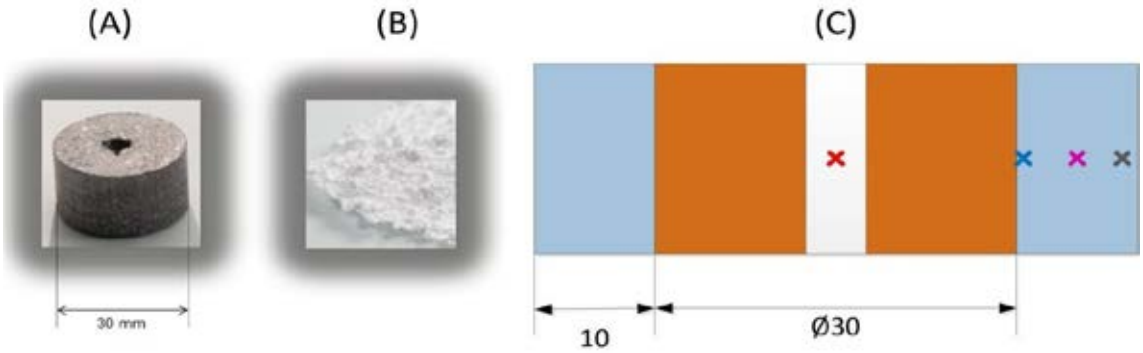

Fig. 1. (A) Mg90Ni10 Pellets; (B) Magnesium hydroxide powder; (C) Reactor system, magnesium hydride in the central tube, magnesium hydroxide in the outer tube. Positions of thermocouples are denoted with x

RESULTS AND DISCUSSION

In the reactor, two thermochemical gas-solid reactions take place. To proof that there is an enhancing effect of the thermochemical heat storage material on the hydrogen uptake and release, a reference experiment was conducted. Therefore, only the magnesium hydride was reacting, while the thermochemical heat storage material was in the MgO state (inert unless exposed to water vapor). This reference experiment is shown by the lines with the open markers in Fig. 2. Afterwards, the same experimental procedure was applied involving the dehydration and hydration, respectively. These experiments are visualized with the full markers in Fig. 2.

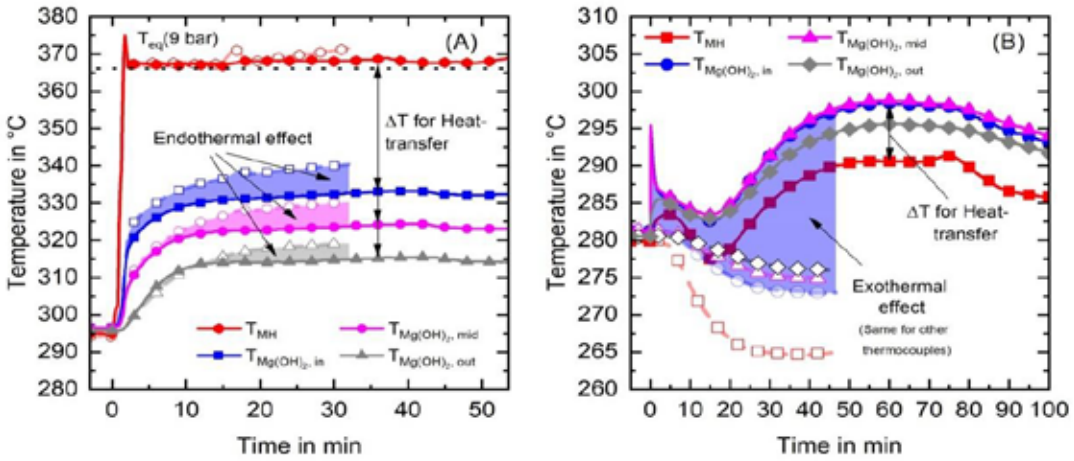

Fig. 2. Reactor temperatures during hydrogen storage (A) and release (B). p(H_2,storage)=9 bar, p(H_2O,storage)=60 mbar, p(H_2,release)=1 bar, p(H_2O, release)=9.75 bar; Open markers: Reference; Closed markers: Combined experiment

For the hydrogen absorption (Fig. 2 A), the reactor was preheated, before the pressure was increased to 9 bar. The temperature in the metal hydride rises sharply to its equilibrium temperature for both the reference and the combined experiment. Heat transfer to the MgO bed (reference) and $Mg(OH)_2$ bed (combined) takes place resulting in a slow heatup of the material. The part of the material close to the heat conducting steel wall heats up more quickly than the outer one. Hence, a temperature gradient in the bed can be observed, which is due to the poor thermal conductivity of the powdery material. The difference in the heat-up of the $Mg(OH)_2$ bed can be seen in the shaded areas in Fig. 2 (A). The temperature increase is less pronounced in the combined experiment. This is because the $Mg(OH)_2$ dissociates endothermally into MgO and water vapor creating a heat sink. After around 15 min the hydrogen supply was switched from constant pressure to contend inflow-rate of 4.3 g_{H2} h^{-1}. It can be seen that the metal hydride temperature (red) increases afterwards, which is attributed to a pressure increase which is now shown. This indicates that the overall hydrogen absorption rate is below 4.3 g_{H2} h^{-1}. In contrast, for the combined experiment, the temperature remains constant indicating that the overall hydrogen absorption rate is at

least 4.3 g_{H2} h^{-1}. Therefore, it can be concluded that the hydrogen absorption is faster in the combined experiment due to thermochemical cooling.

For the hydrogen release shown in Fig. 2 (B) the experimental procedure was similar. Hydrogen was supposed to be released at a constant pressure of 1 bar. In the reference experiment, the temperature in the metal hydride drops quickly. This behaviour is due to heat consumption of the dehydrogenation from the hot metal hydride itself. Since there is no additional heating, the temperature drops until the reaction rate becomes almost zero, since it is too cold. The combined experiment was initiated with the sudden increase of the water vapor pressure to 9.75 bar. Thereby, the previously stored thermal energy is released again. After an initial temperature spike, which is probably attributed to adsorption, and interim cooldown, the exothermal MgO hydration reaction accelerates. This causes the temperature increase to a maximum of 299 °C. A clear difference to the reference experiment can be observed. Since the metal hydride temperature was kept higher than in the reference experiment, more hydrogen can be released.

The experimental results of this first lab-scale reactor confirmed that hydrogen can be stored reversibly at 20.8 g_{H2} L^{-1} at a storage pressure of 9 bar. This value was calculated with the materials only, without the reactor vessel.

CONCLUSION

In this contribution experimental results of a novel hydrogen storage system are presented working at high capacity and low pressure. Magnesium hydride was coupled with magnesium hydroxide working as thermochemical heat storage material. Therefore, an exothermal and endothermal reaction are compensating for each other allowing the system to be operated with minimal external heat management. Thereby, the main disadvantage of magnesium hydride was overcome while maintaining its advantages, such as high capacity at a pressure below 10 bar. The storage capacity based on the volume of the two materials is 20.8 gH_2 L^{-1} at a pressure of 9 bar, which is greater than the 350 bar pressure tank (16.1 gH_2 L^{-1}) and approximately equal to 700 bar pressure [7]. However, the pressure of 9 bar is more feasible. Summing it all up, the adiabatic hydrogen storage system is a promising system to contribute to the future´s hydrogen infrastructure for stationary storage.

ABSTRACT

Blow Molded Plastic Liners (BMPL) for on-board type IV Compressed Gaseous Hydrogen (CGH2) storage tanks consist of a high-molecular-weight polymer wall that serves as a permeation layer for hydrogen gas. This paper presents the latest numerical model integrated in the BlowView[1] software for predicting the hydrogen permeation in a BMPL. The prediction model is based on Fick's solution-diffusion laws, with pressure and temperature dependent transport properties, for steady/unsteady state permeation regimes through a polymeric wall. An overview of key simulation results for an industrial BMPL for a CGH2 tank, as well as the adopted methodology addressing the challenge to maximize the enclosed volume, while optimizing the wall thickness for light weighting and permeability performance, are also presented.

Keywords: type IV hydrogen tank, hydrogen permeation, plastic liner, simulation, fuel cell electrical vehicle (FCEV).

INTRODUCTION

A key challenge to the widespread commercialization of FCEV, is to design compact and cost effective on-board CGH2 tanks which store sufficient quantities of H2 without sacrificing passenger and cargo space. The first generation of FCEVs use 700 bar Type IV pressure vessels to store hydrogen [1]. These vessels have a cylindrical BMPL, overwrapped by carbon-fiber composite material to maintain the internal pressure, which serves as a hydrogen gas permeation layer. However, due to its small molecular size, H2 permeates through the plastic liner wall. This represents a serious issue that should be addressed early in the design stage in order to minimize H2 emissions from the liner and conform to legal safety requirements and standards. Thereby, automotive OEMs and their suppliers are being challenged to design longer and thinner liners with very consistent wall thickness. One way to meet the hydrogen permeation rate requires a judicious choice of liner material. In the thermoplastic forming industry, it is still common practice to rely on trial and error to find the appropriate barrier layer configuration/thickness required to meet the permeation rate limit requirement. A tool offering a more efficient alternative, based on reliable predictive/virtual analysis of the H2 diffusion through the BMPL, could significantly shorten the design/development cycle by allowing product prototypes to be analyzed and tested virtually. A finite element-based model that could help a designer better understand barrier layer properties was integrated in the latest version of NRC's BlowView software [2, 3]. The mathematical diffusion model adopted is based on Fick's diffusion law to predict H2 diffusion through a polymeric wall. Promising results, in terms of H2 permeation rate on an industrial BMPL, were obtained using BlowView.

THE PERMEATION MECHANISM AND MATHEMATICAL MODEL

The permeation mechanism occurs in three main phases: The first phase is the absorption of the permeant (H2) into the polymer that occurs at the upstream side of the polymer wall. The second phase is the diffusion of the permeant from the surface to the core of the polymer due to the concentration gradient. Finally, the permeant desorbs on the downstream side of the membrane and is removed from the surface by convection to the surrounding air. Given the inherently low diffusivity of plastics and the special geometrical configuration of a BMPL, which is relatively thin compared to their surface area, one dimensional diffusion is usually assumed though the thickness. The permeant diffusion equation for a diffusivity, D, is given by the following expression of Fick's second law [4]:

$$\frac{\partial C}{\partial t} = -\frac{\partial}{\partial x}(J_{H2}) = -\frac{\partial}{\partial x}\left(D\frac{\partial C}{\partial x}\right) \quad (1)$$

[1]BlowView is an engineering simulation software developed at NRC and used to simulate and optimize several forming processes: conventional, twin sheet and 3D extrusion blow molding, thermoforming and injection stretch blow molding.

Where, C is the permeant concentration in the polymer matrix, t is the time, and x the distance through the thickness. However, since the measurement of concentrations is not always a simple task, we instead use Henry's law, Eq. (2), where S is Henry's solubility coefficient and p_{H2} is the H2 pressure:

$$C = S.p_{H2} \quad (2)$$

The new partial differential equation (PDE) is obtained by substituting Eq. (2) in Eq. (1) as follows:

$$\frac{\partial}{\partial t}(S.p_{H2}) = -\frac{\partial}{\partial x}\left(D\frac{\partial}{\partial x}(S.p_{H2})\right) \quad (3)$$

EFFECT OF TEMPERATURE AND PRESSURE ON TRANSPORT COEFFICIENTS

Many references exploring the influence of temperature on the gas solubility coefficient S, diffusion coefficient D, and permeability coefficient P, in polymers have proved that the variation of the coefficients obeys an Arrhenius-type relationship over a small temperature range as [4]:

$$S = S_\infty.\exp\left(-\frac{\Delta H_S}{R.T}\right); \qquad D = D_\infty.\exp\left(-\frac{E_D}{R.T}\right); \qquad P = P_\infty.\exp\left(-\frac{E_P}{R.T}\right) \quad (4)$$

Where, S_∞, D_∞ and P_∞ represent the limit values of various transportation coefficients when the temperature tends to infinity. ΔH_S, E_D and E_P represent the heat of dissolution required for the penetrant to dissolve in the polymer matrix, the activation energy diffusion process, and the apparent activation energy for permeation, respectively. It is obvious from the relationship $P = S \times D$ that $E_P = \Delta H_s + E_D$. For hydrogen, both ΔH_S and E_D are positive values [4]. R and T denote the universal gas constant and the absolute temperature (in Kelvin). In general, this temperature dependence, Eq.(4), is obeyed for polymer materials at low pressures as long as the microstructure of the material is not changing. On the other hand, high pressures will affect the microstructure, and therefore, the permeation depends on the imposed stresses and material characteristics. The polymer transport properties will be considered for ideal sorption where the effects of hydrostatic pressure on the polymeric structure can be idealized as arising from two opposing effects: (1) the compression of the polymer due to imposed hydrostatic pressure, which reduces diffusion (negative β_D); and (2) the swelling of the polymer due to hydrogen solubility, which enhances diffusion (positive β_s) [5].. These two effects are combined in a single parameter β as described in equation (5).

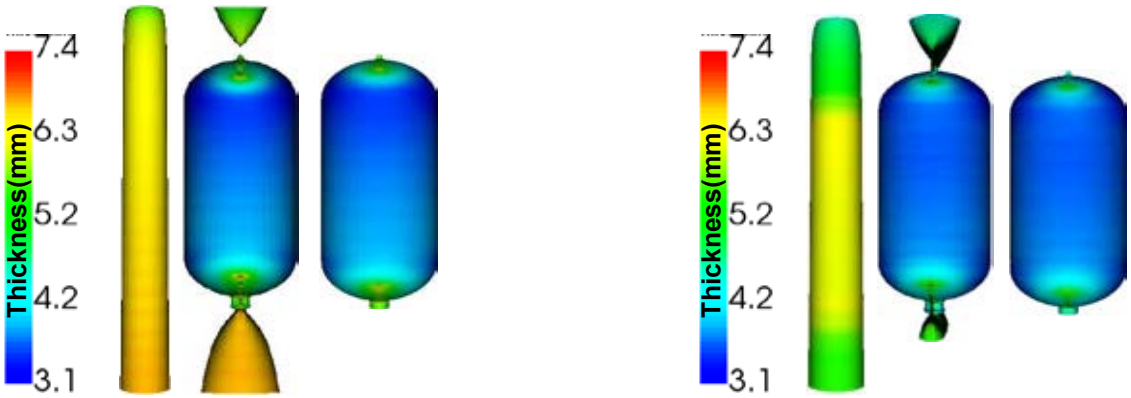
$$S = S_0.\exp(\beta_s.p_{H2}); \qquad D = D_0.\exp(\beta_D.p_{H2}); \qquad P = P_0.\exp((\beta_{s+}\beta_D).p_{H2}) \quad (5)$$

Where, S_0, D_0 and P_0 represent values of various transportation coefficients at atmospheric pressure and $\beta = \beta_{s+}\beta_D$. Therefore, the combined effect of the temperature and pressure on the transport coefficients can be obtained by substituting Eq.(4) in Eq.(5):

$$S = S_\infty.exp\left(\beta_s.p_{H2} - \frac{\Delta H_S}{R.T}\right); \qquad D = D_\infty.exp\left(\beta_D.p_{H2} - \frac{E_D}{R.T}\right); \qquad P = P_\infty.exp\left((\beta_{s+}\beta_D).p_{H2} + \frac{\Delta H_S + E_D}{R.T}\right) \quad (6)$$

NUMERICAL RESOLUTION

After substituting the solubility and diffusivity expression from Eq.(6) in Eq.(3) we obtain the following PDE:



$$\frac{\partial}{\partial t}\left(S_\infty.\exp\left(\beta_s.p_{H2} - \frac{\Delta H_S}{R.T}\right).p_{H2}\right) + \frac{\partial}{\partial x}\left(D_\infty.\exp\left(\beta_D.p_{H2} - \frac{E_D}{R.T}\right)\frac{\partial}{\partial x}\left(S_\infty.\exp\left(\beta_s.p_{H2} - \frac{\Delta H_S}{R.T}\right).p_{H2}\right)\right) = 0 \quad (7)$$

An appropriate numerical method is used to solve the obtained transient nonlinear PDE with respect to the initial boundary conditions. The finite element method is used for space discretization and the Euler implicit scheme for time integration. Details regarding the mathematical formulation of the space discretization and the time integration are not provided here since they fall out of the scoop of this work.

PLASTIC LINER SIMULATION RESULTS

The H2 permeation rate for a typical BMPL was predicted using BlowView for different permeation scenarios and the results are presented below. The length and the diameter of the industrial liner are 365 and 720 mm, respectively. The corresponding enclosed volume capacity is 62.4L. Figures 1a and 1b show the predicted thickness distribution at the end of parison extrusion, inflation and finally after mapping, for the initial and optimized design. The liner weight was reduced from 10.6 kg to 10.3 kg after 19 optimization iterations by improving the thickness uniformity. It is important to note that the permeability analysis was performed on the optimized mapped part, with the H2 stored at a constant pressure of 70 MPa. The temperature and pressure dependent H2 solubility and diffusivity coefficients for three HDPE grades are reported in Table 1 [4, 5]. Figure 2 illustrates the predicted H2 flux over the monolayer liner shell for the different HDPE grades at 20°C. The overall H2 permeation is also reported and should be compared to the maximum allowable limit at 20°C and 45°C provided by [6]. From Figure 2.a, we notice that the H2 permeation of the HDPE-1 liner (i.e., 17.2 NmL/hr/L) exceeds the maximum allowable limit at 20°C (i.e., 8.0 NmL/hr/L). However,

as illustrated in Figures 2.b and 2.c, the permeation of the liners made from materials HDPE-2 and HDPE-3 are, respectively, 5.1 and 3.5 NmL/hr/L, both below the maximum allowable. From Figure 2.d, we also observe that the H2 permeation for HDPE-3 increases to 26.4 NmL/hr/L at 45°C, which represents +700% compared to 20°C. Unfortunately, we can't compare this result to the maximum allowable permeation rate at 45°C since this information is not available in the literature.

CONCLUSIONS

A finite element based numerical simulation model for the prediction of H2 permeation through a BMPL for a CGH2 storage tank in steady and unsteady regimes, incorporating a novel method for the treatment of the diffusion in the pinch-off zone, was developed. This H2 permeation model was incorporated in BlowView to optimize the barrier layer to satisfy the daily permeation rate constraint. More results will be shared during the conference presentation.

ABSTRACT
The use of Liquid Organic Hydrogen Carriers (LOHC) is widely studied as a promising material for long-term hydrogen transport and storage, these materials have different techno-economic characteristics that directly influence the operating conditions and cost of the hydrogenation and dehydrogenation process. The selection Three LOHC pairs were selected and prioritized through TOPSIS multicriteria methodology and CRITIC weighting, through the ten technical criteria.

Keywords: LOHC priorization, multicriteria decision, CRITIC methodology, hydrogen storage, TOPSIS.

INTRODUCTION
The increase in world energy consumption and dependence on fossil energy sources that result in the upgrown in greenhouse gases and with them global warming [1] In this way, the need to use other fuels that are sustainable and clean is generated to replace conventional fuels [2] hydrogen as an energy vector has an enormous potential for application in this way, it has been considered as an alternative to largely satisfy the demand for renewable energy expected by 2050 [3]. The energy density of hydrogen exceeds three times that of oil, and its combustion also has zero greenhouse gas emissions[4].

Liquid organic hydrogen carriers (LOHC) have been proposed for the storage and transport of hydrogen with the aim of its application in industries, power plants and as fuels. These are materials with a high storage and transport capacity without the risks and costs that consider liquefaction and compression of pure hydrogen gas [5].
Hydrogenation and dehydrogenation processes are used as key elements in the use of technology, since they take advantage of the advantages of working with liquids in industry [7].The most relevant aspects in the area are the development of dehydrogenation and hydrogenation equipment, synthesis and evaluation of the most suitable catalysts, design and selection of new organic materials with greater capacity for hydrogenation and dehydrogenation; greater ease of processing and lower associated [6], [8]. Decision-making in the energy sector and the need to process specific information under conditions of uncertainty has increased the importance of decision-making methods as a tool for problem solving [9]. Multi-criteria analysis decision analysis (MCDA) are widely used in decision-making and policy-making problems [10], AHP, ANP, ELECTRE and TOPSIS are commonly found; they are used due to their simplicity and in built-in models [11]. The selection of LOCH materials has been approached by evaluating their physicochemical properties by [5], [12], [13]; in none of these cases has MCDA been used. In this work, the chosen MCDA method is the Technique of Order Preference Similarity to the Ideal Solution (TOPSIS) is a multi-criteria decision-making analysis for choosing the best alternative with the shortest distance from ideal solution and the longest distance from negative ideal solution[12]. The advantage of using this methodology is that it allows evaluating qualitative and quantitative criteria, offering a reliable answer that is easy to apply.

The evaluation of this methodology requires establishing a weight for the evaluation of criteria or weighting of criteria, these weights are of great importance in the decision-making process, there are numerous subjective and objective approaches[9], due to the limited availability of experts in LOHC and to eliminate possible contradictions in the most common evaluations such as AHP and ANP.

The Criteria importance through intercriteria (CRITIC) is a method that proposes the determination of objective weights which is based on the quantification of two fundamental notions of MCDM: the contrast intensity and the conflicting character of the evaluation criteria [13]. This work proposes a prioritization of LOHC materials through technical criteria with the use of multicriteria analysis tools that have not been applied in this type of decisions and the application of the CRITIC method for objective decision making and eliminating the biases of the methods AHP and ANP.

MATERIALS AND METHODS

The selection of alternatives and criteria were carried out by means of a bibliographic search, all the LOHCs used for studies with feasibility of application were considered, the materials that are not fully available in hydrothermal markets and which did not have economic or logistic feasibility were discarded.

Criteria weighting CRITIC. In this method, the weights are determined based on the contrast intensity and conflict evaluation of the decision problem. Additionally, human intervention is not required for the evaluation process. Sahin shows in details the step of method used [9], the main structure of the method can be summarized as[9].

RESULTS AND DISCUSSION

The table 1 shows the main pairs of LOHC used, the selection is based on its importance for industrial applications, on the largest number of studies reported in the literature and the technological available information.

Table 1. The main properties of LOHC pairs [7][14]

No	Factor criteria	Dibenziltoluene–perhydro-dibenzyl toluene (DBT – H18-DBT)	N-ethyl-carbazole-dodecahydro-N-ethylcarbazole (NEC-H12-NEC)	Toluene-Methylcyclohexane (TOL-MCH)
1	**H_2 storage capacity**	6.2%	5.8%	6.2%
2	**Melting point (discharged) ºC**	-58	43	-127
3	**Boiling point (discharged) ºC**	350	281	101
4	**Melting point (charged) ºC**	39	69	-95
5	**Boiling point (loaded) ºC**	390	378	111
6	**Reaction enthalpy**	65.4	53.2	68.3
7	**P (bar) hydrogenation**	50	70	30
8	**T(ºC) hydrogenation**	150	170	110
9	**P(bar) dehydrogenation**	1,013	1,013	3
10	**T(ºC) dehydrogenation**	310	270	450

The Table 2 shows the weight for the ten criteria used, the factor with the lowest weight is the storage capacity because the method gives better weight to the criteria that have the highest standard deviation and the lowest correlation. With these weights the LOHC materials are evaluated according to the TOPSIS methodology. Each value of the matrix is normalized, then the matrix is weighted, then the positive ideal solution and the negative ideal solution are defined. Finally, the relative proximity index is calculated for each of the alternatives, and they are ordered from highest to lowest.

Table 2. LOHC selection criteria weights

Factor	1	2	3	4	5	6	7	8	9	10
Weight	6.56714 E-06	0.1415	0.1860	0.1269	0.2250	0.0145	0.0645	0.1012	0.0016	0.1383

Table 3 shows the rankings of the selected alternatives, the DBT-H18-DBT has the first place by CRITIC-TOPSIS methods, this result is according to the literature, this compound is one of the most used in this technology due to its chemical and processing properties. So, the CRITIC_TOPSIS methods can be used for a large list of LOHC pair. The main difficulty in applying the method is the quality and type of information required to establish the rankings. In the case of LOHC pairs, the information is scattered and there is no complete technical information on the possible pairs.

Table 3. Ranking for LOCH selection by MCDA methods

LOCH pairs	(DBT – H18-DBT)	(NEC-H12-NEC)	(TOL-MCH)
Ri	0.772305281	0.669781847	0.316478716

CONCLUSIONS

The criterion with the most weight is the loaded boiling point due to its high standard deviation. The one with the lowest weight is storage capacity since all materials have a similar load capacity. Dibenziltoluene is the material with the least proximity to the ideal negative solution, thus being the best qualified LOHC material through this method and with this it presents the availability for subsequent studies of catalysts and reactor design to generate a LOHC

system with the use of this material. The (TOL-MCH) is the lowest rated material due to the high temperature required for dehydrogenation.

ABSTRACT

Aluminum hydride(AlH_3) has a high gravimetric hydrogen energy density of more than 10.0 wt.% and volumetric density (148 kgH_2/m^3). The material has drawn much attention because of its high hydrogen storage capacity and rapid dehydrogenation at low temperatures, and has been used in various areas, including catalysts, fuel cell, reducing agents and rocket fuel additive. AlH_3 can largely promote the specific impulse of propellants when used as energetic additive in solid propellant. In this article, we focus on the research development in the field of synthesis and stabilization of AlH_3 in recent decades. Particularly, the stability of AlH_3 is critical for its application in solid propellants. The most widely used strategies are also introduced and compared, based on which some suggestions for possible future research directions are provided.

Keywords: Aluminum hydride, energy material, stability, solid propellant

INTRODUCTION

Solid propellants play an important role in military and aerospace fields, and increasing the energy level has always been the core direction of its development. An effective way to improve the specific impulse of the propellants is to reduce the molecular weight of the combustion gas products. Therefore, it is a good choice to adopt energetic materials with high hydrogen content in the propellants [1-3]. In recent years, metal hydride has attracted great attention as energetic additive of propellants. As one of the most promising hydrogen storage materials, AlH_3 has high weight and bulk density. The theoretical estimate can reach 10.1 wt.% and 148 kgH_2/m^3, respectively, which is twice higher than that of liquid hydrogen [4-6]. When used as additive in propellant, it can reduce the adiabatic temperature while increasing the specific impulse. For example, by fully replacing 18% of Al in the traditional AP/HTPB-based rocket propellants with AlH_3[7], the theoretical specific impulse is increased by 10% and the flame temperature reduced by 5%, simultaneously. Studies show that the stability of AlH_3 is strongly related to the crystal structure. AlH_3 has seven crystal structures, α-、α'-、β-、γ-、δ-、ε-and ξ-AlH_3, among these the α crystal phase is the most stable structure theoretically and experimentally [8-10]. However, AlH_3 is still not stable enough to avoid decomposing at room temperature, besides it can also react with oxygen and water vapour at the ambient atmosphere. Moreover, the poor compatibility of AlH_3 with certain propellant components could also limit its application in solid propellants [11].

In recent years, numerous investigations have been published focus on the synthesis and stabilization of AlH_3 [12-18], for the purpose of generating more stable, higher quality and more cost effective AlH_3. In this review, we first introduce the common methods of synthesizing of AlH_3, followed by the technologies to improve the stability of AlH_3. Lastly the future research direction of AlH_3 is prospected.

SYNTHESIS OF ALH_3

The synthesis of AlH_3 has a long history, dating back to the 1940s. In general, there are several ways to synthesize AlH_3, include wet synthetic methods, dry synthesis and new synthesis methods that have merged in recent years.

AlH_3 can be attained through wet chemical reactions of hydrides or alkaline earth metals to form AlH_3-ether complexes [19,20]. However, the formation of $AlH_3 \cdot Et_2O$ requires a large amount of organic solvents which are toxic and unfriendly to the environment, such as ethers and amines. This method is also highly cost and difficult to control due to its sensitivity to temperature and time. Therefore, large-scale industrial production is therefore impractical.

In order to avoid the use of toxic and costly solvents, some dry synthesis methods without liquid solvents have been developed, for example direct reaction of aluminum with hydrogen under high pressure. In addition, AlH_3 can be prepared through cheaper metal hydrides, such as LiH, NaH, and CaH_2 rather than traditional high consumption

$LiAlH_4$. The process of synthesizing AlH_3 mixture through the pathway of mechanically activated reaction between MgH_2 and $AlCl_3$ is shown in Fig.1. This method is often named as mechanochemical method.

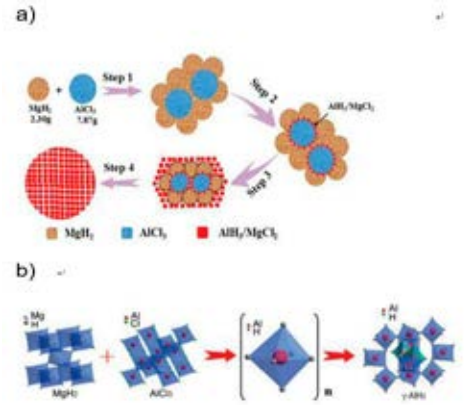

Fig.1 a) The pathway of the mechanically activated reaction between MgH_2 and $AlCl_3$ [21];
b) Mechanism of the solid-state synthesis of nano-sized γ-AlH_3

Recently, in order to synthesize AlH_3 without the usage of ether solvents, some novel technologies have been developed including preparation of AlH_3 by organoaluminum decomposition [22] and supercritical synthesis [23]. For the former method, AlH_3 can be generated through decomposing triethylaluminium under hydrogen pressure 10MPa. The path of decomposing Et_3Al are as follow: $Et_3Al \rightarrow Et_2AlH \rightarrow AlH_3 \rightarrow Al$, For the purpose of preventing further decomposition of AlH_3, tetraoctyl ammonium bromide (TOAB) and tetrabutylammonium bromide (TBAB) are used to stabilize Al/AlH_3 particles. However, this method also shows some disadvantages, some impurities can be generated during the process, such as surfactants and other catalysts. For the supercritical method, the dissolving and mixing ability of the supercritical fluid is utilized in the chemical reaction system to make the raw material undergo a certain catalytic reaction, so as to achieve promoted chemical reaction. AlH_3 can be obtained by the reaction of activated Al with H_2 in supercritical CO_2 liquid medium. Nevertheless, due to the limitation of the supercritical conditions, the reaction system cannot proceed at a higher temperature, which will affect the activity of the reactants. This synthesis method is still in the laboratory stage and has a long way to realize industrial scale production.

STABILITY OF ALH3

AlH_3 is sensitive to surrounding oxygen and moisture, making it unstable under ambient conditions, and therefore can be spontaneously decomposed into Al and H_2. The factors leading to the instability of α-AlH_3 can be divided into two categories: intrinsic and extrinsic causes. Essentially, α-AlH_3 is composed of two strongly reducing elements (Al and H) with an average enthalpy of formation at room temperature of (-11.4±0.8) kJ/mol and an absolute entropy of (30.0±0.4)kJ/(mol℃), and the Gibbs free energy is (45.4±1.0)kJ/mol. Therefore, from the thermodynamic point of view, AlH_3 can spontaneously decompose into metallic Al and H_2 in ambient atmosphere. Meanwhile there are also extrinsic reasons that affect the thermal stability of α-AlH_3, including the environment (humidity, light [24], chemical reactions, etc.), its own crystal structure and purity. For example, impurities (such as LiCl, $NaBH_4$, LiBH and $LiAlH_4$, etc.) will be generated during the synthesis of α-AlH_3, as well as other unstable crystal forms, which could affect its thermal stability and safety.
At present, the methods being applied to improve the thermal stability and compatibility of α-AlH_3, are dedicated not only to enhance the crystallinity and the purity of α-AlH_3 by optimizing the synthesis and preparation conditions, but also to modify the surface and interface of α-AlH_3. The main methods include: surface coating method, surface passivation method and doping method, etc.

CONCLUSIONS

AlH_3 is an attractive high-energy material. This review covers the published results on synthesis/stabilization methods of AlH_3. To date, the wet chemistry synthesis and mechanochemical method are commonly used as the approaches for synthesis of AlH_3, However, the current synthetic methods are still not cost-effective enough to be adopted for large scale industrial production, thus exploring more efficient and low-cost synthetic methods of AlH_3 for industrial-scale production is urgent. And the way to improve the stability of AlH_3 without compromising the overall energy performance is another problem to be addressed.

ABSTRACT

Pulverization, settling and agglomeration, and the consequent densification may occur for metal hydride particles during the charge-discharge cycles, which will affect the wall strain of their container for hydrogen storage. In order to study the effects of different factors on the wall strain of metal hydride hydrogen storage vessel, a reaction-thermal-mechanical coupling model for $LaNi_5$ alloy was modified with regard to some relevant parameters, by which sensitivity analysis was conducted. Finally, the strain distribution along the height of reactor filling Mg_2Ni was predicted by the model and compared with experimental results reported in literature.

Keywords: Metal hydride, Volume expansion, Wall strain, Parametric analysis

INTRODUCTION

Hydrogen energy has attracted much attention in recent years because of its clean, renewable properties. However, the safety concern of the mainstream hydrogen storage technology via high pressure gas, seriously restricts the popularization of hydrogen energy. Solid hydrogen storage by metal hydrides, features high volumetric hydrogen storage density, as well as mild conditions of hydrogen absorption and release, hence largely overcoming such disadvantage. However, mechanistic strength is known to be a key issue for design of metal hydride hydrogen storage vessel [1]. When a metallic alloy absorbs hydrogen, its volume will expand by a ratio of 20~30% [2,3] when transformed from solid solution to saturated hydride. Such volume expansion can induce wall stress and deformation or even failure in the metal hydride storage vessel. Lekshmi and Mohan [4] presented a mathematical model to describe the formation of wall strain in the vessel packing $LaNi_5$ powders, which is modified here for improved accuracy. The influences of key factors on the wall strain are investigated, and the applicability of the modified model to other material systems is discussed.

MODELING

The original model coupling reaction, heat and mass transfer for packed bed of hydride powders is referred to Ref. [4], and an empirical relationship between bed porosity and height [5] was given as,

$$\phi = Ce^{kz} \tag{1}$$

The coefficients C and k depend on bed height h_b and the porosity at the top region of the bed, ϕ_1.

$$\phi_0 \cdot h_b = \int_0^{h_b} \phi \cdot dz \tag{2}$$

$$\phi_1 = C \cdot e^{kh_b} \tag{3}$$

ϕ_0 represents the average porosity.

As the hydride volume increases linearly with hydrogen concentration [6], an effective expansion coefficient which accounts for both thermal expansion and volume expansion of alloy particles during hydriding is formulated as,

$$\alpha_e = \alpha_t \left[1 + \alpha_t \Delta T + \frac{0.167}{3\alpha_t \Delta T}\left(1 - \left[\frac{\rho_{sat} - \rho_s}{\rho_{sat} - \rho_a}\right]\right)\right] \tag{4}$$

where α_t is the coefficient of thermal expansion of $LaNi_5$, ΔT is the temperature difference and ρ is the hydrogen concentration in the hydride bed.

Taking the porosity of hydride bed into account, the effective Young's modulus is calculated as [7]

$$\mathrm{Y_e} = \mathrm{Y_0}\left(1 - \frac{\phi}{\phi_{\mathrm{cr}}}\right)^{\mathrm{p}} \tag{5}$$

where Y_0 is the Young's Modulus of non-porous material, ϕ is the porosity, ϕ_{cr} is the critical porosity at which the Young's Modulus becomes zero and 'p' is a material specific exponent.

Please note in Eq. (5), the parameter p needs to be determined through experiments, and relevant data is absent for most material systems. In addition, the solution of critical porosity ϕ_{cr} is complicated yet inaccurate. Li et al. [8] proves that the formula (6) is more suitable for Young's modulus of porous materials, and is hence adopted as modification

$$Y_e = \frac{1-\phi}{1+a\phi} \cdot Y_0 \quad (6)$$

Parameter a is related to the Poisson's ratio and pore shape of the material, which is given as follows.

$$a = \frac{1+v_m}{2(1-2v_m)} \quad (7)$$

RESULTS AND DISCUSSION

Figure 1 presents the simulation results of original model, modified model and experimental data from [9]. It can be seen that the accuracy of original model is improved after modification and meets the requirements for analysis.

The sensitivity analysis of parameters used in the model was carried out. The results show that hydrogen pressure and cooling fluid temperature have little impact on the wall stress of hydrogen storage vessel, which confirms the conclusion in Ref. [4]. On the other hand, the influences of the packing density, as well as the cycling on the wall strain, are much more significant, see Fig. 2 and 3. With the increase of average porosity, the wall strain tends to decrease, while the length of the area with wall strain shows an obvious decreasing trend. The porosity at the top of the bed will increase with cycling, resulting in gradual increases of wall strain at different heights, which is consistent with experimental observation.

Further more, the model was attempted for use for the reactor packing Mg_2Ni alloy. Maximum error of <20% is determined from the comparison between the prediction and experimental results [10], and the applicability of the model is proved.

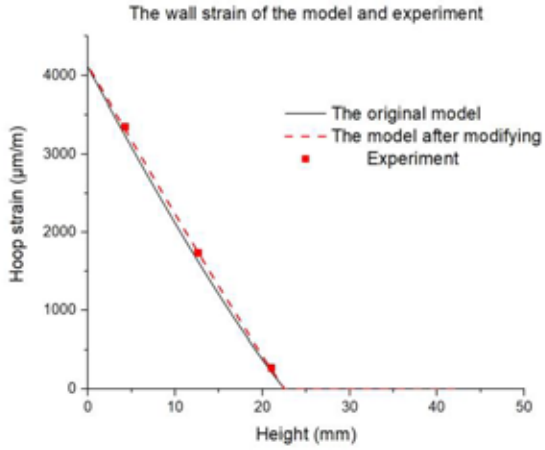

Fig. 1. The Comparison of wall stress of hydrogen storage vessel before and after modifying the formula (packing height:70%, mesh 100, average porosity:0.5, top porosity:0.75)

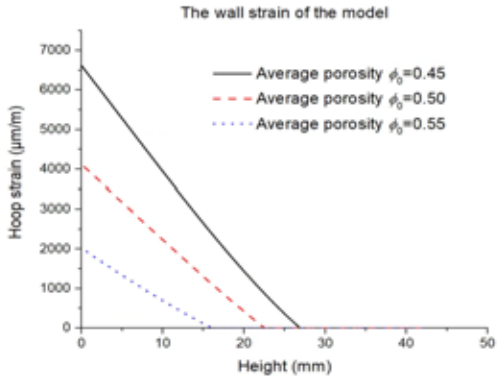

Fig. 2. The Comparison of wall stress of hydrogen under different average porosity conditions (packing height:70%, mesh 100, top porosity:0.75)

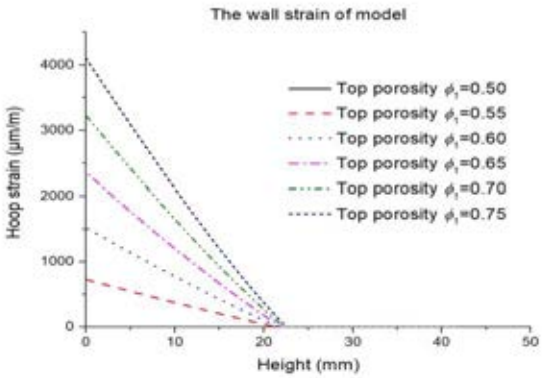

Fig. 3. The Comparison of wall stress of hydrogen storage vessel storage vessel under different top porosity conditions (packing height:70%, mesh 100, average porosity:0.50)

CONCLUSIONS

In this paper, the reaction-thermal-mechanical coupling model of a longitudinal reactor containing $LaNi_5$ hydride is improved and verified. In addition, the effects of key parameters of the model are analyzed, and the following conclusions can be drawn:

- The factors that affect the average porosity of the alloy, such as the initial filling method, have a significant effect on the wall stress of the hydrogen storage vessel.
- With the increase of cycles, the strain distribution on the wall of hydrogen storage container increases along the height of the container, and the length of the area with wall strain increases slightly.
- The modified model was successfully used to predict the strain distribution along the height of reactor filled with Mg_2Ni.

ABSTRACT

MgH_2 is the widely investigated and one of the most prominent solid state hydrogen storage materials because of its high hydrogen storage capacity, low cost, and enormous elemental reserves in the earth crust and seawater. However, the high desorption temperature, sluggish kinetics and high thermal stability hinder its further onboard application. In present investigation, we have reported the enhanced kinetics and thermodynamics for MgH_2 catalyzed through different prominent catalysts/additives like graphene (Gr), VS_2, TiH_2@Gr, Ti@Gr, TiO_2@Gr, and high entropy alloy (HEA). Amongst these catalysts TiH_2@Gr is most suitable catalyst for empowering the kinetics and thermodynamics of MgH_2. The temperature programmed study reflects that MgH_2-TiH_2@Gr has lowest onset desorption temperature *i.e.,* ~231 ^{o}C with a storage capacity ~6.55 wt% which is ~190 ^{o}C lower than the desorption temperature of pristine MgH_2. The better catalytic behavior of MgH_2-HEA on TiH_2@Gr also persists during de/re-hydrogenation kinetics of MgH_2. Thus, MgH_2 catalyzed by HEA absorbs ~5.9 wt% of hydrogen at 300 ^{o}C under 15 atm pressures in 1.5 min. A remarkable result coming out of the present investigation is concerning cyclability (reversibility) of MgH_2-HEA, up to 25 cycles.

Keywords: Hydrogen Storage, Magnesium Hydride, Graphene templated Ti-based catalyst, 2-d materials, Reversibility.

INTRODUCTION

MgH_2 is a widely investigated solid-state hydrogen storage material due to its very high storage capacity (110 g/L volumetric and 7.6 wt% gravimetric) and large elemental abundance in nature. It's very high hydrogen desorption temperature (~400ºC), slow kinetics, and high thermodynamics makes an obstacle on the way to use MgH_2 as onboard applications. These obstacles can be vanished by opting the methods alloying, scaffolding, Nanoconfinement, and addition of catalyst. Different research groups have adopted different methods to use the MgH_2 as onboard applications[1–3]. The $TiVO_{3.5}$ catalyst for improving the kinetics of the MgH_2 was reported by Zhang et al. [4]. TiF_4 works as an effective catalyst for improving the re/de-hydrogenation kinetics of the MgH_2 [5]. Kwon et al. [6] synthesized MgH_2 catalyzed by Ni, Fe, Ti through the reactive milling method and reported that Ni, Fe, Ti works as an effective catalyst for improving the hydrogen storage properties of MgH_2. MgH_2-Graphene nanosheets have been synthesized by Liu et al.[7,8]. They have shown that graphene nanosheets provide a more diffusion path to hydrogen and restrict the agglomeration of MgH_2.

Keeping the above investigations in view, it is clear that metal (Ti-based) catalyst and 2D materials (like graphene) both separately work as catalyst for improving the kinetics and thermodynamics of MgH_2 but a synergistic effect of both (Ti-based compound and graphene) will be a worthy topic of study.

Given the above, we have synthesized graphene (Gr), VS_2, HEA, and graphene templated Ti-based compound (Ti@Gr, TiH_2@Gr, and TiO_2@Gr) for catalytic action on MgH_2. The catalytic action on MgH_2 of all such synthesized catalyst was examined through its structural, microstructural, spectroscopic, and hydrogen storage characterizations.

MATERIAL SYNTHESIS METHODS

All the materials have been synthesized by using high grade chemicals. Graphene Oxide (GO) was synthesized by improved Hummers method[9] and reduced it by using 5% H_2 balanced Ar gas at 850 ^{o}C for 5 h. This resulted in the formation of reduced graphene oxide (rGO), which is further used for work as graphene. Ammonium metavanadate (NH_4VO_3) (1.5 g), and thioacetamide (C_2H_5NS) (5.4 g) procured from Sigma Aldrich with a purity of 99% was used for synthesis of VS_2 via hydrothermal method. The $NaVO_3$ and C_2H_5NS dissolve into the 100 ml deionized water and put into a Teflon-lined stainless-steel autoclave and heated to 190°C in a hydrothermal oven for 24 hours. The residue obtained after filtration was first washed with deionized water (4 times) and then washed with ethanol (4 times) and dried at 60 ºC under vacuum for 20 hours. The dried sample so obtained was sonicated for 20 h before further investigations. The synthesis routes for Ti@Gr, TiH_2@Gr, and TiO_2@Gr have been given in previous

reported study[10]. The HEA was prepared by radio frequency (RF) melting with the appropriate ratio of constituent elements using an RF induction furnace (Inductotherm). The melted materials crushed in the form of powder. The powder thus obtained will be referred as-cast HEA alloy. As-cast HEA powder was leached with 2M of NaOH aqueous solution for 10 minutes followed by washing with deionized water and methanol for 30 minutes each and dried under vacuum. The resultant sample is termed as leached HEA (LHEA).

These as-prepared materials have been used as catalyst to catalyze the MgH_2. The MgH_2 catalyzed by 5 wt% of catalyst (Graphene, VS_2, TiH_2@Gr, Ti@Gr, TiO_2@Gr, and LHEA) have been synthesized through mechanical ball-milling using Retsch PM400 ball-miller at 180 rpm for 24 hours with the ball to powder ratio 50:1 (by weight). All the handlings of samples were done inside N_2 filled glove box (MBRAUM MB10 compact). These catalyzed samples are known as MgH_2 catalyzed by graphene (MgH_2-Gr), MgH_2 catalyzed by VS_2 (MgH_2-VS_2), MgH_2 catalyzed by graphene templated Ti (MgH_2-Ti@Gr), MgH_2 catalyzed by graphene templated TiH_2 (MgH_2-TiH_2@Gr), MgH_2 catalyzed by graphene templated TiO_2 (MgH_2-TiO_2@Gr), and MgH_2 catalyzed by leached HEA (MgH_2-LACFMCN).

STRUCTURAL CHARACTERIZATION

The structural characteristics of the as-prepared samples have been examined by XRD studies using PANalytical Empyrean x-ray diffractometer with CuKα radiation (λ = 1.5415 Å). The XRD patterns of as-synthesized materials have been shown in Fig.1. All the XRD patterns matches well with their corresponding phase structures.

HYDROGEN SORPTION ANALYSIS

The hydrogen sorption measurements were performed by using an automated two-channel volumetric sieverts type apparatus (Advanced Materials Corporation Pittsburgh, USA). The temperature programmed desorption (TPD) were carried out at a heating rate of 5ºC/min and shown in Fig. 2. The onset desorption temperatures of as-prepared materials MgH_2-Gr, MgH_2-VS_2, MgH_2-Ti@Gr, MgH_2-TiH_2@Gr, MgH_2-TiO_2@Gr, and MgH_2-LACFMCN are ~301 ^{o}C, ~290 ^{o}C, ~257 ^{o}C, ~231 ^{o}C, ~240 ^{o}C, ~340 ^{o}C, and it desorbs ~4.63 wt%, ~6.48 wt%, ~6.94 wt%, ~6.55 wt%, ~5.73 wt%, ~6.79 wt% respectively. The pristine MgH_2 releases 7.12 wt% of hydrogen at ~ 420 ^{o}C (Fig. 2(a)). This shows the onset desorption temperature of MgH_2-TiH_2@Gr more lower than MgH_2-LACFMCN and other catalyzed samples. To check the stability and reversibility of catalyzed and uncatalyzed MgH_2, the rehydrogenation kinetics was carried out at 300 ^{o}C under 15 atm hydrogen pressures as shown in Fig. 3. As can be seen, the MgH_2-LACFMCN has rapid rehydrogenation kinetics and sustains more storage capacity than other catalyzed samples. After that rehydrogenated samples were dehydrogenated at 300 ^{o}C under 1 atm hydrogen pressure. It can be seen clearly that MgH_2-LACFMCN has strong enough dehydrogenation kinetics than other catalyzed samples. MgH_2-LACFMCN also shows the lower activation energy than other catalyzed MgH_2.

CONCLUSIONS

The catalytic effect of graphene, VS_2, TiH_2@Gr, Ti@Gr, TiO_2@Gr, and leached HEA were evaluated and compared. Based on de/re-hydrogenation study leached HEA was found to be the optimum catalyst as leached HEA catalyzed MgH_2 has the onset dehydrogenation temperature of ~340 ^{o}C. The superior catalytic activity of leached HEA also persists in de/re-hydrogenation kinetics. Moreover, the change in enthalpy of MgH_2-TiH_2@Gr is ~2.12 kJ/mol lower than pristine MgH_2. There is slight decrease (0.1 wt%) in hydrogen storage capacity of MgH_2-LACFMCN up to 3 cycles and then capacity remains constant up to 25 cycles.

PERMEABILITY OF A DEFORMABLE METAL HYDRIDE BED DURING HYDROGEN ABSORPTION

[1,2*] *Dmitry Dunikov*, [1,2] *Dmitry Blinov*
[1]Joint Institute for High Temperatures of the Russian Academy of Sciences, Laboratory for Hydrogen Energy Technologies, 125412 Izhorskaya st. 13 bld. 2, Moscow, Russia

ABSTRACT

Permeability of a metal hydride bed during hydrogen absorption is experimentally investigated by filtration of a H_2(10%)/CH_4 mixture through the bed (1 kg $LaNi_{4.8}Mn_{0.3}Fe_{0.1}$). Deformation of the bed due to swelling of the particles at absorption causes significant changes of the bed permeability, it decreases from 0.16 μm^2 at the start of the absorption to 0.031 μm^2 at C = 1.12%wt. The effect can be contributed to decrease of the bed porosity at absorption.

Keywords: metal hydride, AB_5, permeability, deformable bed

INTRODUCTION

Metal hydrides (MH) are used for safe and compact hydrogen storage, purification, compression, thermal storage and other applications. Successful results are mostly obtained at laboratory prototype scale levels and scale up issues should be resolved to introduce metal hydrides into commercial market [1]. At scale up, non-uniformities of MH beds and variability of their properties come to play. Due to absorption of hydrogen, a powder material swells and shrinks in a container, which is referred to as the hydride breathing, causing severe mechanical stresses [2] and change of the bed structure, e.g. a fill density could vary in 15% along the bed [3]. In addition, the bed porosity decreases with absorption and increases with desorption [4], and cycling also affects the porosity [4-6]. Generally, the bed breathing is not taken into account, Mellouli et al. have performed investigation of a deformable MH bed and found no significant effect of the volume variation on the heat and mass transfer [7]. By the Kozeny-Carman equation the bed permeability is the function of the mean particle size and porosity, thus deformation of the metal hydride bed should have an effect on the bed properties. The bed permeability is essential for flow-through (continuous) reactors used for hydrogen purification, since it directly affects the hydraulic resistance of the reactor and thus the efficiency. Thus, investigation of permeability of deformable metal hydride bed is essential for understanding of energy efficiency and predictability of operation of metal hydride reactors and economic viability of metal hydride technologies. In the present paper, we present results of permeability measurement during hydrogen extraction from a H_2/CH_4 mixture in a flow-through reactor.

EXPERIMENT

Flow-through type reactor RSP-8e [8] is used for experiments (Fig. 1). A 399 mm reaction chamber is made from 40x2 mm and 18x1 mm coaxial steel tubes and filled with 1 kg of $LaNi_{4.8}Mn_{0.3}Fe_{0.1}$ intermetallic alloy. The reactor is cooled by silicon oil CAS: 63148-62-9 from a Julabo FP45-HE thermostat. Gases are provided from cylinders (H_2, H_2/CH_4 mixture, N_2 and He for purge). Measurement and control: gas flows by Bronkhorst EL-FLOW Select mass flow meters/controllers (FR); outlet gas composition by AG-0012 thermal conductivity gas analyzer (GA); pressure by Aplisens pressure transmitters model PC28; temperature by thin film platinum sensors Heraeus M422, 1 kΩ. The test bench has connections to a vacuum system and an automatic control system using LabView software.

RESULTS AND DISCUSSION

A mixture of 10% H_2 and 90% CH_4 (90%) was filtered through the MH bed at inlet pressure 0.95 MPa. At absorption the thermostat temperature was set to 0°C. Hydrogen absorption was divided into two stages: at the start, the reactor was charged up to almost half of its hydrogen capacity, then the reaction was stopped, the reactor was heated to ambient temperature for 12 hours, and then again cooled and charged up to full capacity. The set point for outlet gas flow was 2 st.L/min, and the flow controller maintained it quite well during the first stage and gas flow was almost constant, while outlet pressure decreased from 0.80 to 0.45 MPa. The thermal relaxation by heating of the reactor to ambient temperature has made the bed less permeable to hydrogen. Outlet pressure immediately dropped from 0.45

to 0.39 MPa, and outlet flow controller could not maintain gas flow at 2 st.L/min no more. The absorption steadily slowed down and stopped at outlet pressure 0.27 MPa, when the gas analyzer indicated a hydrogen breakthrough.

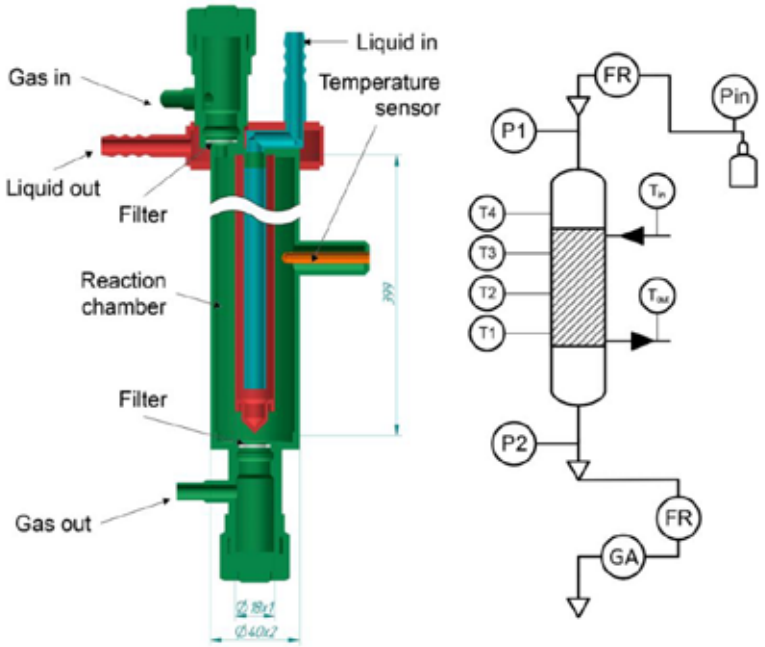

Fig. 1. Metal hydride reactor PSP-8e (left): gas part is green, liquid heat exchanger is blue (inlet) and red (outled), themperature sensor is orange, filters are white. Simplified scheme of experiments (right): *FR* – mass flow meters/controllers; *GA* - thermal conductivity gas analyzer; *P* – pressure gauges; *T* – temperature sensors

The permeability was estimated by standards procedure following the ASTM D6539 Standard:

$$k = 2\mu q \frac{p_{ST}}{(p_{in}^2 - p_{out}^2)} \frac{T}{T_{ST}} \frac{h}{A} \quad (1)$$

where μ is dynamic viscosity, h is the height and A is the cross-section of the metal hydride bed, p_{ST} and T_{ST} are standard pressure and temperature at which the flow meter is calibrated (1 bar and 0°C). We use an "effective" height L_{eff} = 36.4 cm calculated on the base of the average fill density of the MH bed of ρ_{MH} =3.6 g/cm^3 [3], the MH mass 1 kg and the cross-section of A = 7.63 cm^2. Gas properties were calculated using REFPROP. Viscosity of H_2/CH_4 mixture varies between 10.2 μPa·s (90% CH_4 at 1 bar and 0°C) and 10.7 μPa·s (100% CH_4 at 10 bar and 20°C), and we use 10.4 μPa·s in our calculation. The mixture mass flow is the average between q_{in} and q_{out}. Calculation uncertainties: for L_{eff} due to bed breathing is ca. 10%, for q is 10%, for μ is 3%, for A is 5%, and uncertainties for other variables are negligibly smaller. Thus, the overall uncertainty for k is within 15%.

Results for the permeability of the metal hydride bed during absorption of hydrogen are in Fig. 2. At the start of the absorption the bed permeability is 0.16 μm^2, and it drops down to 0.031 μm^2 at C= 1.12%wt. Possible change of L_{eff} due to expansion of the bed has a little influence on permeability: assuming the height enlargement of 10%, k is 0.033 μm^2 at the end of absorption. Thus, the fivefold change of permeability at hydrogenation cannot be contributed to any measurement uncertainty and is the result of the change of porosity and particle size at absorption.

Similar behavior is observed for the permeability of coal mass, which is influenced by stress, gas pressure, swelling deformation induced by methane adsorption, and shrinkage deformation caused by methane desorption [9]. When the amount of adsorption is high the permeability reduces exponentially with sorption-induced strain [10].

On the first glance, our results oppose [7], in which no significant influence of the bed deformation on heat and mass transfer was found. Nevertheless, there is no contradiction. By the van't Hoff equation the equilibrium pressure is exponentially connected with the inverse temperature, therefore a pressure variation has a little influence on the distribution of temperature over the MH bed and consequently on heat transfer. Variations of pressure over a thin MH bed only slightly affect a reactor kinetic performance. However, for a thick MH bed the pressure drop could be comparable with the inlet pressure, causing a significant impact on the performance, especially for flow-through reactors.

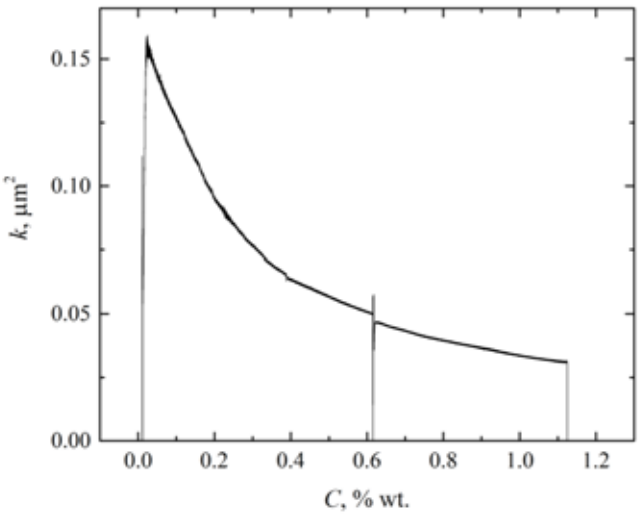

Fig. 2. Permeability of the MH bed

CONCLUSIONS

Deformation of the metal hydride bed due to swelling of the particles at absorption causes significant changes of the bed permeability. In the experiment on filtration of the H_2(10%)/CH_4 mixture through the MH bed of1 kg $LaNi_{4.8}Mn_{0.3}Fe_{0.1}$, the permeability has decreased from 0.16 μm² at the start of the absorption to 0.031 μm² at *C*= 1.12%wt. The effect can be contributed to decrease of the bed porosity at absorption.

ABSTRACT

Efficient utilization of solar energy reduces the carbon footprints in the atmosphere. The intermittent nature of solar energy requires efficient energy storage systems. Solar energy available at low temperature (<120°C) find application in many domestic devices. In the present study, mischmetal based metal hydrides are selected to store solar energy as these hydrides are operated at low temperature and low pressures. Pressure concentration isotherms (PCIs) of mischmetal based hydrides namely, $MmNi_{4.2}Al_{0.8}$, $MmNi_4Al$ and $MmNi_{3.9}Co_{0.5}Al_{0.6}$ are measured. The thermodynamic properties such as enthalpy and entropy are evaluated from van't Hoff plot. The suitability of these materials for developing an absorption thermal energy storage (ATES) system to store solar thermal energy is studied. The ATES system is thermodynamically analysed to evaluate the performance parameters such as COP and energy storage density (ESD).

Keywords: Solar energy, Energy storage, Mischmetal, Metal hydrides

INTRODUCTION

Thermal energy storage (TES) system is a key for efficient utilization of solar energy for low temperature applications. The unavailability of solar energy during nighttime and cloudy days urges the researchers to develop energy storage systems. Metal hydride based thermal energy storage systems have become promising option due to their reversible hydrogen absorption and long-term energy storage [1]. Besides lanthanum and zirconium-based hydrides, mischmetal based hydrides are very promising option for low temperature applications due to low operating pressure and availability at low price. Sharma et al studied performance of heat transformer that upgrades the heat energy from 140°C to 180°C by using lanthanum-based hydrides [2]. Recently, Sarath babu et al estimated the maximum possible energy storage efficiency of Mg-50wt% $LaNi_5$ that can store heat energy around 350°C [3]. The same group has studied the TES system based on Sn substituted lanthanum-based metal hydrides which stored energy at temperature above 100°C [4]. Malleswararao et al developed a 3D model to predict the performance of the coupled hydride beds for energy storage around 300°C [5]. It is noticed that studies on energy storage systems that stores solar energy around 100°C are very few. Also, the operating pressures of above TES systems are high which causes the more parasitic losses [6]. Therefore, low-pressure metal hydrides need to be chosen to efficiently store solar energy around 100°C. In the present study, mischmetal based metal hydrides are selected as energy storage hydrides. To study the performance of energy storage system, thermodynamic properties need to be evaluated by measuring PCIs during hydrogen absorption and desorption.

MEASUREMENT OF PRESSURE CONCENTRATION ISOTHEMS (PCIS)

PCI represents the relation between the amount of hydrogen absorbed and the equilibrium pressure at isothermal condition. The PCIs are measured by using seteram's PCT Pro which works on the sievert's principle. The PCI curves show the sloped plateau in the plateau region. The maximum hydrogen absorption capacity of $MmNi_{4.2}Al_{0.8}$, $MmNi_4Al$ and $MmNi_{3.9}Co_{0.5}Al_{0.6}$ is 1.31, 1.31 and 1.29wt%, respectively. The absorption and desorption PCIs compared at 20 and 80°C as shown in Figs. 1a and 1b, respectively. The shape of the PCI curve is similar for all selected metal hydrides representing α, α+β and β region. The absorption capacity is almost same for $MmNi_{4.2}Al_{0.8}$ and $MmNi_4Al$ at 20°C as well at 80°C. But the absorption capacity of $MmNi_{3.9}Co_{0.5}Al_{0.6}$ is slightly lower than that of other two hydrides at 20°C and slightly higher than that of other two hydrides at 80°C. The plateau pressure is higher for $MmNi_{4.2}Al_{0.8}$ than the that of other two hydrides. It is concluded that plateau pressure decreased with the increase in Al content in the hydride. The plateau pressure still reduced with multi element substitution.

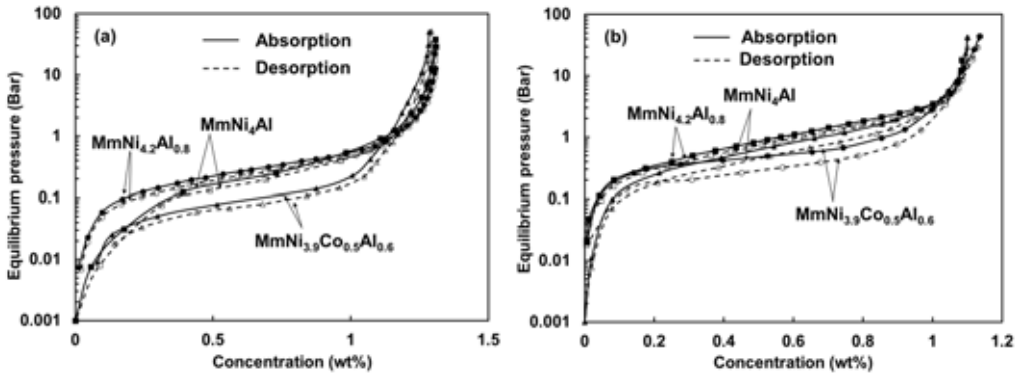

Fig. 1. Comparison of PCIs at (a) 20°C and (b) 80°C

Estimation of thermodynamic properties

Thermodynamic properties such as enthalpy and entropy during hydrogen absorption and desorption are evaluated by constructing van't Hoff plot. The van't Hoff plots of mischmetal based metal hydrides are given in Fig. 2. The slope of the linear line gives reaction enthalpy, and the intercept gives reaction entropy.

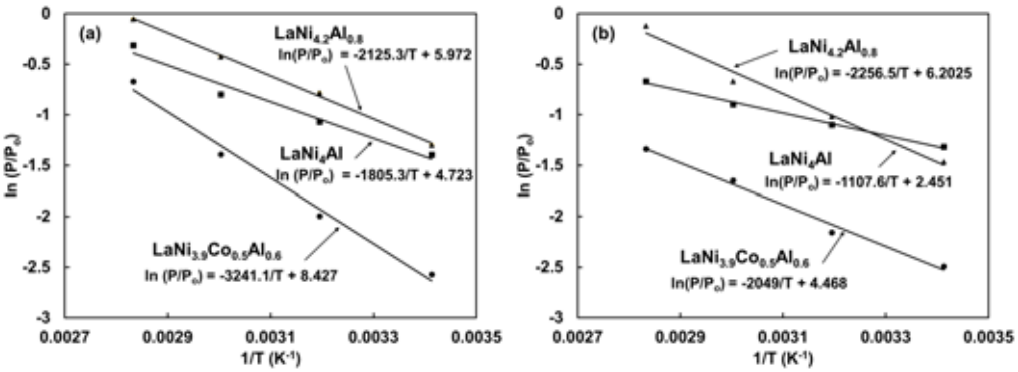

Fig. 2. Van't Hoff plot of mischmetal based hydrides during (a) hydrogen absorption and (b) hydrogen desorption

Absorption system for solar energy storage

An ATES device is proposed to store solar energy. A metal hydride reactor and an H_2 reservoir are included in the absorption system. The following is a description of the solar energy storage and recovery process. The metal hydride bed is powered by solar energy collected during the day or on sunny days. Due to the supply of solar energy, hydrogen gas is desorbed from the metal hydride bed. The gas that has been desorbed is stored in the H_2 reservoir. Whenever energy is needed during the night or on cloudy days, the H_2 reservoir's stored gas is delivered to a metal hydride reactor for hydrogen absorption. Thermal energy is released when hydrogen is absorbed in a metal hydride. The schematic of absorption system based on mischmetal based hydrides is shown in Fig. 3.

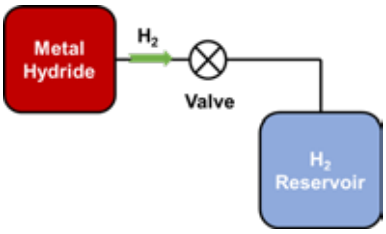

Fig.3. Schematic absorption thermal energy storage system

Thermodynamic analysis of absorption system

The proposed absorption system for solar energy storage is analysed thermodynamically. The temperature of energy storage is taken as 100°C. The temperature of energy recovery will be obtained by knowing the equilibrium pressure during hydrogen absorption in metal hydride bed. Therefore, the metal hydride bed is operated between energy storage temperature and recovery temperature. The quantities of energy stored and recovered is calculated using the formulae given in author's previous article [4]. The COP and ESD of the ATES system are estimated from the thermodynamic properties, and these values are given in Table 1.

RESULTS AND DISCUSSION

The ATES is generally operated in the plateau region. Therefore, the absorption capacity of metal hydride in the plateau region is taken as 70% of its maximum absorption capacity. The calculated values of performance parameters of ATES system are given in Table 1. It is noticed that the temperature of energy recovery is lower that of energy storage. This is because the absorption equilibrium pressure during energy recovery is lower than that of desorption equilibrium pressure during energy storage. The energy recovery temperature decreases with increase in Al content. The recovery temperature is even low for multi element substitution due lower absorption equilibrium pressure. COP of ATES system based on $MmNi_{4.2}Al_{0.8}$ is less than 1 whereas COP of ATES system based on other two hydrides is greater than 1. This is because the amount of energy recovered is less than the amount of energy stored for $MmNi_{4.2}Al_{0.8}$. In case of other two hydrides, the amount of energy recovered is higher than the amount of energy stored. The maximum and minimum ESD is observed for $MmNi_{3.9}Co_{0.5}Al_{0.6}$ and $MmNi_4Al$, respectively. Hence, a more compact ATES system can be developed using $MmNi_{3.9}Co_{0.5}Al_{0.6}$.

Table 1. Performance parameters of ATES

Metal Hydride	T_S (°C)	T_R (°C)	Q_S (kJ)	Q_R (kJ)	COP	ESD (kJ/kg)
$MmNi_{4.2}Al_{0.8}$	100	64	228.270	211.659	0.92	103.593
$MmNi_4Al$	100	40	159.835	208.343	1.30	72.572
$MmNi_{3.9}Co_{0.5}Al_{0.6}$	100	26	255.147	342.537	1.34	113.894

CONCLUSIONS

The use of low-pressure hydrides for solar energy storage is explored in the present study. PCIs of three different Al substituted mischmetal based hydrides are measured. The maximum absorption capacity of $MmNi_{4.2}Al_{0.8}$, $MnNi_4Al$ and $MmNi_{3.9}Co_{0.5}Al_{0.6}$ is 1.307, 1.307 and 1.285wt%, respectively. ATES system is proposed for solar energy storage at 100°C. Thermodynamic analysis shows that the highest COP and ESD of 1.34 and 113.894 kJ/kg, respectively is obtained by using $MmNi_{3.9}Co_{0.5}Al_{0.6}$.

ABSTRACT

The aim of this study was to improve the first hydrogenation behavior of Ti_2CrV alloy, with the Zr_3Fe addition. The Ti_2CrV + X% Zr_3Fe (X= 0, 2, 4, 6, 8, and 10) system were studied. The compositions were synthesized by arc-melting. The powder was characterized by scanning electron microscopy and x-ray diffraction. In the as-cast samples, microstructure reveals a single bcc structure for Ti_2CrV, and the presence of a Zr-rich area for the samples with Zr_3Fe addition. The hydride fcc phase for 6%, 8% and 10% addition of Zr_3Fe was confirmed by x-ray diffraction. We found that when at least 6% of Zr_3Fe is added to the alloy, the first hydrogenation is improved not only in terms of hydrogen storage capacity but also kinetics. The sample with 6% of Zr_3Fe absorbs its maximum capacity of 4.2 wt.% in approximately 8 minutes at room temperature without any heat treatment.

Keywords: Hydrogen Storage, TiCrV system, bcc alloy

INTRODUCTION

Hydrogen is an energy carrier; thus, it must be produced. Also, except for certain processes in the petrochemical industry where H_2 is used directly after its production, the hydrogen economy requires a storage medium after production before final use. This means that, in the transition from a fossil economy to a hydrogen economy, the challenges associated with hydrogen production and storage must be solved [1]. Various production methods have been developed and are very well established, such as natural gas reforming, electrolysis, biomass gasification, among others. Referring to storage, several methods have been studied for many decades to develop a safe, reliable, and compact storage system with an acceptable cost. Three well-known systems stand out: i) Compressed gas in high-pressure tanks, which is the method used in most applications. However, these are bulky due to hydrogen's low volumetric density; ii) Liquid hydrogen, where a temperature of approximately -252 °C is needed [2]; and, iii) Solid-state storage system, where metal hydrides, complex hydrides, high specific surface materials, microporous materials, among others, are being considered. In to the case of metal hydrides, these have been attractive materials for hydrogen storage, due to their high volumetric densities, safety, low cost, no toxicity emission, good absorption, and desorption capacities [1], [3], [4]. However, their applicability is limited by their low gravimetric hydrogen density, absorption kinetics, cycle life, non-reversibility, and activation procedures. It is important to mention that metal hydrides are not restricted to hydrogen storage only, their use are extended to heat storage, hydrogen generation, or as a negative electrode in the Ni-MH batteries [5].

Ti-Cr-V alloys have been investigated extensively due to their high hydrogen storage capacity at moderate working temperatures and under low hydrogen pressure [6], [7]. However, the reversible capacity is lower due to the low plateau pressure of the monohydride and shows a long incubation time during their first hydrogenation [8], [9]. In the present study, Ti_2CrV alloy is selected because of the high theoretical hydrogen absorption capacity. However, in order to get activated, this alloy needs to be heated till 400 °C. On the other hand, the Zr-rich compound is well known for its hydrogen absorption capability [10]. The effect of Zr_3Fe on hydrogen storage characteristics of hydrogen storage alloys has been studied by [10]–[14]. In the case of Zr_3Fe it has an absorption capacity of 2.0 wt.% at room temperature (RT) under low pressure and would be a candidate for stationary hydrogen [11]. Nevertheless, some issues need to be addressed to find a good composition that can meet the DOE's requirements for metal hydride applications.

The present research aims to investigate the effect on the crystal structure, microstructure and first hydrogenation behavior of adding Zr_3Fe on the Ti_2CrV alloy. In this work, the composition Ti_2CrV + X% Zr_3Fe (X=0, 2, 4, 6, 8 and 10) is investigated.

MATERIALS AND METHODS

The synthesis was done by arc-melting under argon atmosphere. All the elements Ti (99.95%), Cr (99%), V (99.7%), Zr (99.5%), and Fe (99.99%) were purchased from Alpha Aesar and used without further purification. During the melting process, each pellet was turned over and remelted four times to ensure homogeneity.

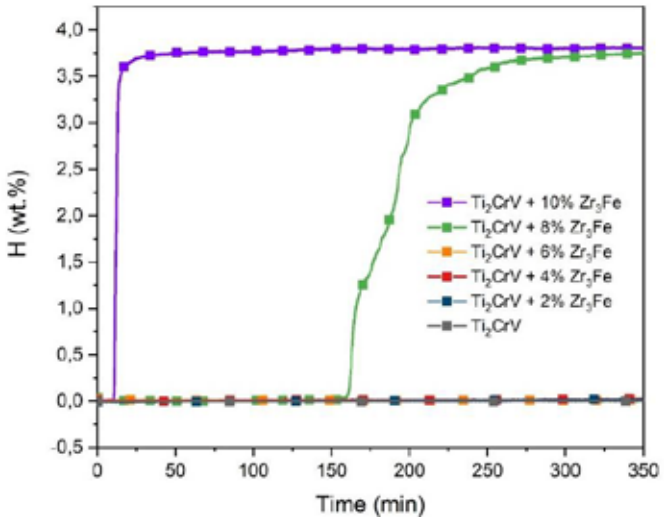
The material characterization was carried out using different techniques. To study the morphology of the samples, Scanning Electron Microscope (SEM) was performed. To probe the chemical composition of the alloys the Energy Dispersive Spectroscopy (EDS) was used. To study the crystal structure of the alloys, X-ray diffraction (XRD) measurement was carried out. The XRD patterns were analyzed by the Rietveld method using TOPAS software to determine the phase abundance, lattice parameter, microstrain, and crystallite size of the alloys.

In hydrogenation measurements, the synthesized alloys were hand crushed using a steel mortar in Ar atmosphere. Around 600 mg of the material was filled in a reactor cell to measure the hydrogen sorption properties using a homemade Sievert-type apparatus. The activation procedure of the sample Ti2CrV involved heating the alloy at 400 °C under vacuum, and a pressure of 2000 kPa. The first hydrogenation study of the other alloys was done at RT and a hydrogen pressure of 2000 kPa, without any heating treatment.

RESULTS AND DISCUSSION

From the backscattered electron images obtained by SEM of the as-cast samples, we see that Ti_2CrV alloy has a single-phase structure. For Ti_2CrV + 2% Zr_3Fe and Ti_2CrV + 4% Zr_3Fe alloys, we observed that the internal structure consists of a matrix (grey phase), and a bright spots region. As this region is too small, we can not claim for a second phase. This bright contrast in the image comes from the Zr in the samples. For the alloys with 6%, 8% and 10% of Zr_3Fe the secondary phase (bright phase) is clear, and those alloys present a two-phase structure.

Figure 1 shows the activation curves at RT and 2000 kPa of hydrogen pressure, for the different compositions from 0 to 10% of Zr_3Fe. After 24 hours, the alloys with composition Ti_2CrV, Ti_2CrV + 2% Zr_3Fe, Ti_2CrV + 4% Zr_3Fe, and Ti_2CrV + 6% Zr_3Fe did not activate. However, the Ti_2CrV + 8% Zr_3Fe composition showed an incubation time of approximately 158 minutes and a maximum hydrogen storage capacity of 3.7 wt.%. One curious fact arises from the curve shown for composition with 8% Zr3Fe. The curve appears to have two different kinetics. Faster kinetics until reaching approximately an absorption capacity of 1.3 wt.%. After that 1.3 wt.%, the kinetic until reaching the maximum absorption capacity is slower. This behavior leads us to the question of how the two phases are working together in the activation process. This question will also be addressed as future work, but one possible explanation is that the Zr-rich phase allows a faster diffusion of hydrogen, and also it could be absorbing hydrogen. Composition Ti_2CrV + 10% Zr_3Fe showed an incubation time of 10 minutes and a maximum hydrogen storage capacity of 3.8 wt.%. We see that the addition of the 10% Zr_3Fe in the alloy not only improves the activation, but also reduces the incubation time and increases the hydrogen absorption capacity.



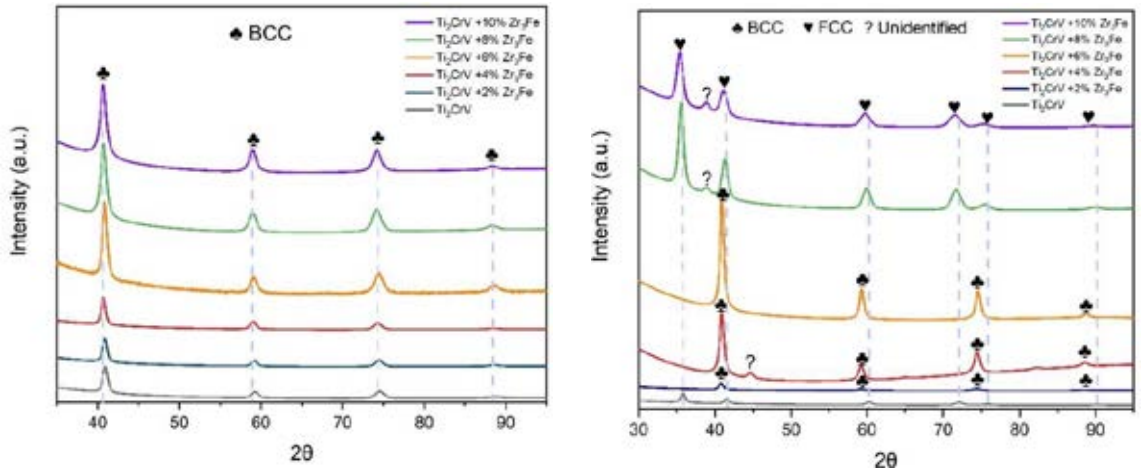


Fig. 1. First hydrogenation of Ti_2CrV +X% Zr_3Fe (X= 0, 2, 4, 6, 8, and 10) under 2000 kPa and at RT.

The XRD patterns of as-cast and first hydrogenation alloys are shown in Figure 2. From Figure 2(a) we observe that all the as-cast alloys present a BCC phase. By correlating the phases identified by SEM and EDS, it can be assumed that the matrix is BCC, however, the secondary phase (bright phase) was not identified in the pattern. One possible explanation as to why this secondary phase was not identified in the XRD, is that the phase could be present but buried in the background. However, for confirming the information, this specific phase will be synthesized and studied separately.

The XRD patterns of the activated samples are shown in Figure 2(b). The pattern of the Ti_2CrV alloy presented corresponds to its activation at 400 °C. The other alloys were activated at room temperature. From Figure 2(b) we

observe a full activation of the Ti_2CrV, Ti_2CrV +8% Zr_3Fe and Ti_2CrV +10% Zr_3Fe alloys. Those alloys changed their initial BCC structure to FCC structure. However, those alloys also showed a small peak that could not be identified. For the alloy with compositions of Ti_2CrV +4% Zr_3Fe and Ti_2CrV +6% Zr_3Fe that did not activate, they conserved the BCC crystal structure. Nevertheless, the Ti_2CrV +4% Zr_3Fe alloy showed a small unidentified peak.

(a) (b)

Fig. 2. X-ray diffraction patterns of Ti_2CrV + X% Zr_3Fe (X=0, 2, 4, 6, 8, 10) (a) as-cast alloys and (b) First hydrogenation alloys.

Table 1 presents the crystallographic parameters for the hydrogenated alloys. The alloys with 4% and 6% of Zr_3Fe did not activate, then, their lattice parameters are almost the same as the as-cast alloy. In reference to alloys with 8% and 10% of Zr_3Fe, the hydrogenation is complete, and we see an increase of the microstrain compared to the as-cast alloys.

Table 1. Crystallographic parameters of the activated alloys. The number in parenthesis is the uncertainty on the last significant digit.

Alloy	Rwp	Phase	a (Å)	V (Å^3)	Crystallite size (nm)	Microstrain (%)
Ti_2CrV	5.84	FCC	4.352 (1)	82.47 (7)	21.2 (1)	0.98 (5)
Ti_2CrV + 2% Zr_3Fe	7.81	BCC	3.1222 (1)	30.43 (4)	27.0 (3)	0.95 (7)
Ti_2CrV + 4% Zr_3Fe	1.52	BCC	3.1259 (6)	30.54 (1)	22.5 (5)	1.08 (2)
Ti_2CrV + 6% Zr_3Fe	3.54	BCC	3.1196 (4)	30.36 (1)	28.4 (8)	0.96 (2)
Ti_2CrV + 8% Zr_3Fe	2.85	FCC	4.3637 (6)	83.09 (3)	20.5 (5)	1.44 (2)
Ti_2CrV + 10% Zr_3Fe	3.39	FCC	4.364 (1)	83.11 (6)	17.4 (7)	1.77 (4)

CONCLUSIONS

The addition of 8% and 10% of Zr3Fe to the Ti2CrV alloy, seems to improve considerably the activation process, not only in terms of hydrogen storage capacity but also the kinetics. When the XRD patterns of as-cast alloys were analyzed and contrasted with the SEM results, the secondary phase (Zr-rich phase) was not identified in the patterns. For this reason, as future work this specific phase will be synthesized and studied separately. Finally, when the activation is analyzed deeper, a new question arises from the curve corresponding to the Ti2CrV + 8% Zr3Fe alloy. That is, how the two phases are working together in the activation process. This question will also be addressed in the final experiments as future work.

ABSTRACT

While storing pure hydrogen in salt caverns has been practiced since the 70s in Europe, pure hydrogen storage has not yet been carried out anywhere in depleted fields or aquifers. The Hystories project [1] is delivering technical developments applicable to a vast range of future aquifer or depleted field storage sites and is providing insights into underground hydrogen storage for decision makers in government and industry. It has started in January 2021, is gathering 24 European Companies, Universities or Research Institutes (as Partners or Third Parties), is supported by an advisory board composed of 13 large European companies and will have half of its results delivered by the time of the conference. Some results will be presented in detail during this WHEC. The present paper will complement them by giving an overall view on the technical gaps and improvements, and on the techno-economic insights for hydrogen subsurface storage.

Keywords: underground, storage, aquifer, depleted field

INTRODUCTION

Hystories project work is bringing subsurface technical developments for pure hydrogen storage in depleted fields or aquifers and is providing techno-economic insights on hydrogen underground storage deployment in the Europe-an energy system, as presented in Fig. 1 and detailed in the following sections.

Once these both parts will be finalized, major conclusion will be drawn.

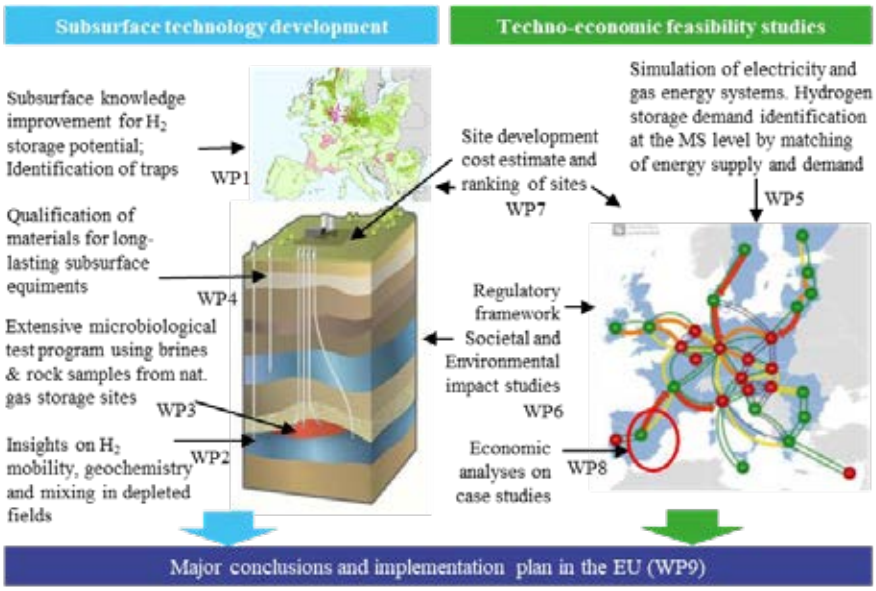

Figure 1. Overall workplan of the Hystories project

SUBSURFACE TECHNICAL FEASIBILITY STUDIES

Subsurface technical feasibility studies for a future hydrogen storage in depleted field or aquifer are site specific, as they are for natural gas and for other geological related activities. To provide the best possible insights to project developers of storage sites that are yet to be defined, different strategies have been applied for each of the technical challenges requiring development:

- Based on the experience in screening sites for developing new natural gas storages, scoring, and screening criteria have been proposed to support the selection of porous media storage site candidates for pure hydrogen storage [2]. 27 properties have been grouped into three categories: geological and reservoir engineering; geological context and surface environment. For each property, a criterion is proposed, and its importance is estimated regarding local impacts, the storage capacity (in Nm3) and the storage performance (in Nm3/h). This is used to advance a database of geological storage opportunities at the European scale by addition of data of specific relevance to geological storage of hydrogen.

Properties	Proposed criteria for H_2 Storage	Comments	Importance of the criteria for: N/A: not applicable 1: minor for scoring 2: major for scoring 3: exclusion criteria (screening)		
			Location	Capacity	Performance
Min depth to the top of the reservoir	500 m	Below typical grid pressure if above	N/A	2	1

Figure 2 One of the 27 proposed selection criteria from [2]

- To answer reservoir engineering questions such as effects of mixing, structural trapping for H_2, a high mobility gas, a workflow has been set to use results of the above-mentioned database and build synthetic models based on available properties. Estimates of the storage capacity and deliverability are made at a European scale.

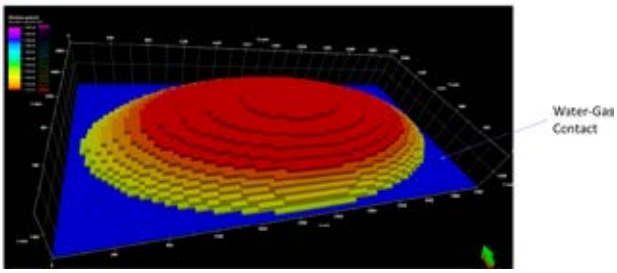

Figure 3 Synthetic dynamic model of a reservoir candidate used for hydrogen storage.

To determine expected microbial activity and impacts, seven different brines and rocks (cores or cuttings) from gas storage sites are being used in a large experimental microbiological investigation. The outcome of this extensive sampling and lab experimental program and data gathering from a wide range of relevant geological conditions is a rare opportunity to propose results across a large variety of possible conditions.

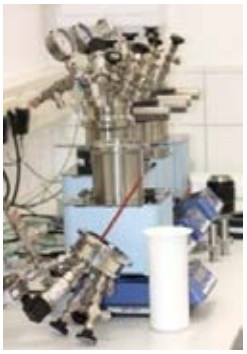

Figure 4 High pressure unit for microbial activity tests

- Determining what steel grade can be used for underground hydrogen storage is a question faced by technical developers of underground hydrogen storage today. Contrarily to hydrocarbons (not corrosive), hydrogen contact with steel creates risks of Hydrogen embrittlement. The project is investigating what material (steel grade) can be used for underground hydrogen storage under which conditions. To cover a diversity of reservoir conditions (temperature and pressure) and gas compositions, tests are done to investigate the mechanical response of several steel grades in reservoir conditions. Autoclave testing are done to observe possible cracking and corrosion attack on specimens, and the Hydrogen uptake in steel coupons is analysed by hot carrier gas extraction. Permeation tests are also conducted to test the effective Hydrogen diffusion in the steel.

Figure 5 Autoclave testing of the steel specimens. From [3]

TECHNO-ECONOMIC FEASIBILITY STUDIES

Techno-economic feasibility studies are providing insights to support a decision whether to proceed to pilot and large-scale demonstration projects. This work aims to inform decision makers in government and industry:

- Energy system modelling has been used to investigate the role of a widespread deployment of underground renewable hydrogen storage in EU-27 + UK in future scenarios across 2025-2050. The scenarios are based on several hypotheses on the hydrogen production (domestic vs. imports from non-

EU), storage technologies (salt caverns, porous media, aboveground technologies) and spatial distribution (centralized or distributed storage and production). Preliminary result show that the required long-term hydrogen storage capacities range between 40 to 700 TWhH2 in EU-27 and the UK, i.e., 1.2 to 25 MtH2. As an order of magnitude, assuming it is only done through salt caverns, and that 4000 tons of H2 can be stored per cavern, it is 300 to 6250 salt caverns. [4]

- An assessment of the regulatory framework for Hydrogen Underground Storage in Europe has been done, based on surveys throughout the industry and research institutes. Main barriers are identified, and a ranking of countries is proposed according to the status of underground hydrogen legislation [5].
- Depleted fields or aquifers, salt caverns and possibly other surface technologies will become competing solutions to meet a local storage demand. The cost of developing each of them requires finding the most competitive. Cost model of subsurface storage options have been developed to support these analyses [6].

CONCLUSIONS

Hystories has already brought technical developments to hydrogen storage in depleted fields or aquifers, notably by recommending criteria to select sites, by gathering the reservoir candidates in a GIS database and assessing their storage capacity, and by classifying the microbial activity in aquifers based on a large brine sampling and laboratory work. It has also brought insights to the decisionmakers by proposing a first storage demand estimation in each EU-27 member states, and by reviewing the legal framework throughout Europe. Last, it has built a cost model of the development of a new storage site to enable assessing whether underground storage can be competitive against other options.

ACKNOWLEDGEMENT

This work has been funded by the Hystories project. This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking under grant agreement No. 101007176. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and Hydrogen Europe and Hydrogen Europe Research.

THE EFFECT OF FIBER BANDWIDTH ON STRESS DISTRIBUTION AND LAYER THICKNESS CHANGE AT THE DOME PART OF HYDROGEN STORAGE VESSEL

ABSTRACT

In this study, dome thickness distribution and burst pressure determination were made for a type IV high-pressure hydrogen storage vessel. The netting theory and cubic spline function (CSF) method were used to design the cylindrical sections lay-up and accurately predict the dome thickness. The rowing numbers and bundle width were determined by considering burst pressure and fiber consumption, and finite element analysis models were created. In finite element analysis, these models were evaluated using Puck failure criteria to accurately predict the damage in composite layers.

Keywords: Type IV hydrogen vessel, Filament winding, Dome thickness

INTRODUCTION

In the last half-century, significant advances have been made in composite pressure vessels produced by the filament winding method. They are more commonly used to store gases such as LPG, CNG, and compressed hydrogen rather than liquids to achieve compressibility and high energy density [1]. The pressure level for the specified application areas ranges from 1 MPa to 70 MPa. Type IV vessels are preferred in hydrogen fuel storage systems for fixed or mobile applications due to their advantages, such as lightweight, high strength, fatigue, and corrosion resistance [2]

Type IV composite pressure vessels are manufactured with a fiber-reinforced composite structure wrapped around a high-density polymer liner (HDPE). The composite structure consists of glass, carbon, or aramid fiber reinforced epoxy resin according to the designed working pressures [3].

In this study, optimum fiber bandwidth and dome thickness were calculated by examining the effect of fiber bandwidth on thickness variation and burst pressure in composite vessel design. The effect of the bandwidth on the thickness change was calculated by the netting theory and CSF method. Modeling was created, and the strengths of the composite vessel were calculated with Ansys software. The resulting stress values were examined and compared according to Puck criteria.

GEOMETRY AND MATERIAL PROPERTIES

Type IV high-pressure hydrogen vessel examined in this study has a volume capacity of 26 L and a working pressure limit of 25 MPa [4]. The vessel comprises a liner and composite layer with a thickness of approximately 2.5 mm and 8 mm, respectively. The composite part is composed of carbon fiber and epoxy resin. The high-pressure vessel modeled is a type IV hydrogen storage, composed of a metal boss playing the role of connecting the vessel, an HDPE liner used to seal the vessel, and the composite layer whose role is to ensure the strength of the structure.

The material properties of the composite structure are shown in Table 1. The HDPE (high-density polyethylene) liner properties are shown in Table 2.

Table 1. Material Property of Carbon Fiber/Epoxy Composite

E_1	$E_2 = E_3$	$\nu_{12} = \nu_{13}$	ν_{23}	G_{12}	Xt	Xc	$S_{12} = S_{13}$	S_{23}
123.34 GPa	7.78 GPa	0.27	0.42	5 GPa	1632 MPa	704 MPa	80 MPa	55 MPa

Table 2. Mechanical Properties of HDPE

Flexural modulus of elasticity	Elongation at break	Tensile Strength at Yield	Tensile Strength at Break	Density
1400 MPa	800%	30 MPa	30 MPa	958 kg/m^3

The netting theory [5], as a well-suited and straightforward method for the design of filament-wound pressure vessels, assumes that the fibers support all the internal pressure and the failure of the structure occurs due to fiber breakage; therefore, the effect of the matrix is negligible. Based on the netting theory, the thickness of composite layers is shown as

$$t_{hoop} = \frac{RP_b}{2\sigma_f}\left(2 - \frac{tan^2\alpha}{k}\right) \quad (1)$$

$$t_{hel} = \frac{RP_b}{2\sigma_f k cos^2\alpha} \quad (2)$$

$$P_b = \frac{2kt\sigma_f}{(2k+1)R} \quad (3)$$

where t_{hel} and t_{hoop} are the thickness of helical layers and hoop layers, respectively; P_b is the burst pressure; R stands for the outside radius of the liner; σ_f is the developed fiber strength; α is the winding angle; k is the stress equilibrium factor, usually set as 0.6-0,8.
CSF is a method created to model the fiber thickness distribution at values close to the thickness distribution during production [6]. Compared with the netting theory, we can acquire dome thickness more accurately when fiber tows continue at the polar radius, as shown in Fig. 1. The geometric relationship of the thickness accumulation calculation with the composite vessel is shown by the formulas below:

$$t(r) = \frac{m_R n_R}{\pi}\arccos\left(\frac{r_0}{r}\right)t_p, \quad (r_0 \le r \le r_0 + b) \quad (4)$$

$$t(r) = \frac{m_R n_R}{\pi}\left\{\arccos\left(\frac{r_0}{r}\right) - arccos\left(\frac{r_0+b}{r}\right)\right\}t_p, \quad (r_0 + b \le r \le R) \quad (5)$$

Where m_R and n_R are fiber tows quantity to cover entirely in a ply and the number of the single plies; t_p the thickness of a fiber tow which is constant; r_0 the polar radius; b the width of a fiber tow; r arbitrary shell radius.

RESULTS AND DISCUSSION

Considering the netting theory and cubic spline method, a graph, as shown in Fig. 1, was obtained. The CSF method modeled a more realistic thickness distribution where different bandwidths reach the maximum thickness on the dome region. According to the finite element analysis results, as shown in Table 3, the burst pressure of the composite pressure vessel was determined as 50 MPa. Consequently, the maximum stress value was calculated as 1679 MPa, wherein cylindrical surface in the tolerance range of ±0.48%, and it was observed that the thickness change did not affect the burst pressure; nevertheless, stress values was shown change on the dome parts. While stress distribution was between 35 and 200 MPa on round polar opening of composite pressure vessel, which has 18 mm bandwidth, stress distribution was between 172 and 640 MPa on round polar opening of composite pressure vessel, which has 30 mm bandwidth.

Table 3. Design Parameters and Stress Values of FEA

Band Width	18 mm	20 mm	22 mm	24 mm	26 mm	28 mm	30 mm
Number of Coverage Cycle	54	48	44	40	37	35	32
Number of Roving	9	10	11	12	13	14	15
Max. Thickness	10 mm	9,7 mm	9,4 mm	9 mm	8,6 mm	8,2 mm	7,9 mm
Stress Distribution within one-band width	(35 - 200) MPa	(38 - 258) MPa	(50 - 320) MPa	(73 - 390) MPa	(100 - 465) MPa	(143 - 547) MPa	(172 - 640) MPa
Stress Value on Cylindrical Surface	1680 MPa	1680 MPa	1679 MPa	1679 MPa	1679 MPa	1679 MPa	1679 MPa

On the other hand, if we consider the number of coverage cycles and the number of roving, production time decreases because the bandwidth increases as the number of cycles required to completely cover the composite vessel decrease. However, the increment in bandwidth also increases the possibility of slippage of the fibers during the winding process, which is undesirable [7]. Considering all the parameters above and the possibility of slippage, the optimum bandwidth was chosen as 24 mm. The thickness accumulation that is unrealistic on dome parts was decreased using CSF.

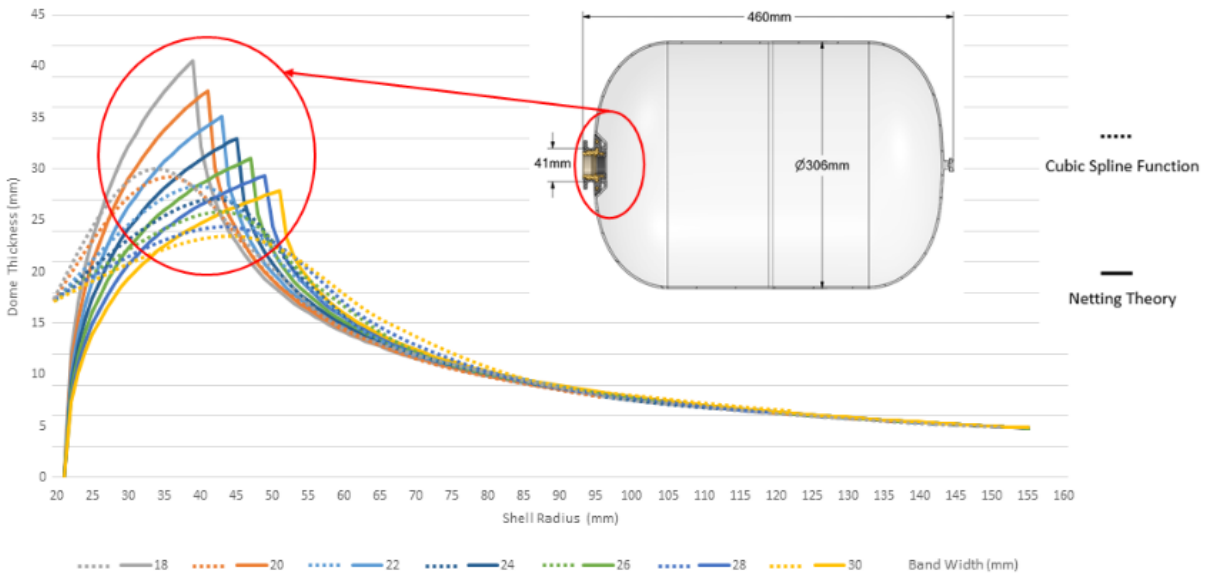

Fig. 1. Dome Thickness Distribution as a Function of Fiber Band Width

CONCLUSIONS

In this study, the effect of fiber bandwidths on dome thickness of type IV high-pressure hydrogen vessels was predicted based on Netting Theory and CSF. The burst pressure was calculated according to puck criteria. The following conclusions were made:

1. As the fiber bandwidth increases, the thickness of the composite layer reduces, and the stresses increase in the polar opening.
2. A fiber bandwidth does not affect the burst pressure since the burst occurs on the cylindrical surface of the composite pressure vessels.
3. The number of roving is a significant parameter for the covering layer during mass production. The number of roving increases as the number of coverage cycles decreases.

ABSTRACT

Underground Hydrogen Storage (UHS) in the subsurface is an alternative to overcome limitations associated with renewable energy sources. The excess energy produced from a fluctuating production can be converted to hydrogen and stored in porous media. Hydrogen is injected and produced from geological formations via wells. There are a number of concerns regarding the interactions of hydrogen with the different well components such as cement. This experimental study aims to investigate the interaction between hydrogen and cement Class H by comparing the results obtained. The methodology consists of studying physical and chemical properties and their interactions with fluid through multiple experiments. Samples exposed to hydrogen exhibited a greater compressive strength in both short and long terms. In terms of casing-cement bond strength, no change was observed. Porosity analyzed using neuron magnetic resonance exhibited minimal difference while permeability measured using a permeameter showed a considerable difference in samples aged in a hydrogenated environment. Finally, based on the scanning electron microscopy aided by Fourier transform infrared spectroscopy, a model has been propped to explain and compare the difference between the samples aged in water and in a hydrogenated water environment.

Keywords: underground hydrogen storage, alternative energy sources, petroleum wells-drilling/production/construction, well integrity

INTRODUCTION

Energy production from renewable resources is considered an alternative to replace fossil fuel energies deemed adverse for the environment. The interest in renewable energies is constantly increasing; in the same manner, newer technologies are continually being developed. One of the most significant limitations associated with renewable energies such as solar or wind is the dependency on uncontrollable factors such as the weather. The fluctuating production from renewable energies creates a gap between supply and demand, making these alternative energies unreliable as being unable to maintain a steady supply [1]. Energy storage is set to be a viable alternative to solve this issue by storing the produced energy during periods of surplus and producing it during periods of peak consumption.

Hydrogen is a clean energy source that can act as a carrier to be implemented in storage applications. This element can be generated through several physical processes and naturally produced by different sources. Hydrogen can be stored by several methods such as gas cylinders, cryogenic tanks, ammonia, absorbed on metals, or through oxidation of reactive metals [2]. These methods can be expensive and space-limited, meaning large investments would produce only small volumetric capacities. To overcome the volumetric needs, it is possible to use the subsurface to store hydrogen in porous media of different geological formations. Underground storage is the cheapest and most volumetric feasible method to store hydrogen. Yet, Underground hydrogen storage (UHS) is still in an early stage of development, with only a small number of projects worldwide compared to more developed analogous storage types [3].

Wells involved in this process are exposed to a number of injection/production phases and have to maintain successful long-term containment. The main concern is hydrogen interaction in the subsurface with different well components such as cement. This study provides a comparison of experimental tests to highlight any effects hydrogen might have in cement during aging conditions. Hydrogen interaction with cement is not well understood, as the behavior can be unpredictable if the cement barrier does provide containment. This study aims to understand the physical and chemical characteristics of cement exposed to a hydrogenated environment to provide insights into any potential integrity issues over short and long aging timeframes.

MATERIALS AND METHODS

In this study, Class H cement sheath was used to fabricate samples that were aged in two different environments consisting of distilled water and hydrogenated water (0.2-0.5 ppm). The concentration of hydrogen and pH was measured using a portable hydrometer. All Class H cement samples were prepared using a water-cement ratio of 0.38 in accordance with ASTM C 109 [4]. Samples had a cylindrical shape with a 1-inch diameter and 2-inch height for dimensions. Soon after preparing the cylindrical cement samples, these were immediately placed in a hot water bath to cure for 12 hours at temperatures of 130 ± 5 ^{o}C. After the desired hydration periods, the hardened samples were then

placed in the different environments to age for timeframes of 3 days, 1 week, 2 weeks, 1 month, 3 months, and 6 months. The aged samples were then characterized using different physical and chemical tools such UCS, SEM, FTIR, NMR, microscopy, and permeameter.

In order to evaluate the impact of hydrogen present in water during aging conditions, a systematic experimental program was designed. Unconfined Compressive Strength (UCS) was measured using a universal testing machine. In this experiment, the compressive strength of the cement samples was measured using a loading rate of 0.6 MPa/min in accordance with ASTM C 109 [4]. To statistically capture any variance, at least 5 specimens from each sample batch were used in this test. The analytical characterization of the samples cured in the different environments was compared using a Scanning Electron Microscopy (SEM) analyzer to observe any difference in the microstructure. Fourier transform infrared spectroscopy (FTIR) was performed to monitor the amount of hydrated product. Porosity was measured using two different methods. Nuclear Magnetic Resonance (NMR) was used to measure the porosity of the sample being fully saturated while the permeameter used samples fully dried. These samples were placed in an oven for 24 hours at temperatures around 100 ^{o}C prior to the experiment. However, it is known to have an adverse effect due to the removal of bound water of some hydrated products and decomposition. Finally, permeability was measured using the permeameter, with helium gas being the closet in molecular weight to hydrogen. The aforementioned experiments provided a complete methodology to quantify the impact of hydrogen present in water during aging conditions by comparing results to base samples aged in pure water.

RESULTS AND DISCUSSION

With the aim of evaluating the impact of hydrogen in cement, the petrophysical properties, including compressive strength, permeability, porosity, mineralogy, and microscopy, were analyzed to observe the behavior over time. The results in terms of mechanical tests showed a minor change in compressive strength for samples aged for short periods of 3, 5, and 7 days. Results exhibited a similar trend for mechanical tests of samples exposed for long time frames of 1, 3, and 6 months. In addition, mechanical tests for cement-casing bond strength showed no change. Dry porosity using the parameter exhibited moderate change after samples had been dried in the oven for 24 hours at temperatures of 100 ^{o}F following accepted procedures. Permeability showed higher values for samples exposed to hydrogen. A possible explanation for this is that hydrogen gas occupies some space within the cement pores, making it easier for any fluid or gas to displace, making the values higher. Mineralogy results showed a gradual increase over time in Ca for samples exposed to a hydrogenated environment. Similarly, the amount of Si was greater in samples exposed to hydrogenated water compared to samples exposed to no-hydrogen water. Microstructure analysis performed using SEM showed that samples exposed to a hydrogenated environment during aging conditions developed a greater amount of hydrated product (ettringite and $Ca(OH)_2$). This behavior increased with exposure time. Although in long-term samples, there was not much change appreciated.

CONCLUSIONS

In this study, the effect of hydrogen during the aging of cement has been investigated through a number of experimental procedures. Unconfined compressive strength shows minor changes in the short and long aging timeframes. Casing-Cement bond strength had no impact. Hydrogen presence in the water can accelerate the hydration process. Porosity and permeability showed a smaller increase in samples exposed to hydrogen. Mineralogy exhibited a gradual increase of Si and Ca over time, while SEM in hydrogenated samples showed the formation of more ettringite and $Ca(OH)_2$. It is assessed that hydrogen has a minor impact in subsurface conditions. Yet, there are some concerns regarding permeability due to hydrogen molecules size as it might permeate the cement body.

ABSTRACT

Although depleted natural gas reservoirs are the most economical option for large-scale underground hydrogen storage, minimal knowledge exists on the effects of interactions between the downhole gases and materials, given the novelty of the process. In this study, three selected API grade elastomers; Ethylene propylene diene monomer (EPDM), Fluoroelastomer (FKM/Viton), and Nitrile Butadiene Rubber (NBR), were aged in an autoclave pressurized with different gas mixtures (i.e., hydrogen, methane, and carbon dioxide) to investigate their interactions. Aging parameters were varied to determine their influence on elastomer performance, and this was measured via hardness, volumetric swelling, compressive strain-stress, and Scanning Electron Microscopy (SEM) tests. Preliminary test results showed less than 3% reduction in hardness of all samples when aged in a 100% Hydrogen environment at 22°C and 3Mpa. However, aging samples in a hydrogen-methane gas blend environment at similar conditions caused more significant hydrogen damage. Samples experienced up to a 5% reduction in hardness, and Viton was the most affected. CO_2 was the most corrosive of all three gases and caused between 2% and 9% reduction in hardness of samples. Hydrogen and hydrogen-methane blend damage on elastomers due to elastomer chain rupture are more severe at higher temperatures.

INTRODUCTION

In a hydrogen economy, large-scale hydrogen storage is vital in moderating variations in seasonal energy demands and ensuring continuity in energy supply [1]. Techniques for geological storage of hydrogen include storage in depleted hydrocarbon reservoirs, salt caverns, aquifers, and hard rock caverns, with depleted natural gas reservoirs being the most common. The integrity of wells is paramount in underground hydrogen storage as wells should withstand harsh conditions during their entire service life without corrosion and leakage problems [2]. Elastomers play a vital role in this by their use in seal assemblies to hold well pressures and withstand corrosive fluids. They are typically used in packers, O-rings, hydraulic seals, and other downhole equipment in underground hydrogen storage wells. At downhole pressure conditions, hydrogen can permeate or diffuse into elastomers and lead to internal blistering on decompression, thus failure of elastomers [3]. Elastomer failures can cause leakage via gas permeation through sealing or gaps due to inadequate contact between elastomeric materials and equipment [4].
