Shi et al. investigated the impacts of hydrogen-methane blends on elastomeric materials used in large-scale underground hydrogen storage in depleted natural gas reservoirs. Elastomers were aged in pressurized incubators with an H_2-CH_4 gas ratio of 13:87 at 26.2Mpa and 353.15K. Their results showed that the diameter of an elastomer aged in H_2 containing gas mixture increased by about 14.3% compared to a 3.05% increase for elastomers aged in a pure methane environment [5]. Yamabe et al. exposed an EPDM elastomer grade to a high-pressure hydrogen environment to quantify the effects of temperature on elastomer damage. They observed more critical damage on the cross-section of the elastomer with higher temperatures [6]. Koga et al. exposed EPDM and vinyl methyl silicon (VMQ) elastomers to 10Mpa of high-pressure hydrogen for a rapid gas decompression (RGD) test. Their results showed that the chances of propagation of fractures in these elastomers are higher for a constant load [3]. However, a gap in research exists in investigating the combined effects of stress changes (i.e., pressure and temperature variation), hydrogen concentration, and hydrogen-methane gas mixtures ratios on the performance of elastomers.

This paper investigates the performance of elastomers in the presence of varied combinations of hydrogen, methane, and carbon dioxide mixtures at different pressures and temperatures. Although the focus was on hydrogen-methane gas blends, CO_2 was included to investigate the impacts of its presence as an associated gas in a typical underground hydrogen storage environment.

MATERIALS AND METHODS

Materials

Three different elastomers; Nitrile Butadiene Rubber (NBR), Ethylene Propylene Diene Monomer (EPDM), and Viton (FKM), were selected and studied based on their wide use in the oil and gas industry. Cylindrical samples with 0 0.0084m and 0.0254m (0.33 and 1-inch) thickness and 0.0191 (0.75-inch) diameter were cut from the three elastomers based on ASTM D575-91[7] specifications. 0.0084m thick elastomers were used for hardness and compressive strength tests, whereas 0.0254m was used volumetric swelling test.

Aging Experiments

All samples would be aged for 24 hours, 3 days, and 1 week in an autoclave reactor vessel. A preliminary test was run for all stipulated gas mixtures, where the samples were aged at 3MPa and 295.1K (22^{o}C) for twenty-four (24) hours. In subsequent experimental batches, aging parameters. i.e., time of exposure, pressure, temperature, and gas mixture ratios would be varied to ascertain their impacts on experimental results. The reactor vessel is pressurized with the gas mixtures based on their partial pressure ratios. Elastomers were stacked on sieve mesh inside the vessel to ensure uniform exposure to the gases.

Mechanical and Physical Property Measurements

The following tests were run on elastomer samples before and after aging to evaluate the influence of aging conditions on the material properties and performance.

Hardness and Compression

Elastomer hardness is an essential property in determining sealing efficiencies at high pressures. A shore A durometer was used to measure the hardness of elastomers in preliminary aging tests. The process would be repeated at different aging conditions for subsequent batches of experiments. The strain in elastomers for a given compressive stress load was determined with ALX-S spiral compression tester machine before and after aging, and the results were compared. The ASTM D575-91[7] "Test Method B-Compressive stress at specified force" was observed in compression tests for samples after preliminary aging experiments and would be repeated for different aging conditions in ensuing experiments. The aim of this test was to measure the extent of damage (change in strain for a given load) due to aging.

Volumetric Swelling

Change in elastomer volume due to chain growth or rupture is vital in failure assessments. Volumetric calculations would be used in measuring elastomer volume before aging, taking its diameter at a single point along its length. After aging, the diameter of elastomers would be taken at three different points along its length; at both ends and at the middle, where there is usually the maximum swelling. The average of these diameters would be taken and used to calculate the elastomers' volume after aging. The difference in volume, before and after aging, would be measured as volumetric swelling.

Material Characterization

Scanning Electron Microscopy (SEM) tests would be run on the elastomer samples for each experiment batch to identify degraded regions and their boundaries. In addition, Energy Dispersive X-Ray (EDX) analysis would be done as a supplementary test to determine the mineral compositions in these zones.

RESULTS AND DISCUSSION

The results obtained for preliminary hardness and compressive strength tests for elastomers are discussed in this section. Two batches of experiments were run for each gas combination, and the standard error in the measurements was calculated.

Hardness Test

No more than 3% reduction in hardness was seen in all samples aged in 100% hydrogen, with EPDM elastomer showing the highest reduction. However, a methane hydrogen mixture caused between 2 to 5% reduction in hardness with the highest seen in Viton elastomer (~4.86%). Aging in 100% CO2 showed the highest reduction in hardness with values between 2 and 9%. NBR was most affected by CO2. Reduction in hardness could be linked with rupturing of cross-linkage in elastomer chains. This implies that CO2 reacted more with elastomer chain structures compared to hydrogen. Also, the hydrogen-methane mixture caused more chemical damage to elastomers than each gas alone. Chemical damage by the hydrogen atom is suspected to be a direct cause of this outcome. However, further tests would be run to ascertain this proposition.

Compression Test

An increase in compressive strain for a given stress load due to a reduction in hardness was observed for all three elastomers after aging. Strain values increased from between 4% to 28%. Results showed that aging in a hydrogen-methane environment caused between a 4% and 9% increase in the strain of samples for a given load. The maximum deflection was seen in the NBR elastomer sample aged in a 100% CO_2 environment.

CONCLUSIONS

- Exposure of elastomers to hydrogen and hydrogen-methane gas mixture causes chemical degradation, which reduces the hardness of elastomers, as seen in this study.
- Aging in a methane-hydrogen mixture environment causes a considerably higher reduction in hardness than in a 100% hydrogen environment. A suspected cause of this is chemical damage by hydrogen atoms.
- Carbon dioxide caused a higher reduction in the hardness of samples compared to methane and hydrogen in this study.
- Further tests are needed to ascertain results from preliminary tests.

ABSTRACT

The theoretical performance of a metal hydride based hydrogen compressor is studied using the materials $La_{1-x}Ce_xNi_5$ (where x=0,0.1,0.2), and the effect of cerium substitution for La in $LaNi_5$ on its performance is discussed. Using these hydrides hydrogen can be compressed from 20 to 142 bar using thermal energy at 140˚C. A maximum isentropic efficiency of 0.23 and a pressure ratio of 7.1 can be achieved.

Keywords: Metal hydride compressor, Pressure Concentration Isotherm, Cerium Substitution

INTRODUCTION

The use of $LaNi_5$ in metal hydride based hydrogen compressor is pretty common because of the versatility and tunability of thermodynamic propreties with parial substitutions for both La and Ni. Researchers have studied the partial substitution of other rare earth materials like Mischmetal, Ce, Ca [1], etc. for Lanthanum. On the other hand, partial substitution of Cu, Fe, Mn, etc. [2] for Nickel resulted in alloys/intermetallics with a varied hydrogen absorption and desorption charcterstics. In this work, the effect of cerium substitution is studied from a performance viewpoint of a metal hydride hydrogen compressor. Performance analyses has already been done by other researchers who considered properties at a fixed operating parameter [3], while this work studies the effect of operating parameters over wide range while looking at the changes and trade-offs that could be made.

MATERIALS AND METHODS

The Pressure Concentration Isotherms (PCIs) of materials $La_{1-x}Ce_xNi_5$ (where x=0, 0.1, 0.2) are measured using a Sievert's instrument at various temperatures ranging from 20 to 140˚C for both hydrogen absorption and desorption. Before measuring the PCIs, the materials were activated by repeated absorption and desorption until there was a negligible difference in the amount of hydrogen absorbed for the two consecutive cycles. The measured PCIs were used to construct van't Hoff plots and thereby calculate Enthalpy of formation (ΔH) and Entropy of formation (ΔS).

The performance parameters like throughput, pressure ratio, and efficiency were calculated by varying the operating parameters like supply pressure (P_s) and absorption (T_c), and desorption (T_h) temperatures. The supply pressure was varied from 20 to 40 bar pressure, the absorption temperature was varied from 20 to 40˚C and desorption temperature was varied from 80 to 140˚C. For the analysis the mass of the material is taken as 1 kg. The equations used for the analysis is taken from the work of V. K. Sharma and E. Anil Kumar [3].

RESULTS AND DISCUSSION

Figure 1 shows the comparison of the absorption and desorption isotherms at 100°C for the three materials. The equilibrium absorption pressure of $LaNi_5$, $La_{0.9}Ce_{0.1}Ni_5$ and $La_{0.8}Ce_{0.2}Ni_5$ is 14.25, 48, 76.5 bar and the maximum weight percentage is 1.31, 1.37, 1.34 wt.%, respectively. There is a significant increase in equilibrium pressures for both absorption and desorption with the increase in cerium content. There is also a noticeable increase in plateau slope and hysteresis with the increase in the cerium content. A similar conclusion can be drawn from the van't Hoff plot (Fig.2), and the enthalpies are tabulated in Table 1. There is a decrease in ΔH as the cerium content increases because of the lattice shrinkage caused by the substitution of Cerium for Lanthanum [4].

Table 1. Thermodynamic properties of the materials

	ΔH absorption (kJ/mol)	ΔH desorption (kJ/mol)	ΔS absorption (kJ/mol K)	ΔS desorption (kJ/mol K)
$LaNi_5$	-25.504	25.102	0.090	0.087
$La_{4.9}Ce_{0.1}Ni_5$	-23.795	22.770	0.0964	0.091
$La_{4.8}Ce_{0.2}Ni_5$	-21.8483	21.364	0.0946	0.092

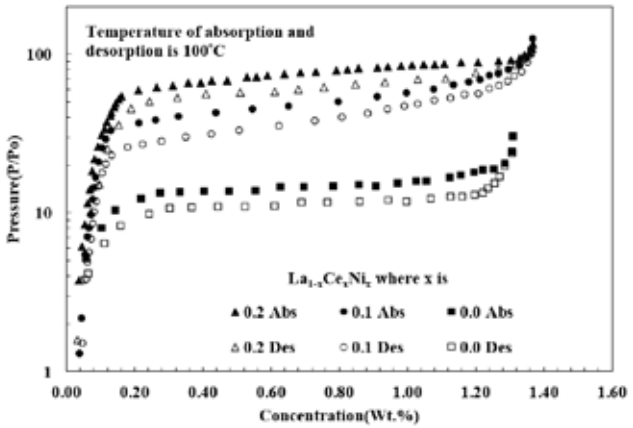

Figure 1 Comparison of PCIs at 100˚C

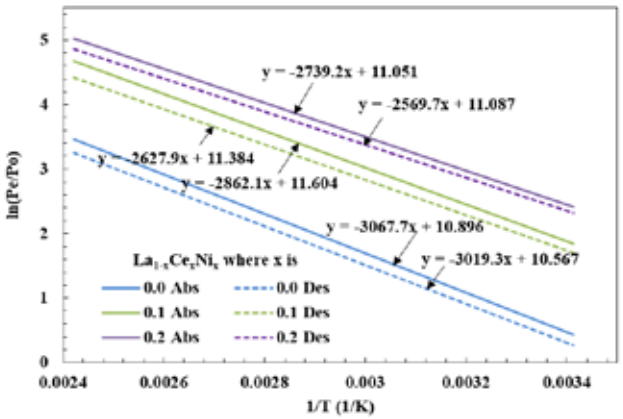

Figure 2 van't Hoff plots of the materials

The variation of throughput is shown in Fig. 3 for the three materials. It can be seen that $LaNi_5$ gives throughput only at 20 bar, whereas it is zero at rest of the pressures studied because it is a low-pressure hydride, i.e., the equilibrium pressure for the desorption falls below the supply pressure. The absorption capacity of the materials decreases with the increase in cerium content but throughput of $LaNi_5$ falls below the $La_{0.9}Ce_{0.1}Ni_5$ because of incomplete desorption. In the case of $La_{0.8}Ce_{0.2}Ni_5$ a slight increase in the throughput is noticed at higher supply pressure because of the increase in absorbed quantity. Fig. 4 describes the change of pressure ratio with desorption temperature. The steady increase in Pr is noticed with the increase of T_h due to the rise in equilibrium pressure, and higher Cerium content material has equilibrium pressure for any desorption temperature. 80˚C is the minimum temperature of desorption at which $La_{0.9}Ce_{0.1}Ni_5$ starts giving out hydrogen where $La_{0.8}Ce_{0.2}Ni_5$ gives proper pressure output even at 80˚C. $LaNi_5$ fails to work at high supply pressures at almost all desorption temperatures.

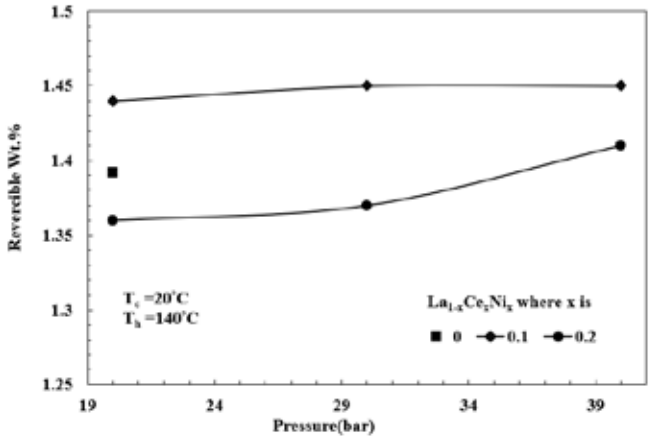

Figure 3 Comparison of Throughput at various P_s

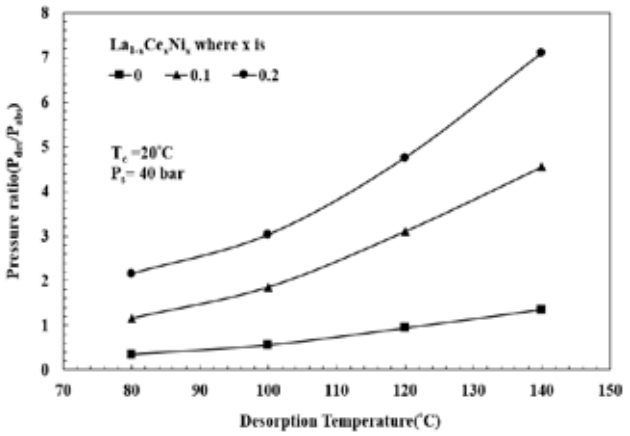

Figure 4 Variation of Pressure ratio with T_h

Fig. 5 explains the variation in isentropic efficiency with T_h for the three materials. The efficiency of $LaNi_5$ is almost zero at all the studied operating conditions because of the low throughput whereas, a steady increase in efficiency is noted in $La_{0.9}Ce_{0.1}Ni_5$, but a dip is noted for $La_{0.8}Ce_{0.2}Ni_5$ at higher absorption temperature because of the decrease of throughput for the material at higher temperature. A similar drop in performance can be noted in Fig. 6, which explains the isentropic work done at different desorption temperatures. Work done is directly proportional to the pressure ratio, which explains the increase in work done with T_h, but the rate of increase is low for $La_{0.8}Ce_{0.2}Ni_5$ because of the reduction of throughput at higher absorption temperatures.

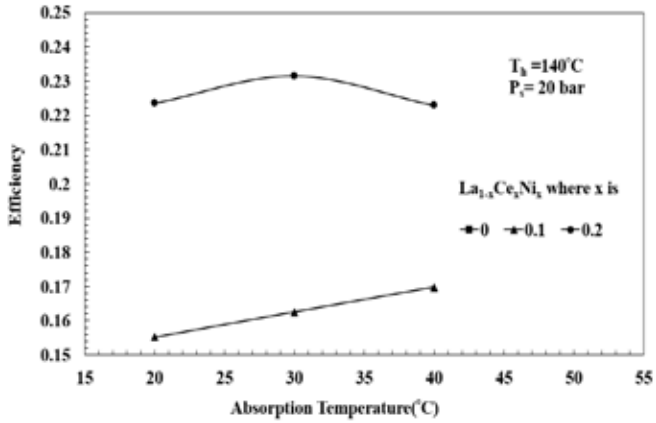

Figure 5 Isentropic efficiency achieved at various T_c

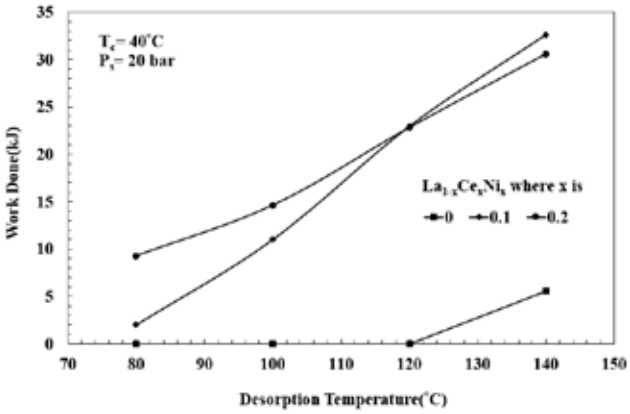

Figure 6 Variation of Isentropic work done with T_h

CONCLUSIONS

The performance of metal hydride based hydrogen compressor using $La_{1-x}Ce_xNi_5$ (where x=0, 0.1, 0.2) hydrides is estimated at various operating conditions. The alloys with cerium substitution allow the compressor operation at high supply pressures i.e., around 20 bar, while $LaNi_5$ can be used where the supply pressure is around 5 bar. $La_{0.9}Ce_{0.1}Ni_5$ hydride gives better throughput at low supply pressures. The maximum efficiency of 0.23 is achieved within the studied operating conditions for $La_{0.8}Ce_{0.2}Ni_5$ at 30˚C absorption temperature, 140˚C desorption temperature, and 20 bar supply pressure with a pressure ratio of 7.1.

THE EFFECT OF DIFFERENT ORGANIC ACIDS ON THE HYDROLYSIS OF MAGNESIUM HYDRIDE

[1*] *Moegamat Wafeeq Davids,* [1] *Tshepo Kgokane Sekgobela,* [1] *Mykhaylo Lototskyy,*
[1]University of the Western Cape, South African Institute for Advanced Materials Chemistry (SAIAMC), Bellville, South Africa

ABSTRACT

The influence of organic acids such as acetic acid, citric acid and oxalic acid and their concentration in aqueous solutions on the hydrolysis of magnesium hydride (MgH_2) has been investigated. The hydrolysis of MgH_2 was performed in a hydrogen generation reactor operated in a batch mode where the temperature and H_2 flow rate were logged. Different organic acid concentration of 1, 2, and 3 wt. % was used to study the effect on the hydrolysis of MgH_2. The hydrogen generation results indicate that the addition of organic acids to the aqueous solution increases the rate of H_2 generation as it limits the formation of the $Mg(OH)_2$ passivation layer. The increase in the concentration of the organic acid solutions leads to the increase in the rate and generation of H_2 via hydrolysis of MgH_2. The organic acid with the fastest hydrogen generation rate is oxalic acid, acetic acid and then citric acid. The pH before and after hydrolysis was recorded and showed that the addition of organic acids suppress the formation of $Mg(OH)_2$ passivation layer causing the aqueous solution to be more acidic which leads to less OH^- being formed during hydrolysis in the solution.
Keywords: Hydrolysis, Hydrogen generation, MgH_2, Organic acids

INTRODUCTION

Hydrogen as energy carrier is one of the most promising solutions to address the energy and environment issues and to meet future energy needs. Energy systems based on hydrogen fuel cells are characterised by high efficiency and power density and presently used in a number of stationary, portable and vehicle applications [1,2]. However, the main issue that hinders further implementation of hydrogen fuel cell technologies is compact, safe and efficient hydrogen storage. In recent years, special attention of researchers and engineers has focused on the on-board generation of hydrogen by the hydrolysis of various lightweight materials like ammonia borane, NH_3BH, sodium borohydride, $NaBH_4$, aluminium, Al, magnesium hydride, MgH_2, and so on. These materials can undergo hydrolysis at near-ambient conditions, in alkaline or acidic medium. Potentially, they can be used for efficient generation of hydrogen on-board thus mitigating the hydrogen storage challenge. Their practical implementation, however, requires solution of a number of problems including; (i) suppression of side reactions (particularly dangerous for the boron-containing compounds when a toxic diborane can appear), (ii) improvement of reaction kinetics and, at the same time, (iii) possibility to control H_2 release depending on the fuel cell need. Therefore, looking for a cheap and practical technology to generate hydrogen remains a keen focus of research all over the world.

Magnesium is an inexpensive and readily available metal, which is abundant in the earth's crust (2.4 %) and not harmful on the environment making it a suitable candidate for high-quality hydrogen generation material. Magnesium hydride readily oxidized when it comes in contact with water to form $Mg(OH)_2$ accompanied by H_2 gas evolution. Hydrogen is generated by hydrolysis of MgH_2 according to equation 1.

$$MgH_2 + 2H_2O \rightarrow Mg(OH)_2 + 2\,H_2 \qquad \Delta H^{\ominus}(298\ K) = -134.325\ kJ/mol.H_2 \quad (1)$$

Hydrolysis of MgH_2 has a high theoretical hydrogen yield, 15.2 wt.% and 6.4 wt.% without and with accounting the weight of water, respectively. This is almost double than the amount of H_2 generated by hydrolysis of individual Mg.

Though the hydrolysis of MgH_2 occurs immediately when in contact with water but it is interrupted because of the formation of a passive magnesium hydroxide layer, which prevents the diffusion of the water to the particle inside, therefore the hydrolysis reaction is quickly stagnates. To improve the hydrolysis efficiency and the reaction rate of MgH_2, the main methods employed were carrying out the process in acidic medium [6], alloying with other metals [7], addition of chlorides [8] or ammonium salts [9], ball milling [**Error! Reference source not found.**], addition of graphite [**Error! Reference source not found.**], as well as ultra-sonication [**Error! Reference source not found.**]. The above-mentioned methods are all actively investigated and have been shown to enhance hydrogen generation during the hydrolysis of MgH_2. The crucial issue relating to hydrolysis of MgH_2 remains the avoidance of the barrier of hydroxide layer formation during the hydrolysis process to realize complete hydrolysis. The present work is aimed at studying the effect of organic acids such as acetic, citric and oxalic acids, which potentially have a smaller

environmental impact than that of mineral acids on the hydrolysis of MgH_2 by limiting the $Mg(OH)_2$ passivation layer to enhance the hydrolysis rate and hydrogen generation yield.

MATERIALS AND METHODS

MgH_2 powder 99.8% purity (Rockwood Lithium Germany) with average particle size of 50 μm was used as the substrate for hydrogen storage media. Different organic acids, acetic acid 99.8 %, citric acid 99.5 % and oxalic acid 99.5% purity (Alfa Aesar), were used to increase the rate of hydrogen generation. The investigation of the influence of different concentrations of organic acids (1 wt. %, 2 wt. % and 3 wt. %) on the hydrolysis rate and hydrogen generation was performed.

The hydrogen generation set-up consists of a three-neck round bottom flask that serves as the reaction vessel, thermostatic regulated water bath, the moisture absorbent unit, the flow meter (Bronkhorst 1 NL/min) and the data logger. The hydrolysis reaction of MgH_2 (m=200 mg, theoretical H_2 generation after complete hydrolysis 0.34 NL) with different organic acids was carried out in a 250 ml round bottom flask with three openings, one for water/organic acid addition, one for hydrogen exhausting and one for inserting the thermocouple. The reaction flask was submerged in a thermostat. Hydrolysis reaction was initiated by quick pouring of the acid solution (50 mL) in the reaction flask. The generated hydrogen was passed through a moisture absorbent before entrance to the flow meter. The pH of the solutions before and after hydrolysis were recorded using a Metrohm 827 pH meter.

RESULTS AND DISCUSSION

Figure 1 shows the hydrolysis performance of MgH_2 with different organic acids such as acetic, citric and oxalic acid at different concentrations 1, 2 and 3 wt. %. It can be observed that hydrogen generation from MgH_2 in deionized water is extremely slow: only 0.048 NL H_2 released after 10 minutes, this was expected due to the formation of the $Mg(OH)_2$ passive layer on the surface of the unreacted MgH_2. In contrast, the addition of organic acids considerably improves the hydrogen generation of MgH_2. In all cases both the rate and degree of hydrogen generation increased with higher concentrations of organic acids shown in figure 1 (A), (B) and (C); for the acids concentration of 3 wt. %, 100% hydrogen yield is achieved in 3–5 minutes after reaction started. From figure 1 (D) it is shown that the organic acid with the fastest hydrogen generation rate is oxalic acid, followed by acetic acid and then citric acid.

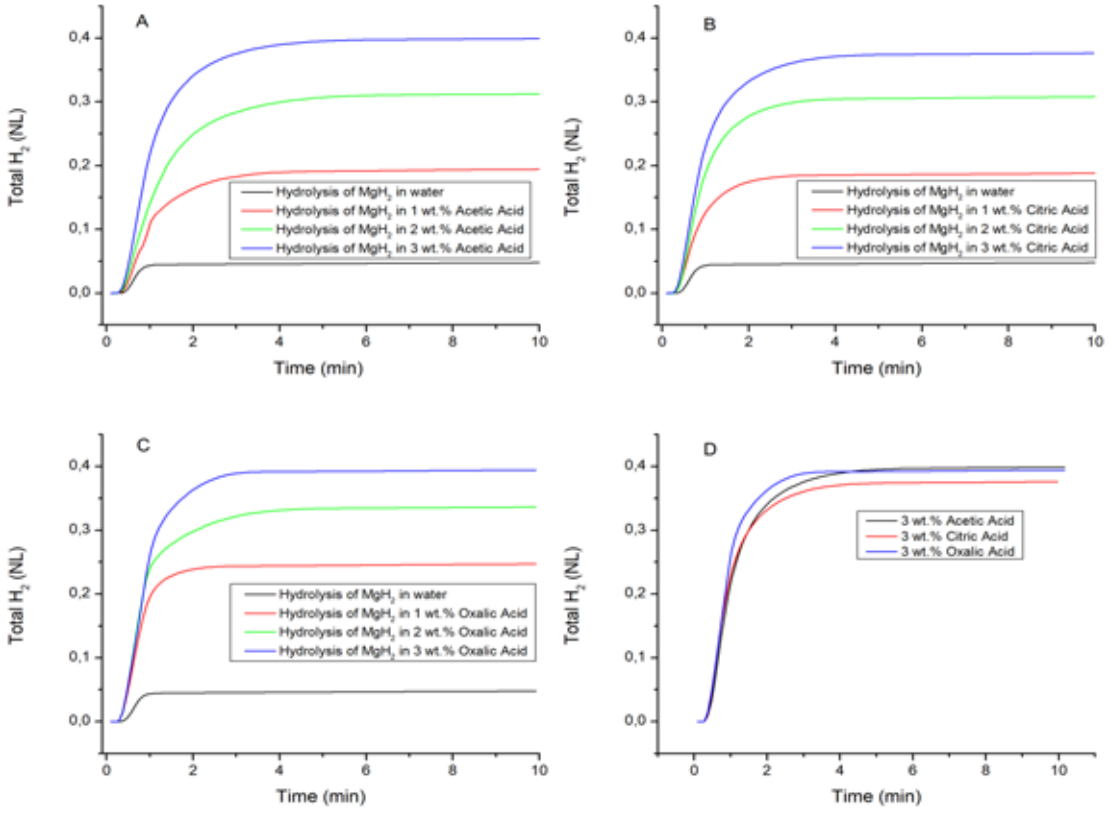

Figure 1. Hydrogen generation curves of MgH_2 at T=20 °C in different concentration of organic acids 1, 2 and 3 wt. %, (A) Acetic Acid, (B) Citric Acid, (C) Oxalic Acid, (D) Hydrogen generation of MgH_2 in 3 wt. % organic acid solutions.

The hydrolysis of MgH_2, leads to an increase in the pH of the reaction solution, this is due to the release of OH^- as a result causing the formation of the $Mg(OH)_2$ passive layer on the surface of MgH_2. This is a major problem with generating hydrogen by MgH_2 hydrolysis. From Table 1 it can be observed that the hydrolysis of MgH_2 in deionized water the pH increased drastically, which is expected due to the $Mg(OH)_2$ passive layer being formed. The addition of organic acids however suppress the formation of $Mg(OH)_2$ this was mainly due to the initial pH becoming acidic which causes less OH^- to be released into the solution. It can be seen that the samples with the lowest pH after hydrolysis have the fastest rate and amount of hydrogen generated, which was oxalic acid, acetic acid then citric acid the same as the hydrogen generation results

Table 1. pH of MgH_2 solution before and after hydrolysis

	Deionized Water	Acetic Acid			Citric Acid			Oxalic Acid		
Concentration		1 wt.%	2wt.%	3wt.%	1 wt.%	2 wt.%	3wt.%	1 wt. %	2 wt. %	3 wt. %
Initial pH	6.55	2.95	2.81	2.69	2.43	2.25	2.16	1.53	1.32	1.21
Final pH	11.04	5.54	5.28	4.28	5.32	4.98	4.53	4.84	3.32	2.11

CONCLUSIONS

The effect of organic acids such as acetic, citric and oxalic acid on the hydrolysis of MgH_2 at various concentration on hydrogen generation were evaluated experimentally. The main results are shown below.

- The hydrogen generation was considerably improved by using organic acid solution instead of only deionized water, this is due to the organic acid dissolving the $Mg(OH)_2$ passivation layer.
- By increase the concentration of the organic acid solutions, the rate of hydrogen generation and amount increased as well, the organic acid with the fastest hydrogen generation rate is oxalic acid, followed by acetic acid and then citric acid. For all the acids applied, at the acid concentration of 3 wt. %, 100% H_2 yield was observed after 3–5 minutes after starting the hydrolysis reaction.
- The addition of organic acids to the hydrolysis solution caused the solution to be acidic, therefore during hydrolysis of MgH_2 in the acidic solution causes less OH^- to be released into the solution and in-turn limiting the formation of the $Mg(OH)_2$ passivation layer.

ABSTRACT

Metal hydrides (MH) offer promising solutions in several niche applications related to hydrogen storage – the most challenging problem which hinders implementation of efficient and environment-friendly hydrogen energy technologies. Additional motivation for the development and implementation of the MH materials and technologies in South Africa is in the necessity to beneficiate vast mineral resources of the country which include all the components used as raw materials for the manufacturing of main kinds of practically important MH alloys, particularly, AB_2- and AB_5-type ones. This presentation overviews research, development and innovation (RDI) activities in South Africa in the field of MH materials and related technologies. Since the first decade of 2000s, these activities are mostly carried out by the South African Institute for Advanced Materials Chemistry (SAIAMC) at the University of the Western Cape (UWC). The MH-related activities are one of the key technologies developed within Hydrogen South Africa (HySA) RDI Strategy in hydrogen and fuel cell technologies (2008–2023) coordinated by the Department of Science and Innovation (DSI). This key technology is implemented by HySA Systems Centre of Competence hosted by SAIAMC / UWC.

Keywords: metal hydrides, South Africa, hydrogen storage, hydrogen separation and purification, hydrogen compression

INTRODUCTION

In 2008, the South African Government launched a long-term (15 years) National Strategy on the development and commercialisation of hydrogen and fuel cell technologies “Hydrogen South Africa” (HySA). The implementation of HySA Strategy is managed by the Department of Science and Innovation of South Africa and performed by three Centres of Competence established at the leading South African universities and research institutions, including the System Integration and Technology Validation Centre of Competence (HySA Systems) hosted by the South African Institute for Advanced Materials Chemistry (SAIAMC) at the University of the Western Cape (UWC). One of the HySA Systems activities is development and implementation of metal hydride (MH) materials and technologies. Main motivation for these works is in the beneficiation of vast mineral resources of the country. Apart from Platinum Group Metals (PGMs) whose beneficiation is a primary goal of the HySA Strategy, South Africa is in the top-ten countries which have the highest mineral reserves of all the components (Ti, Zr, V, Ni, Mn, etc.) used as raw materials for the manufacturing of main kinds of the practically important MH alloys, particularly, AB_2- and AB_5-type ones [1].

The most promising path towards beneficiation is through the applied chemistry and engineering solutions related to metal hydride technologies for hydrogen storage and related applications. Specifically, it relates to R&D on the use of South African minerals to produce metal hydrides for hydrogen storage, its separation and purification, and thermally driven compression. National industries, such as the petrochemical sector (PetroSA), production of synthetic fuels from coal (Sasol), metallurgy of PGMs and base metals (Anglo-American, Impala), – are currently consumers and/or producers of hydrogen. As the Hydrogen economy develops, these industries will shift into commercial producers and suppliers, and power generation companies (Eskom) may also become producers and/or consumers of hydrogen. Thus, within South Africa there will be a growing demand for the potential technological outputs, including hydrogen storage systems and thermal sorption technologies utilising metal hydrides.

This presentation overviews research, development, and innovation activities in South Africa in the field of MH materials and related technologies, mainly considering the works performed at the HySA Systems Centre of Competence hosted by SAIAMC / UWC.

BACKGROUND

Applications of metal hydrides (MH) utilise a reversible interaction of a hydride-forming metal/alloy, or intermetallic compound with hydrogen (either from gas phase or electrolyte). Due to unique combination of their properties, MH found numerous applications belonging to three main groups [2,3]:

- Gas phase applications (compact hydrogen storage; thermally-driven hydrogen compression and heat management; hydrogen separation and purification; catalysis; powder metallurgy; vacuum-plasma technologies).
- Electrochemical applications (NiMH batteries; air – MH batteries and fuel cells).
- Other applications (nuclear technologies; switchable mirrors; H_2 sensors).

MH technologies is a typical application-driven niche area able to provide very efficient solutions for hydrogen handling in a particular end-use application, by the tuning of a number of parameters, including component and phase composition of the parent MH material, system layout, operating conditions, etc. For every particular case, the success requires to pass whole way from material to system, including specification of target composition of the MH material, its manufacturing in the necessary amounts, development and further manufacturing of non-standard system components on the basis of MH materials, and, further, the system as a whole.

Most of the MH applications are very important for energy storage technologies including hydrogen and fuel cell ones. Metal hydrides can become an important link between components of such systems, allowing to combine realisation of processes of compact and safe hydrogen storage and its supply, along with the utilisation of waste heat released during operation of other system components [4].

Significant past activities on the MH research in South Africa took place in 1970's at CSIR. The research outputs were focused on the thermodynamics and kinetics of metal – hydrogen systems, including investigations on magnesium hydride [5,6]. Over the next two decades, the work carried out by South African researchers in the field of metal hydrides included theoretical investigations on electronic properties of metal hydrides including the palladium – hydrogen system [7,8]. More recent publications, from the year 2000 onwards, comprise of articles on the problems associated with hydrogen embrittlement of metals [9], theoretical studies on metal – hydrogen bonding [10], and the palladium hydrogen system [11].

Launching the HySA Strategy, where MH for hydrogen storage and related applications were recognised as a key technology allocated at HySA Systems, resulted in a significant increase of the South African contribution into R&D activities in this field. A brief overview of these activities is presented below.

METAL HYDRIDE RELATED ACTIVITIES AT SAIAMC AND HYSA SYSTEMS

The R&D on MH materials and technologies carried out at SAIAMC and HySA Systems since 2007 were focused on:

- Development of poisoning-tolerant MH materials and their use in systems for hydrogen extraction and purification [12,13].
- Ti-based MH alloys: development, preparation (up to 10 kg/load) and characterisation [14,15].
- Modelling of phase equilibria in the systems of H_2 gas with hydride-forming metals and alloys [16], as well as heat-and-mass transfer in the metal hydride reactors [17].
- New highly efficient hydrogen storage nanocomposites on the basis of magnesium hydride [18,19].
- Development of metal hydride systems for gas-phase applications including hydrogen storage tanks for utility vehicles [20] and industrial-scale hydrogen compressors [21].
- Development of the integrated hydrogen energy systems utilising MH [4] including a pilot prototype of hydrogen refuelling station with integrated MH compressor [22].

Presently, HySA Systems develops and implements specific products for the local and international markets, particularly, metal hydride-based technologies for hydrogen storage and compression (HySA Key Programme KP6). The Key Programme presently includes two projects: KP6-S01 "Metal hydride-based hydrogen storage systems" and KP6-S02 "Metal hydride hydrogen compressors and their integration in hydrogen refuelling stations". The focus is put on the MH-based technologies of hydrogen storage on-board heavy-duty utility vehicles (e.g., forklifts and underground mining vehicles), as well as development of MH hydrogen compressors and their integration in refuelling stations.

CONCLUSIONS

South Africa has a solid background in the R&D on metal hydride materials and technologies mainly motivated by a possibility to beneficiate the abundant local feedstock suitable for the manufacturing of the MH materials. The RDI

activities in the field have been intensified after launch of HySA Strategy in 2008 and are mainly carried out by HySA Systems CoC hosted by SAIAMC / UWC.

ACKNOWLEDGEMENT

The MH Related Activities at SAIAMC and HySA Systems were funded by the Department of Science and Innovation of South Africa, as well as by South African industry partners including Eskom Holdings Ltd and Impala Platinum Ltd. The international collaboration in the field was supported by the EU including FP7 ERAfrica and Horizon-2020 RISE programs.

ABSTRACT

With its relatively high hydrogen storage capacity (1.8 wt%), TiFe hydrogen storage alloy is expected to be a low-cost material compared to other storage alloys. However, TiFe requires an initial activation process under high temperature and pressure. In order to improve the initial activation properties, the mechanical alloying (MA) process has been proposed to give a disordered surface structure; the MA process can obtain alloys with less energy than the solidification process and is considered to be environmentally and economically suitable.

In this study, we have investigated how the difference between metallic Ti and Ti hydride (TiH_2), the starting material of the MA process, affects the alloy formation. Ti hydride is obtained during the refining process of metallic Ti and is easily pulverized. We also added a small amount of a third element, such as Mn, to TiFe to study its effect on alloying and absorption properties. The obtained sample powder was observed by scanning electron microscopy (SEM) and the structure of the sample was identified by powder X-ray diffractometer (XRD).

Keywords: Hydrogen storage alloy, crystallization, storage capacity

INTRODUCTION

Currently, Japan is being urged to shift from fossil resources to renewable energy sources in response to global warming issues and the international situation. However, renewable energy has the inherent characteristics of unstable supply and low energy density. Using hydrogen as an energy carrier to store and dense renewable energy is the most suitable means to overcome the negative characteristics of renewable energy.

However, the use of hydrogen is not sufficiently widespread at present because the infrastructure for its storage, transportation, and utilization is not well developed. Metal hydrides made of hydrogen storage materials have a higher hydrogen density than liquid hydrogen at normal temperature and pressure [1]. Low-cost, lightweight, and high-hydrogen-capacity hydrogen storage alloys may contribute to the realization and diffusion of future energy systems.

Among the many hydrogen storage materials proposed, TiFe is expected to be used because of its relatively low cost [2]. However, it requires high temperature and high pressure for the activation process, and research to improve the activation properties of TiFe has been continued and discussed [3-5]. As one of them, it is known that the activation of alloys prepared by the mechanical alloying (MA) process is easy, and the MA requires less energy input than the conventional melting method, which may reduce the environmental impact [6,7]. In this study, we examined to fabricate an alloy with a small amount of a third element such as Mn to facilitate the activation of TiFe, and to investigate the effect of the difference between metallic Ti and Ti hydride as the starting material for fabricating the alloy.

EXPERIMENTAL

We attempted to synthesize samples by the MA method from powdered metallic Ti, Ti hydride, and Fe (particle size less than 45 μm). The particle size of metallic Ti was adjusted to be the same as that of Ti hydride powder by ball milling for 50 hours before. In the grove box (GB), 20 stainless steel balls of 10 mm in diameter and the sample powder were sealed in a 60 ml stainless steel ball mill container. A planetary ball mill was used as the MA method, and ball milling (grinding) was carried out for 10 to 100 hr. The volume ratio of sample, stainless steel balls, and space was 1:20:100, and the rotation speed was 300 rpm. We also prepared a sample with a small amount of Mn as a third element to investigate the characteristics of the material obtained by the MA method. The shapes of the obtained samples were observed by scanning electron microscopy (SEM) and the structures of the samples were identified by powder X-ray diffractometer (XRD). In addition, 1 g of the sample containing Mn was sealed in a reaction tube in GB and hydrogenated in a high-pressure Sieverts' type apparatus to evaluate its hydrogen sorption properties.

RESULTS AND DISCUSSION

In the case of the alloy prepared using metallic Ti as the starting material, the XRD diffraction results showed that the samples milled for 10 and 20 hours were not alloyed. However, as the milling time increased to 50 and 100 hours, the alloying process was observed. However, it was also observed that the crystallinity became disordered as the milling time increased.

In the case of the sample prepared with Ti hydride as the starting material, the XRD diffraction results showed no alloying up to 50 hours, while the sample milled for 100 hours showed alloying. 50 hours of milling showed a clear difference, indicating that more time is required for alloying when using Ti hydride. A clear difference was observed at 50 hours of milling, indicating that more time is required for alloying when using Ti hydride. It was observed that the crystallinity of both Ti metal and Ti hydride was disordered.

Scanning electron microscopy showed that the shorter the milling time, the more angular the grains were, and the more the grains stuck to each other. However, as the milling time increased, the powder grains became more rounded and the grain size became 5 to 10 μm.

In both cases, the longer milling time disturbs the crystallinity of the material, and the amorphous like structure contains more grain boundaries and defects that can trap hydrogen, resulting in an increase in the alpha phase region of the phase diagram. At the same time, however, greater crystallinity disorder leads to a decrease in the number of hydrogen storage sites and thus a decrease in the maximum hydrogen storage capacity. Considering these effects, using metallic Ti as the starting material is more suitable for the fabrication of hydrogen storage alloys, as it can be alloyed in a shorter time.

CONCLUSIONS

It was found that the process of MA using metallic Ti as starting material enable faster alloying than that using Ti hydrides. Although Ti hydride is often regarded as a more suitable starting material for alloying than Ti metal because of its brittleness, ease of powdering, and reducing effect of hydrogen, Ti hydride requires extra energy to break the bond between hydrogen and titanium, thus needs a longer milling time.

ABSTRACT

Hydrogen energy carrier system is indispensable for decarbonisation through the expansion of renewable energy. The organic chemical hydride method for storing and transporting hydrogen under normal temperature and pressure conditions in the liquid state by incorporating hydrogen atoms into the molecular structure of liquid organic hydrogen carrier (LOHC) is safe and low risk method. Chiyoda started the development of a system employing the method since 2002, named the system “SPERA Hydrogen™” and system completed the international demonstration of massive hydrogen supply chain from Brunei Darussalam to Japan in 2020. It is the only system that has completed the international demonstration of the entire process and has moved to the commercialization stage. It is considered that the system is the most inexpensive except ammonia direct combustion with boiler at present and also has a high potential for cost reduction towards the future compared to other methods.

Keywords: Hydrogen, Storage, Transportation, SPERA Hydrogen

INTRODUCTION

Expanding the use of renewable energy is essential for the decarbonization, and the role of hydrogen energy, which can be used as a clean fuel converted from primary energy including renewable energy, is indispensable. In order to expand the use of hydrogen energy, technologies that can "store" and "transport" hydrogen on a large scale, as well as fossil fuels such as oil and natural gas are essential. The method for storing and transporting hydrogen under normal temperature and pressure conditions in the liquid state by incorporating hydrogen atoms into the molecular structure of liquid organic hydrogen carrier (LOHC) is safe and low risk method.

Chiyoda started the development of a system employing the method since 2002, named the system “SPERA Hydrogen™” and system completed the international demonstration of massive hydrogen supply chain from Brunei Darussalam to Japan in 2020. It is the only system that has completed the international demonstration of the entire process and has moved to the commercialization stage. In addition, the organic chemical hydride method, which uses LOHC as a hydrogen carrier, is a chemical method that allows for innovative technological improvements such as simplification of the process. It is considered that the system is the most inexpensive except ammonia direct combustion with boiler at present and also has a high potential for cost reduction towards the future compared to other methods. In this presentation, we will introduce the outline of the method, International Demonstration Project with “SPERA Hydrogen™” system, and prospect for the commercialization and innovative cost down scenario toward the future.

SPERA HYDROGEN SYSTEM

Hydrogen is reacted with toluene (TOL) to produce methylcyclohexane (MCH), which is converted to a liquid with hydrogen in its molecule enables that hydrogen to be "stored" and "transported" in a liquid state at normal temperature and pressure. Hydrogen can be generated at the place of use through dehydrogenation reaction. TOL is used repeatedly. Figure 1 shows scheme of SPERA Hydrogen System.

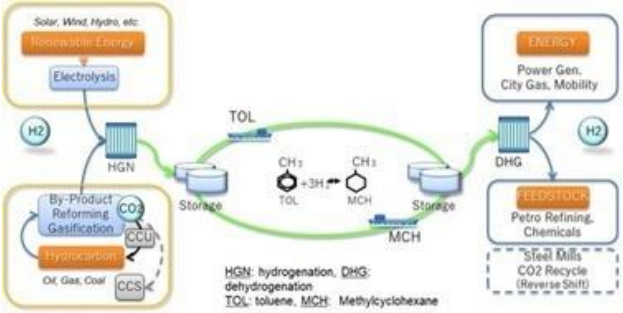

Fig. 1. Scheme of SPERA Hydrogen System

INTERNATIONAL DEMONSTRATION PROJECT

That project launched in 2015, was conducted by the Advanced Hydrogen Energy Supply Chain Association for technology Development (AHEAD) which was established by Chiyoda Corporation, Mitsubishi Corporation, Mitsui & Co., Ltd. and NYK Line. It was founded by New Energy and Industrial Technology Development Organization (NEDO). The demonstration was more than 100 tons of hydrogen transported from Brunei Darussalam to Japan over ten month and the project was successfully completed in Dec.2020[1,2].

The demonstration verified that the system is technically ready for commercial use and confirm SPERA Hydrogen's potential contribution to global carbon neutrality in 2050. Since the entire system for demonstrated in large-scale internationally was the first demonstration in the world, SPERA Hydrogen System is the only system for massive hydrogen storage and transportation in the commercialization phase. Fig.3 shows the photograph of the international demonstration.

Fig. 3. Photograph of the international demonstration

PROSPECT OF COMMERCIALIZATION AND INNOVATION FOR THE FUTURE

Chiyoda joined the "Hydrogen Utilization Study Group in Chubu, Japan" to commercialize the system in Japan[3] and signed a MOU on with Sembcorp industries (Singapore) to explore the feasibility and implementation of a commercial scale supply chain to deliver decarbonized hydrogen to Singapore[4]. The Ministry of Economy, Trade and Industry (METI) of Japan selected Chiyoda and Mitsubishi Corporation to conduct a "Feasibility Study on the Construction of a Hydrogen Supply Chain using SPERA Hydrogen", as part of their "Feasibility Study for the Overseas Development of High-quality Energy Infrastructure"[5].

The Japanese government's Basic Hydrogen Strategy targets a hydrogen supply cost of 30¥/Nm3 (3$/kg) by 2030 and 20¥/Nm3 (2$/kg) by 2050, and we aim to meet the 2030 target based on the current scheme demonstrated above. For the 2050 target, since innovative technologies such as direct production of MCH by photo-catalyst and direct MCH fuel cells etc. are required, we have already started basic research. We are also cooperating with ENEOS in the practical application of their Direct MCH electrolysis technology.

CONCLUSIONS

SPERA Hydrogen System has shift to commercialization phase. It is the only system that has completed the international demonstration of the entire process in Large-scale. It is considered the system is the most inexpensive method except ammonia direct combustion with Boiler, and the system also has a high potential for cost reduction towards the future compared to other methods since it is chemical method. Chiyoda would like to contribute the hydrogen business through the system licence, catalyst supply etc. to the player enterprise globally.

ACKNOWLEDGEMENT

The international hydrogen supply chain demonstration project was found by the New Energy and Industrial Technology Development Organization (NEDO). We express words of gratitude to NEDO.

PERFORMANCE OF BENZYLTOLUENE AS PURE HYDROCARBON LIQUID ORGANIC HYDROGEN CARRIER (LOHC) IN STORAGE CYCLES

[1*] *Timo Ruede, [1]Patrick Preuster, [1]Moritz Wolf, [1]Peter Wasserscheid*
[1] FZ Jülich, Helmholtz-Institute Erlangen-Nuernberg for Renewable Energy (IEK 11), Egerlandstr. 3, Erlangen, Germany

ABSTRACT

This study presents benzyltoluene/perhydro benzyltoluene (H0-BT/H12-BT) as favourable liquid organic hydrogen carrier (LOHC) system for potential technical applications. LOHCs can enable safe and efficient hydrogen logistics using the existent fuel infrastructure. Compared with the well-established LOHC systems toluene/methylcyclohexane and dibenzyltoluene/perhydro dibenzyltoluene (H0-DBT/H18-DBT), the H0-BT/H12-BT system combines a similarly high volumetric storage density and excellent robustness in hydrogenation/dehydrogenation cycles with low viscosity for easy handling in colder operation conditions. Herein, we report repeated hydrogenation and dehydrogenation cycles of technical grade LOHCs in semi continuous operation at 290 °C with a commercial platinum on alumina catalyst (Pt/Al_2O_3). Reaction rates for both, hydrogen uptake and release, are generally found to be higher for H0-BT/H12-BT when compared to the DBT-based LOHC system at identical reaction conditions. By-product formation is low during cycling of the H0-BT/H12-BT system and only small amounts of the dehydrocyclisation products, such as methylfluorene species, are formed that can themselves act as hydrogen carrier.

Keywords: Chemical Hydrogen Storage, Benzyltoluene, repeated storage cycles, reaction rate, by-product formation

INTRODUCTION

Transformation of the global energy system requires green hydrogen technologies since they enable energy storage in large quantities and over long periods of time as well as global energy distribution. For such large-scale hydrogen storage and transport, many different technology options have been discussed. The LOHC technology offers a unique selling point, as the hydrogen is reversibly chemically bound in a liquid hydrocarbon carrier by catalytic hydrogenation and dehydrogenation reactions. This enables the utilisation of existing infrastructure for liquid fuels for the hydrogen logistics [1, 2]. To date, two hydrocarbon-based heteroatom-free LOHC systems have been intensively studied in the literature, namely toluene/methylcyclohexane [3, 4] and dibenzyltoluene/perhydro dibenzyltoluene [5-7]. Despite the fact, that the benzyltoluene/perhydro benzyltoluene system was already mentioned in 2014 [8], this alternative system has been studied far less. Only recently, two studies examined the H0-BT/H12-BT LOHC system in greater detail [9, 10]. They concluded that H0-BT/ H12-BT is particularly interesting as it combines fast production of high purity hydrogen, which is typically associated to dibenzyltoluene-based LOHC systems, with the technically relevant low viscosity and fast pore diffusion characteristics during dehydrogenation, which is typically associated with methylcyclohexane. Motivated thereby, we conduct a more detailed study of the H0-BT/H12-BT LOHC system with analysis of the rate of hydrogen storage and hydrogen release and assessed the stability of this LOHC system in repeated storage cycles.

EXPERIMENTAL

Semi continuous experiments for studying the hydrogenation/dehydrogenation cycles were carried out in a stainless-steel high pressure/high temperature autoclave (Type 4575A, Parr Instruments). The general procedure for performing the cycles was adopted from a previous study focussing on catalyst testing and LOHC stability [5, 11]. Hydrogenation reactions were performed in a dead-end mode and a pressure of typically 30 bar_{abs} was maintained in the reactor by a pressure regulator. The dehydrogenation reactions were initiated by stopping hydrogen supply and opening the reactor to a back pressure regulator. For dehydrogenations, the overall pressure was set to ensure a hydrogen partial pressure of 1.6 bar_{H2}. The temperature was controlled by an electric heating mantle and an immersed cooling coil. The utilized LOHC of technical quality was applied without further preconditioning or purification and the finely ground EleMax-102D (Cl#102, 0.3 wt.-% Pt/Al_2O_3, Clariant) served as catalyst [12].

The degree of hydrogenation (DoH) and the by-product formation were determined by liquid sample analysis by means of gas chromatography (GC). The GC was equipped with mass-spectrometry (MS) and flame-ionisation (FID) detectors to identify and quantify the LOHC species. The DoH of the sample is calculated from GC peak areas (equation (1)):

$$DoH\ /\ \% = \frac{100\ \% \cdot Area_{H12BT} + 50\ \% \cdot Area_{H6BT}}{Area_{H12BT} + Area_{H6BT} + Area_{H0BT} + Area_{MeFl}} \quad (1)$$

RESULTS AND DISCUSSION

Hydrogenation/dehydrogenation reaction path analyses

Our experiments confirmed that hydrogenation of the toluene ring in H0-BT is slower than hydrogenation of the unsubstituted benzene ring [13]. In contrast, neither the methylcyclohexyl nor the cyclohexyl ring was preferentially formed during dehydrogenation. The applied commercial catalyst has been optimised to suppress by-products formed by cleavage of C-C bonds and condensation to heavy boilers [14]. Accordingly, the concentration of cracking products, such as benzene, methylcyclohexane, toluene or diphenylmethane (and their hydrogenated analogues), in the liquid samples after each hydrogenation/dehydrogenation reaction was consistently below 0.1%. Nevertheless, the GC-MS data of our Hx-BT storage cycle experiments revealed the formation of small amounts of methylfluorenes. Traces of anthracene can also be identified as oxidative cyclisation product of the ortho-BT regioisomer, but to substantially lower quantities than methylfluorenes. Figure 1 summarises the more comprehensive reaction scheme of the H0-BT/ H12-BT LOHC system developed from our detailed intermediate product and by-product analysis.

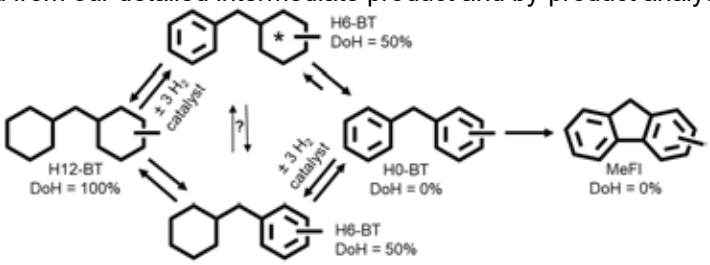

Figure 1. Reaction scheme of the H0-BT/H12-BT LOHC system showing the two different reaction pathways via H6-BT; the main by-products are methylfluorene regioisomers formed by oxidative cyclisation of H0-BT [11].

Hydrogenation of H0-BT and dehydrogenation of H12-BT in repeated cycles

Single hydrogenation/dehydrogenation reactions of the H0-BT/H12-BT LOHC system have been demonstrated in the literature [8, 13, 15-17]. Here, we demonstrate up to seven repeated storage cycles at 290 °C. Hydrogenation was completed after 4 h with a mean DoH of (99.6 ± 0.2)%. In the subsequent dehydrogenation sequences over , DoHs of 26.2% were reached as consequence of the relatively elevated hydrogen partial pressure. The prolonged 5th dehydrogenation resulted in a DoH of 17.9%, which represents the chemical equilibrium under the applied conditions [11]. In another experimental series, the H0-BT hydrogenations were repeatedly demonstrated to be 260% more productive than the H0-DBT hydrogenations. The H12-BT dehydrogenations were 30% more productive than H18-DBT dehydrogenations, with the latter showing a decreased hydrogen storage capacity over the cycles, whereas the H12-BT dehydrogenation sequences showed remarkably stable productivities up to a total operation time of 216 h [11].

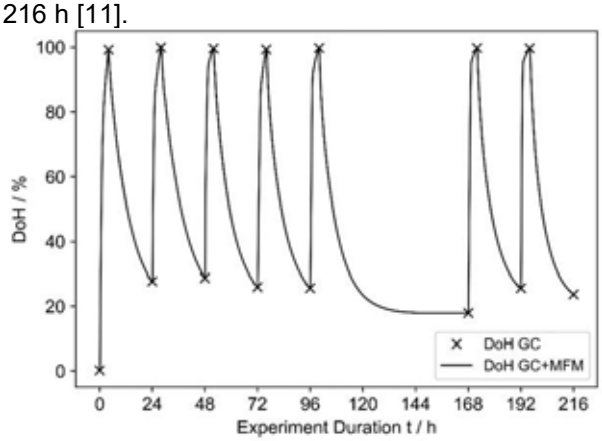

Figure 2. Left: Seven one-pot storage cycles with semi-batch hydrogenation of H0-BT and subsequent dehydrogenation of H12-BT – long-term 5th dehydrogenation over 70 h (270 g H0-BT; CI#102; 0.3wt.-% Pt/Al_2O_3 ground catalyst; n_{Pt}:$n_{H2,max}$ = 1:60000; 290 °C, $p_{H2,hy}$ = 30 bar_{H2}, $p_{H2,dehy}$ = 1.6 bar_{H2}). Right: 15 liquid samples taken at the start and after each hydrogenation/dehdrogenation [11].

Comparing these results from Figure 2 with literature reports on storage cycles with H0-DBT/H18-DBT under identical conditions is quite instructive. Jorschick et al. reported significant catalyst deactivation during long-term dehydrogenation [18]. In contrast, the herein reported storage cycles with H0-BT/H12-BT, the catalyst activity and LOHC stability appeared unaltered. Even the long-term 5th dehydrogenation over 70 h reaching equilibrium

conversion did not impair the catalyst, while yielding exactly the same DoH (25.6%) in the 6th as in the 4th dehydrogenation.

Monitoring of fluorene formation during extended storage cycles

Exposure of the hydrogenation/dehydrogenation catalyst to LOHC systems at low hydrogen partial pressures in combination with elevated temperatures may result in catalyst deactivation and high-boiling by-product formation [18]. In our experiments, four high-boiling regioisomeric methylfluorenes were the only significant by-products detected by means of GC-MS and GC-FID. Expectedly, their concentration increased with every storage cycle. However, fluorene derivatives themselves have been considered as promising LOHC compounds in the literature reflecting their ability to store/release six hydrogen molecules resulting in a comparable hydrogen storage capacity as the H0-BT/H12-BT LOHC system [19]. Unfortunately, fluorene derivatives can also trigger the formation of even larger condensation products and finally coke [20]. Therefore, we investigated the methylfluorene formation in four storage cycles at 290 °C and 1.0 bar_{H2} during dehydrogenations. By linear regression, an increase of fluorene derivatives with each dehydrogenation of about 0.32%-points can be estimated (Figure 3). The experiments indicate that BT could form less by-products than DBT [11]. Aside from this quantitative analysis, the liquid samples of BT experiments (such as those shown in Figure 2) hardly displayed any visible coloration with increasing operation time. This can be seen as strong indication for the formation of only trace amounts of heavy-boiling by-products, which are distinguishable by a yellow or brownish colouring [21].

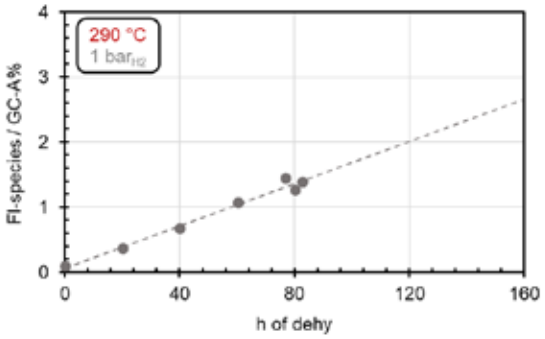

Figure 3. Fluorene-species accumulation during four dehydrogenation sequences for H18-DBT and H12-BT. Dashed lines indicate a linear trend. (270 g LOHC-; Cl#102; 0.3wt.-% Pt/Al_2O_3 ground catalyst; n_{Pt}:$n_{H2,max}$ = 1:30000; 290 °C, $p_{H2,dehy}$ = 1 bar_{H2}) [11].

CONCLUSIONS

Inspired by the low viscosity of H12-BT, when compared to H18-DBT, we have collected additional technically relevant data to assess the H0-BT/system for technical use in the frame of the LOHC technology. In detail, we have studied the stabilities of the LOHC compounds and the performance of a technical Pt-based hydrogenation/dehydrogenation catalyst over repeated storage cycles. We found that the hydrogen storage cycles under benign conditions (290 °C with 30 bar hydrogen pressure in loading and 1.0 – 1.6 bar_{H2} hydrogen pressure in release sequences) showed an excellent reproducibility. Seven storage cycles with one long-term dehydrogenation over several days neither showed signs for degradation of the catalyst nor of the LOHC compounds. We anticipate that the H0-BT/H12-BT LOHC system may represent the preferred hydrocarbon-based and heteroatom-free LOHC system for further technical application with clear advantages over the more traditional toluene/methylcyclohexane and H0-DBT/H18-DBT LOHC systems.

NOMENCLATURE

DoH	Degree of Hydrogenation, %
n	*Moles, mol*
p	Pressure, bar

Subscripts

H2	Hydrogen
H2,dehy	Hydrogen during dehydrogenation
H2,hy	Hydrogen during hydrogenation
Pt	Platinum

ABSTRACT

In this paper, an exergy-economic model is developed to analyze the performance of a direct steam solar tower - steam turbine - organic Rankine cycle (ORC) power plant under different working conditions. The solar power plant is connected to a power grid, and it is integrated with a hydrogen storage system. The hydrogen storage system is composed of an electrolyser, fuel cell, steam turbine and organic Rankine cycle. When solar energy is not available, electrical power is generated by the fuel cell, steam turbine and ORC using the hydrogen produced by the electrolyzer. The analyses are made for the maximum solar irradiation that is available in the city of YAZD in Iran. The effects of the current density and operating temperature on the performance of the solid oxide electrolyzer cell (SOEC) and solid oxide fuel cell (SOFC) are investigated. The effect of solar irradiation on the energy and exergy efficiencies of the cycle is investigated. The results indicate that increase of the solar irradiation leads to an increase of the energy and exergy efficiencies of the cycle. The solar tower has the highest exergy destruction and capital investment cost.

Keywords: Direct steam solar power tower, Solid oxide electrolyzer cell, solid oxide fuel cell, Organic Rankine cycle

INTRODUCTION

Finding efficient power systems is of major concerns, especially with the depletion of fossil fuel sources with time. Energy demands are expected to keep increasing in the future. Thus, finding efficient systems is vital to reduce the unit of energy produced per the unit of fuel consumed. On the other hand, producing energy from fossil fuel causes some problem to the environment, such as global warming, air pollution, acid precipitation, ozone depletion, forest destruction and emission of radioactive substances [1].

The solar power tower is one of the most unique technologies for converting solar energy to electricity due to its high working temperature and thermodynamic efficiency [2]. Solar tower power system uses a central tower as a solar collector that is used to heat or evaporate the working fluid the thermal energy of the fluid force is utilized to generate electricity by a turbine.

To better harness renewable energy, hydrogen has been identified as a potential alternative fuel as well as an energy carrier for the future energy supply. Hydrogen is produced in different ways such as thermolysis, coal gasification, biomass conversion, electrolysis, etc. The benefits of water electrolysis include low pollution, reliability, large-scale applications, durable and inexpensive materials and capability of integration with renewable sources such as solar energy systems [3].

Solid oxide fuel cells (SOFC) are considered an emerging technology as characterized by their high efficiency and lowCO2 emissions. An SOFC operates at high temperature and thus has high waste energy that can be integrated efficiently with a bottoming cycle. One of the potential systems that can be integrated with SOFC is organic Rankine cycle (ORC). ORC is similar to steam Rankine cycle; however, it uses organic working fluid instead of steam and requires less input heat to operate compared with steam Rankine cycle. SOFC and ORC are potential subsystems that can be used in trigeneration plants [4].

SYSTEM DESCRIPTION

The schematic of investigated system in this current research paper is shown in Figure 1. The solar tower-hydrogen power plant consists of a direct steam solar tower, solid oxide electrolyzer (SOEC), solid oxide fuel cell (SOFC), steam turbine (ST), Organic Rankine cycle (ORC) and hydrogen and oxygen storage tanks. During charging cycle, solar radiation is reflected from the heliostats to the receiver above the solar tower where liquid water is converted into superheated steam. The thermal energy of the steam is then used in the steam turbine 1 (ST1) to generate electric power. A part of the generated power with the capacity of 70 MW is fed to the grid and the rest is supplied to the SOEC. In the SOEC, water is decomposed to hydrogen and oxygen gases. The produced gases are sent to the hydrogen and oxygen tanks for storage. The high-pressure hydrogen and oxygen stored in the tanks are first used in SOFC to generate electricity during the discharge mode. Outlet water steam used in the steam turbine 2 and then flow through

heat exchangers to transfer heat to the ORC fluid. The discharge cycle is performed when solar energy is not available. Based on the solar irradiation data of Yazd city, the operating hours of the charging and discharging cycle are considered as 11 hours and 7 hours, respectively. The Yazd city, with an area of 110 km^2 is at an altitude of 1216 m and in coordinates of 54.3569 °E, 31.8974 °N.

THERMODYNAMIC ANALYSIS

The thermodynamic analysis is performed to determine the system's energy losses and exergy destructions in detail.

The total exergy per unit mass is summation of physical and chemical exergies as follows:

$$Ex = Ex^{ph} + Ex^{ch} \quad (1)$$

$$Ex^{ph} = (h - h_0) - T_0(s - s_0) + \left[\frac{v^2 - v_0^2}{2}\right] + g(z - z_0) \quad (2)$$

$$Ex^{ch} = \sum x_n Ex_n^{ch} + RT_0 \sum x_n \ln x_n \quad (3)$$

first and second laws of thermodynamics for an open system at steady state condition is as follows:

$$\sum_k \dot{Q}_k + \sum_i^N (\dot{m}_i h_i)_k = \dot{W}_k + \sum_e^N (\dot{m}_e h_e)_k \quad (4)$$

$$\sum_k \left(1 - \frac{T_0}{T}\right) \dot{Q}_k + \sum_i^N \dot{E}x_{i,k} = \dot{E}x_{w,k} + \sum_e^N \dot{E}x_{e,k} + \dot{E}x_{D,k} \quad (5)$$

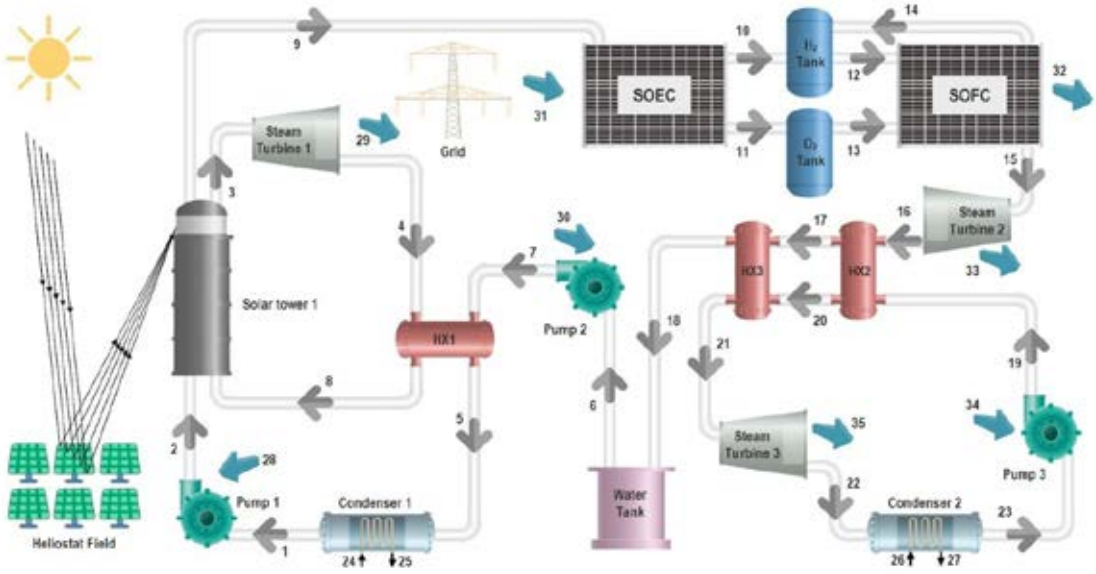

Figure 1. Diagram of the solar power tower, Hydrogen and ORC hybrid power plant

EXERGOECONOMIC ANALYSIS

Exergoeconomic analysis is performed to determine the exergy cost of the system's products. The analysis is based on the exergy- cost principle as suggested by Noaman et al. [5].

The cost balance for each component based on exergy of the fuel and products is as follows:

$$\sum_e^N \left(c_e \dot{E}x_e\right)_k + c_{w,k}\dot{W}_k = c_{q,k}\dot{W}_{q,k} + \sum_i^N \left(c_i \dot{E}x_i\right)_k + \dot{Z}_k \quad (6)$$

where c and $\dot{Z}_k$ denote the average cost per unit exergy and the capital investment, operation, and maintenance cost rate of k_{th} component, respectively. The term $\dot{Z}_k$ is calculated as follows:

$$\dot{Z}_k = \frac{Z_k CRF \varphi}{N} \quad (7)$$

The capital recovery factor (CRF) is calculated based on lifetime (n=20) and interest rate (ir=10%) as follows:

$$CRF = \frac{ir(1+ir)^n}{(1+ir)^n - 1} \quad (8)$$

The cost of exergy destruction in each component, the relative cost difference (r_k) and exergoeconomic factor (f_k) for each component are defined as follows:

$$\dot{C}_{D,k} = c_{F,k}\dot{E}_{D,k} \quad (9)$$

$$r_k = \frac{c_{P,k} - c_{F,k}}{c_{P,k}} \quad (10)$$

$$f_k = \frac{\dot{Z}_k}{\dot{C}_{D,k} + \dot{Z}_k} \quad (11)$$

RESULTS AND DISCUSSION

The performance of the direct steam solar power-hydrogen power plant is modeled based on the first and second laws of thermodynamics. Moreover, the exergy destruction of each component is also calculated. The exergy analysis and exergo-economic results are given in Table 1. The highest value of the exergy destruction rate is related to the solar tower system that; this is due to the conversion of a large amount of solar energy to thermal energy at a specific operating temperature and the high heat loss in the receiver of the solar tower. It is concluded that the highest value of the cost rate of the capital investment ($\dot{Z}$) is related to solar tower system. The exergoeconomic factor for the solar tower shows that the capital investment cost is the primary determinant in the exergy destruction cost.

Table 1.The results of exergies and efficiencies and exergy economic for all components of the entire cycle

Component	$\dot{E}X_{f,k}$[kW]	$\dot{E}X_{p,k}$[kW]	$\dot{E}X_{D,k}$ [kW]	η [%]	ψ [%]	$\dot{C}_{D,k}$ [$/h]	$\dot{Z}$ [$/h]	r_k [%]	f_k [%]

Steam Turbine 2	626.8	592.6	34.18	86.8	94.55	3.06	9.402	23.49	75.45
Heat Exchanger 2	296.9	99.19	197.7	90	33.41	17.7	0.7959	208.3	4.304
Heat Exchanger 3	104.7	56.81	47.91	90	54.25	4.288	0.934	102.7	17.88
Steam Turbine 3	132.7	117.5	15.22	86.8	88.53	3.901	3.044	23.06	43.83
Condenser 2	23.54	17.23	40.77	90	76.13	10.45	0.0691	43.55	0.6569
Pump 3	7.459	0.2698	7.189	75	3.617	2.267	0.0133	2680	0.5813

In Figure 2 and Figure 3 the exergy destruction rates related to charge and discharge cycle are shown. In charge cycle, the exergy destruction rate of the solar tower is 61.81% and it has the highest exergy destruction rate because of low solar irradiation absorbed by receiver in comparison with high solar radiation reflected to heliostats. The highest exergy destruction rate in discharge cycle occurs in the SOFC i.e., is 94.26%.

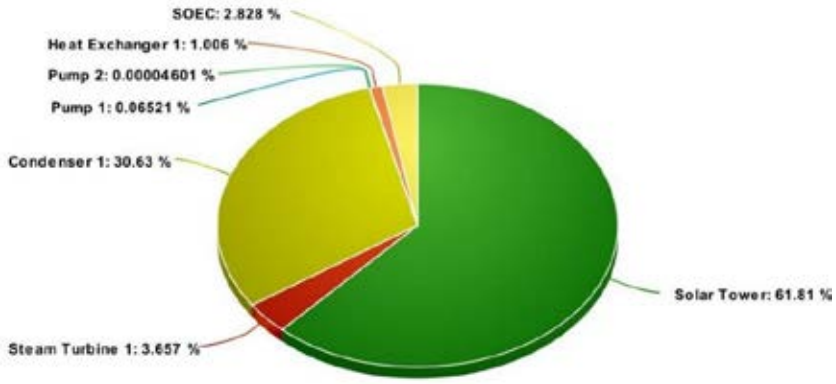

Figure 2. The rate of the exergy destruction of the components in charge cycle

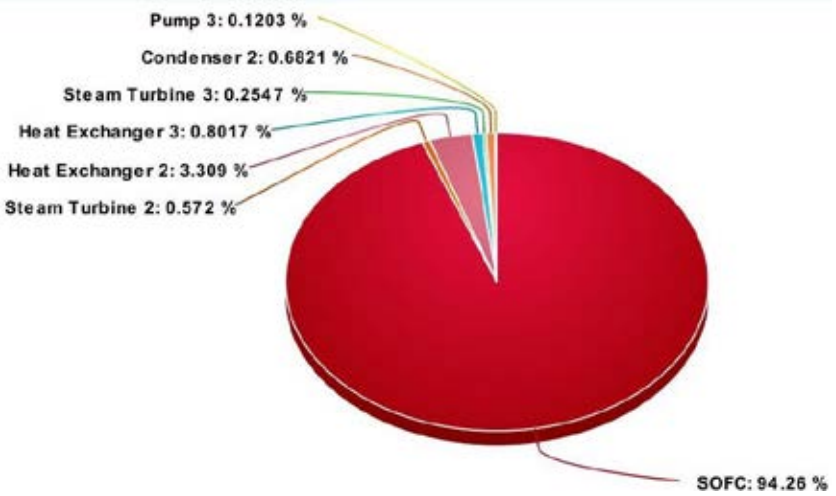

Figure 3. The rate of the exergy destruction of the components in discharge cycle

CONCLUSIONS

The following conclusions are made in summary:

- Inlet steam to the steam turbine has the highest rate of exergy destruction due to the conversion of large amounts of solar energy to lower quality energy at fluid operating temperatures. The ambient temperature affects the exergy destruction of the components.
- Exergy destruction of condenser 1 decreases with increasing ambient temperature due to the lower fluid temperature difference with ambient temperature in the phase change process.
- The exergo-economic factor for all components is calculated and it was found that solar tower, pump 1 and ST1 have the highest exergoeconomic factor which shows it is needed to be considered these components from the economic view. Condenser1, SOEC and SOFC have the highest cost of the exergy destructions.

3D COFs FOR PHOTOCATALYTIC N_2 FIXATION: A COMPUTATIONAL STUDY

[1] Amro M. O. Mohamed,[1] Yusuf Bicer*

ABSTRACT
As a result of permanent porosity, tunability, and structural stability, covalent-organic frameworks (COFs) have been introduced in various environmental-related applications. COFs have been studied for various gas separation-related applications, primarily CO2 capture from natural gas and flue gas. The performance of COFs towards gas separation can be investigated by computational techniques, including density functional theory (DFT) and molecular simulations based on force fields. In this work, several atomistic and molecular simulations techniques are used to identify COFs for the nitrogen conversion to ammonia photocatalytically. The experimental database is screened for desired conduction, valence band, and bandgap. A total of six structures are selected from the 3D structures. COF-300 has been shown to have desirable electronic properties (bandgap approximately 3.5 eV) and the highest N_2 adsorption among the six COFs.The simulations are performed using GCMC simulations to determine the nitrogen capacity of the COFs. Structures with one of the desired valence or conduction bands with desirable bandgaps are coupled in a COF/COF junction that potentially enhances charge separation and reduces charge carrier recombination rates. The study reports a 40 COF/COF heterojunction for the required application. Such high throughput screening typically involves databases (experimental based) and results in an essential structure-function relationship that accelerates materials discovery in several energy applications.

Keywords: Photofixation of nitrogen, Green ammonia, COFs, Computational screening

INTRODUCTION

Covalent organic frameworks (COFs) are orderly porous crystalline organic materials. They have several features that make them intriguing in various applications. COFs have low density and possess high thermal and chemical stabilities. COFs have been investigated as adsorbents, catalysts, sensors, energy storage applications, and membrane treatment [1]. Due to the growth of nanoporous materials, researchers developed frameworks and procedures to screen and select top-performing materials for different applications. Due to the development in computational power, computational modeling and simulation at the molecular level can provide essential information about the applications that a particular material can enhance [2]. Possible nanoporous structures are enormous due to tunability and variations in building blocks. Gas separation applications are by far the most screened for application, either through adsorption-based or membrane-based separations. Materials are compiled first in databases; these databases are either based on experimental synthesis or hypothetical structures.

Screening and properties evaluations of efficient and large-scale databases can result in an essential relationship between structural and topological properties and performance under particular applications' conditions. As a result of efficient databases and tools to differentiate between materials, we can learn more about what strongly governs the performance, leading to better understanding and, thus, the design of modern materials. Various metrics have been developed throughout research to rank materials depending on the type of application. For instance, for the adsorption-based separation, top-performing materials are expected to have high loading of the desired component, high selectivity, and regeneration effectiveness. These properties are essential, but the material should perform exceptionally under conditions near practical operations. Photofixation of N_2 to produce ammonia is considered the most environmentally benign process. Screening for porous 3D structures for photofixation of N_2 was accomplished from hypothetical metal-organic frameworks (hMOFs) database and experimental-based dataset [3,4]. In this work, we investigate the 3D structures of COFs for the photocatalytic activity towards ammonia production from N_2. The study includes electronic properties calculations besides adsorption and structural properties.

MATERIALS AND METHODS

The experimental COFs database is used in this work, comprised of 449 COFs [5]. This screening aims to find 3D structures suitable for the N_2 fixation process. COFs in the dataset are divided into 2D and 3D structures. The most important parameters used in the study are the bandgap and band edges of the structures. Density functional theory (DFT) is used to determine the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO). Two different theories are used to compare and establish a potential correlation. Generalized gradient approximation (GGA) functional in PBE and hybrid functional HSE06 is used. The work uses the HSE06 as GGA functionals tend to underestimate the bandgap of semiconductors. The correlation between PBE and HSE06 bandgap could help reduce the required computational power to compute hybrid functional properties. In this work, the desired

band edges are conduction band higher than -1.26 eV and valence band lower than 1.23 eV vs. standard hydrogen electrode. Besides, adsorption properties are mainly calculated for the selected structure to assess and compare N_2 adsorption in these COFs. The higher the adsorption, the better since the process requires the adsorption of molecular N_2. It has to be mentioned that other photocatalytic properties such as charge separation and recombination could be of higher importance than molecular adsorption of reactant; however, this is still considered an indication of the process. N_2 is modeled using TraPPE force-field with tail correction 12.8 Å. Charges on the structures are calculated using the RASPA equilibration scheme.

RESULTS AND DISCUSSION

The screening is initiated by determining important structural properties for efficient structures. Two parameters are sought: the available surface area (ASA) and pore limiting diameter (PLD). A structure is selected if ASA>0 and PLD ensures the reactant and product can diffuse through the cages. Following that, the COFs are divided into 2D and 3D structures. In this work, initially, we focus on 3D COFs to be proposed for the photocatalysis application. A total of 44 COFs are porous 3D solids having the necessary PLD to facilitate the process. The number of 3D COFs is lower than 2D COFs due to difficulty finding organic units with multiple reactive sites. The 44 eligible structures have a wide range of surface area 280-8500 m^2/g and PLD between 4 and 25 Å.

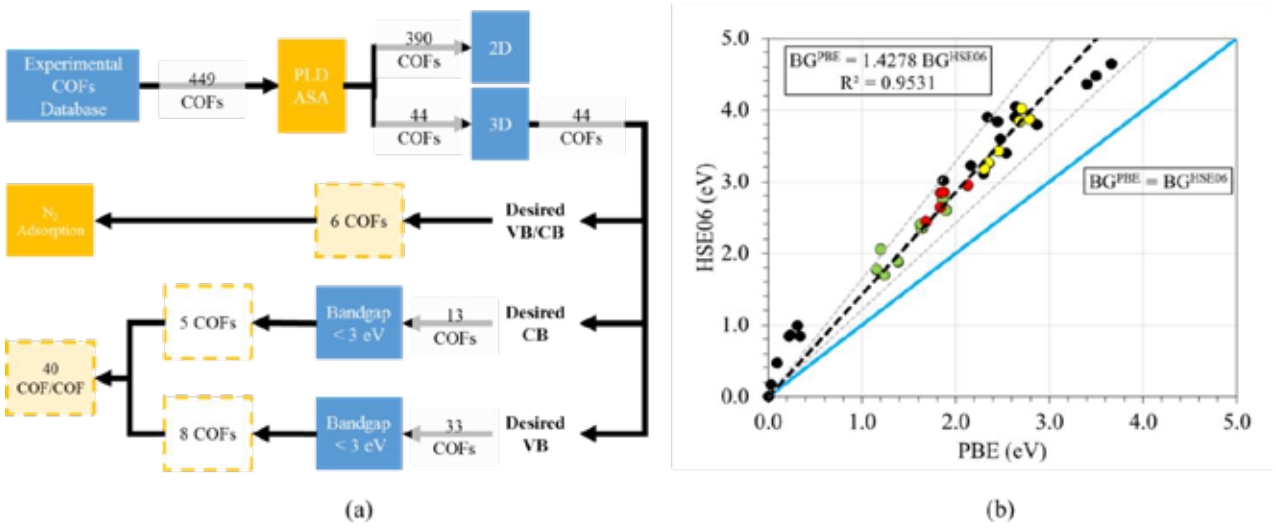

Figure 1. (a) Process flow used in this work starts from the database and ends with selecting desired COFs for photofixation of N_2 and COF/COF heterojunction. (b) Bandgaps of the studied list of COFs using PBE and HSE06 functionals. Yellow circles show the six structures selected for the sole photocatalytic process. Green and red circles are structures selected for heterojunction systems as semiconductors I and II, respectively.

Next, single-point DFT computations are performed on the 3D structures using PBE and HSE06 functionals. The results and comparison between the bandgaps are reported in Figure 2. The figure shows that the bandgaps obtained via the hybrid functional are higher than GGA based functional. A correlation is determined using a straight line with a coefficient of determination of 0.953. Out of the 44 COFs, only 6 had desirable conduction and valence bands (yellow circles in Figure 2). However, these 6 COFs have bandgaps between 3 and 4 eV. To investigate other COFs for the application, COF/COF heterojunctions are planned by combining COFs with desired conduction bands with COFs with a desirable valence band. Also, these COFs have to have a bandgap lower than 3 to increase light absorption in the visible light region. The results showed that 11 and 33 COFs had desired Condiction band and valence band, respectively. However, only 4 and 8 COFs have the set bandgap. This number of COFs makes it possible to manufacture a total of 32 different COF/COF junctions from a theoretical point of view. In order to differentiate between these combinations, a list of computations can be implemented. Additional computational work can follow, including charge separation and mobility, to assess the effectiveness of the junction.

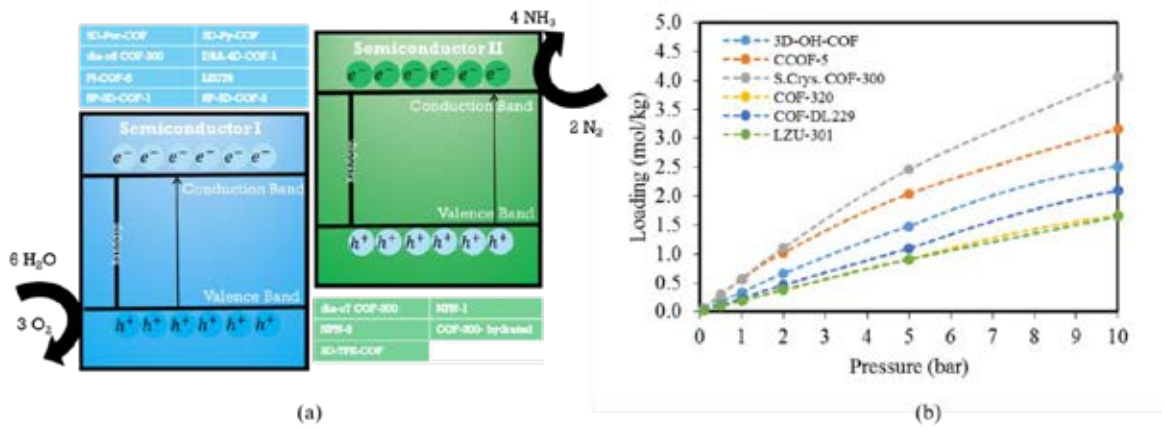

Figure 2. (a) COF/COF heterojunction towards ammonia production representation (b) N_2 adsorption isotherms for the six selected structures at 298K and pressure range of 0.1-10 bar. Dashed lines are used for visual aid.

In this work, following the DFT computations, we use GCMC simulation to compute the N_2 isotherms in the select 6 COFs. The adsorption isotherms are computed at several pressure points, 0.1, 0.5, 1, 2, 5, 10, and 50 bars, adsorption isotherms from 0.1-10 bars are shown in Figure 3. A comparison between the 6 COFs is made based on the N_2 loading at 1 bar. At a pressure of 1 bar and 298K, CCOF-5 and COF-300 have the highest adsorption of N_2 among the 6 COFs, with COF-300 having a slightly higher value. The adsorption at 50 bar is also reported to indicate N_2 saturation in the structure; COF-300 has the edge at the 50 bar pressure point. COF-300 has a higher surface area, three times the surface area of CCOF-5. Nevertheless, CCOF-5 has a lower bandgap (HSE06) than COF-300, which is desirable for the application ($BG^{COF\text{-}300}$=3.462 eV and $BG^{CCOF\text{-}5}$=3.183 eV).

CONCLUSION

COFs are materials with excellent properties desirable for various applications in gas separation, catalysis, and other functionalized applications. In this work, and for the first time, 3D COFs are screened for the efficient N_2 fixation process in a photocatalytic system. The screening uses several atomistic and molecular simulations techniques to determine the structural, adsorption, and electronic properties. Following some atomistic and molecular simulations steps, six different COFs are selected for the application using a pre-selected mechanism for N_2 fixation. These selected COFs were also tested for N_2 adsorption at a range of pressure points. Besides, a list of 3D COF/COF heterojunction materials was proposed that satisfies the required energy levels. At the same time, each has a bandgap of less than 3 to increase the light absorption ability of the composing structure. The work shed light on the possibility of screening COFs and other porous materials for catalytic applications. Also, the results showed an excellent correlation between bandgap obtained via relatively fast PBE functional and slower, more accurate functionals, which can be helpful to accelerate the determination of COFs for various electronic properties.

ABSTRACT

With the growing place taken by hydrogen, some questions still remain about its delivery, transport and storage. In these domains, one of the key challenges to compete is the great permeability of hydrogen through polymer and composite infrastructures (pipes, connecting parts, pressure vessels, …) compared to other gases such as methane for instance. In this context, the compatibility of hydrogen with polymeric components must be carefully qualified regarding permeation properties, blistering and collapse resistance. Long-time behaviour may be assessed with specific modelling. Beyond qualification aspects, this approach can be useful to support standards elaboration.

Keywords: Polymer, Composite, Permeation, Blistering, Hydrogen

INTRODUCTION

In the challenging context of the oil and gas industry, many studies have been carried out at IFPEN to understand, describe and model the permeability and the blistering of thermoplastic polymers and composites [1-3]. This background is a big advantage to deal with hydrogen interactions with polymers, since experimental equipment and numerical tools are available and can be adapted to the specific case of hydrogen.

SEVERAL MECHANISMS INDUCED BY DIFFUSION

The permeability of a polymer to a gas is defined as its property to absorb and transport the species in a molecular state, according to the gradient of chemical potential. Therefore, the permeability coefficient is the product of the solubility coefficient, describing the solute concentration in the polymer at steady-state and the diffusion coefficient, representing the solute mass transport inside the polymer.
When service conditions consist in cyclic fillings and pressurization, one of the main issues regarding polymers is the risk of blistering that can be caused by rapid gas decompression. Linked to the above-described permeation mechanism, after a given service time, a polymer matrix contains a certain amount of dissolved gas. Then, considering a low depressurization rate of the system, this amount of gas could have the time to escape from the material without causing any damage. But, if the decompression rate is high, the dissolved gas can even lead to the formation of bubbles inside the polymer. Therefore, the occurrence of blistering depends on many parameters such as gas and polymer natures, gas-polymer interactions, temperatures and pressures profiles during service and depressurization steps (Fig. 1).

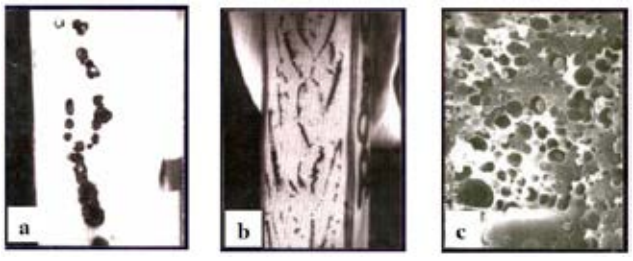

Fig. 1. Illustration of blistering obtained in various gas-polymer systems [4]
(a: PE/CH4 at low decompression rate – b: PE/CH4 at high decompression rate – c: PVDF/CO2 at high decompression rate).

In addition to blistering, another kind of damage due to gas diffusion might be observed in multi-layer systems, such as in type IV pressure vessels, in which a polymer liner is winded up with a fiber composite. During service, gas can be trapped at the interface between the liner and the composite layer. During high-rate decompression, the cumulated gas in the interface exposes the liner to a much larger external pressure in comparison with the internal pressure, thus causing the collapse of the liner.

EXPERIMENTAL APPROACH

For many years, IFPEN has developed specific devices to measure permeation coefficients and assess blistering resistance with the objective to represent, as closely as possible, the real operating conditions of polymers under various settings of pressure and temperature [1-5].
Several permeation devices make it possible to work with pure hydrogen or in mixture with methane. It has been used in previous projects when some preliminary solutions have been evaluated and assessed to cope with present problems for hydrogen gas distribution and to sustain higher pressures compared to classical high-density polyethylene pipe (Fig. 2).
For blistering consideration, we are currently working to make our devices compatible with high hydrogen pressure (typically 1000 bar).

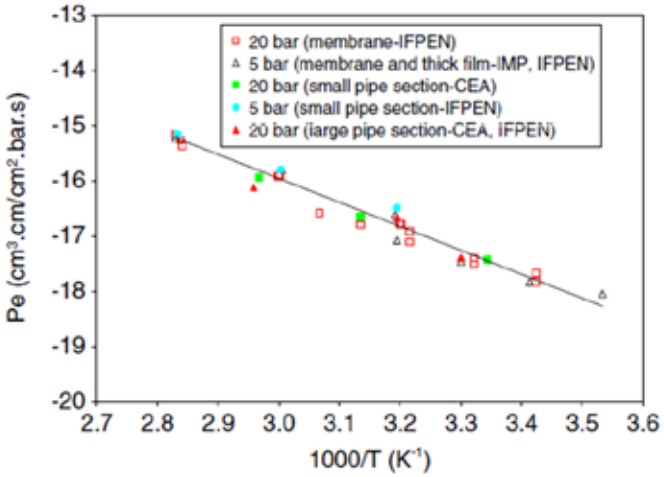

Fig. 2. Evolution of the permeability coefficient (Pe) with temperature (T) in an Arrhenius representation for pure H2 through HDPE at two different pressures, for various geometries and devices - polHYtube project [5]

NUMERICAL APPROACH

In parallel to experimental studies, IFPEN has also developed specific modelling for polymers and composites to simulate and predict long term behaviour. For instance, based on analytic laws [6,7], a specific finite elements model has been developed to evaluate the permeation properties of composites, based on the inner properties of the matrix and the fiber volume fraction. The repartition of the fibers fraction inside the composite and the presence of voids can also be considered as parameters that will impact the transport properties (Fig. 3.).
Dealing with blistering considerations, a coupling has been made between diffusion, mechanics and thermodynamics in order to describe as best as possible the behaviour of the species dissolved in the polymer, their interaction, and the impact on mechanical properties. For that purpose, a diffuso-elastoviscoplastic model for semicrystalline polymers has been developed using a porous media approach [8,9]. The material is represented by two phases: the crystalline phase (skeleton) and the mixture of dissolved gas and free amorphous (fluid). Damage is represented by plastic porosity (cavitation) within the amorphous phase due to a stress gradient induced by a gas concentration gradient during decompression (Fig. 4). The development of this kind of coupled model is still in progress and evolution.

CONCLUSION

IFPEN is in position to cope with the great challenge of the compatibility of polymers and composites with hydrogen. The oil & gas background in terms of permeation, blistering and collapse resistance are key advantages to be quickly relevant on these topics, both on experimental and numerical studies.

ABSTRACT

Elastomers are main components in hydrogen systems. It was reported that these materials could be damaged when submitted to hydrogen high-pressure, especially in case of fast depressurisation. In order to predict this phenomenon, we define a prediction model, and assess it by depressurised elastomer samples.

Keywords: type IV tanks, EPDM, cavitation, fast depressurization, tomography.

INTRODUCTION

Elastomeric materials subjected to gases at high-pressure can have issues during decompression [1]. For instance, a sudden decompression can promote the formation of cavities inside the material [2]. This phenomenon is known as cavitation. There is a body of scientific articles treating different aspects of it, indicating for instance that the damage initiation depends on saturation pressure, depressurisation rate, and material thickness, among other parameters [2]. In the present paper, we use a previously developed general approach by non-dimensional parameters to estimate the risk of cavitation [3]. We subjected EPDM samples to saturation pressure up to 18.5 MPa, followed by a fast depressurisation. Defects formation was confirmed by tomography. Experimental results are in accordance with numerical predictions. Present results suggest that we can use the non-dimensional approach as a guideline for the design of systems involving elastomers under high pressure, such as O-rings in type IV hydrogen containers.

MATERIALS AND METHODS

We studied an elastomer material frequently used to produce O-rings: EPDM 70. Materiel properties were defined in our laboratory using a MTS device (Platform Ametiste, FEMTO-ST). Considering a Neo-Hookean behaviour, we obtained a shear modulus μ=2 MPa. We measured diffusion with hydrogen: D=1.6E^{-10} m²/s. Both values correspond with literature. We made disk samples, obtained from extruded boards with a thickness of 10 mm. In order to favour hydrogen entrance and exit of the sample perpendicular to the geometrical flat surface, we fixed a minimal five-time ratio of samples (Ø > 5 thickness). Under this geometrical condition, we assume that at the centre of the samples border effects are negligible.

Sample handling under hydrogen pressure was attained in a stainless-steel pressure chamber designed to work at 40 MPa. Because of safety reasons, hydrogen handling was performed in a safety pit, with no temperature control: ambient temperature was 10 ± 5°C. Saturation pressure was 18.5 ± 0.5 MPa. We calculated the evolution of hydrogen concentration [4], to conclude that 48 h time was enough to saturate the samples under study. Then, a fast depressurisation was performed. Depressurisation rate was maximized in order to boost cavitation phenomenon, reaching ≈100 MPa/min.

To determine the creation of cavities inside EPDM, tomography analysis was performed on as-received and depressurised samples, with an EasyTom Nano tomography system (RX Solutions/Platform Mifhysto, FEMTO-ST) with a voxel resolution of ≈8 μm^3.

RESULTS AND DISCUSSION

Defects appearance

We saw the formation of a macroscopic defect or blister in one of the samples (Figure 1a). This blister appeared some hours after the depressurisation, and grew during the following days until it reached its maximum size and disappeared. Figure 1b shows a tomography cut view of the blister near its bigger size, at 50h after depressurisation. Figure 1c shows tomography images of the sample as received and 167 h after depressurization, a time when we consider that transient effects are irrelevant. Three depths are presented: surface level, 1 mm depth and 2 mm depth.

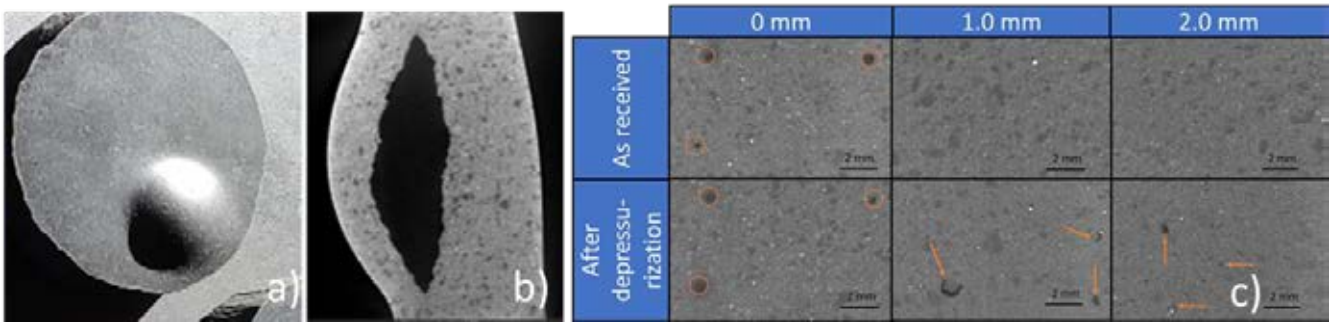

Figure 1: a) Blister appearance on the sample b) lateral tomography of blister c) tomography images before and after depressurisation.

The analysis of tomography images allows exploring the creation of defects inside EPDM samples. Particularly, in Figure 1c, it is possible to see cavities formation (orange arrows). These cavities appeared around higher density areas and charges, and seems to be more frequent as a function of depth. Blister and cavities appearance confirms material degradation through the creation of macroscopic and microscopic defects after exposure to hydrogen.

Degradation predictions model

We developed a numerical approach to address cavitation risk [3]. A spherical defect in which there is a pressure of P_{int}, is embedded in the material, submitted to an external pressure P_{ext}. We consider the sample fully saturated by hydrogen, and a geometry of plane sheet. Then a fast depressurization is applied on it, promoting cavitation as the pressure inside the defect will decrease slowly compared to external pressure. In order to analyse the influence of depressurization rate, Yersak et al. [5] defined a parameter called P_{pore}, which accounts the level of unbalance between P_{int} and P_{ext} ($P_{pore} = P_{int} - P_{ext}$). Comparison of P_{pore} and a defect propagation criterion, called P_y, allows to address cavitation risk.

The expression of internal pressure P_{pore}, depending on P_{ext}, x, t, and P_{int}. In case of a fully saturated sample, it is possible to derive equation (1), calculating P_{int}. Based on the work of Crank [4], this equation is valid for diffusion into a plane sheet of material and a depressurisation situation.

$$\frac{DP_{int}(t_{deso}-t_0)}{(P_{sat}-P_{min})l^2} = \frac{\mathrm{Dt}}{l^2} + \frac{1}{2}\left(\frac{x^2}{l^2} - 1\right) + \frac{16}{\pi^3}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3} exp\left\{\frac{-D(2n+1)^2\pi^2 t}{4l^2}\right\} cos\frac{(2n+1)\pi x}{2l} \quad (1)$$

D is the diffusion coefficient, *l* half-thickness of plate, the term $(P_{sat} - P_{min})/(t_{deso} - t_0)$ accounts depressurisation rate, *x* the position in the plate and *t* the time.

From several works [1, 6, 7], maximal pressure inside an elastomer pore must not excess 5*μ*/2, with *μ* the share modulus of Neo-Hookean model (eq. (2)). Otherwise, external works acting on material will overpass internal energy required to ensure the wholeness of the elastomer [8]. Then, there is risk of plasticization or breakage, the latter being expected elastomer behavior. We assume two reasonable assumptions: there is no heat generation and surface tension are negligible.

$$P_y = \frac{5\mu}{2} \quad (2)$$

Knowing P_{pore} and P_y (eq. (1) and (2)), to simplify our analysis, we moved forward to a non-dimensional approach. This way, we defined a parameter called non-dimensional cavitation (NDCav, eq. (3)), and two complementary M_y and T_{deso} parameters to address if a polymer is likely to cavitate (Eqs. (4) and (5)).

$$NDCav = \frac{P_{pore}}{P_y} \quad (3)$$

$$M_y = \left(\frac{P_{sat}-P_{min}}{P_y}\right) = \frac{\Delta P}{P_y} \quad (4)$$

$$T_{deso} = \frac{Dt_{deso}}{l^2} \quad (5)$$

NDCav lower than 1 implies no cavitation risk. Contrary, the higher the P_{pore} to P_y rate, the higher the risk of cavitation, as the expected pressure inside the pore overpass the mechanical capacity of the material. For further details, refer to [3]. Eq. (3), (4), (5) are still valid in any material situation. Figure 2 shows the numerical results of T_{deso} vs. M_y, for

different NDCav curves. The graph indicates the zone where cavitation is unlikely (NDCav < 1), and on the other corner the zone where cavitation is highly probable.

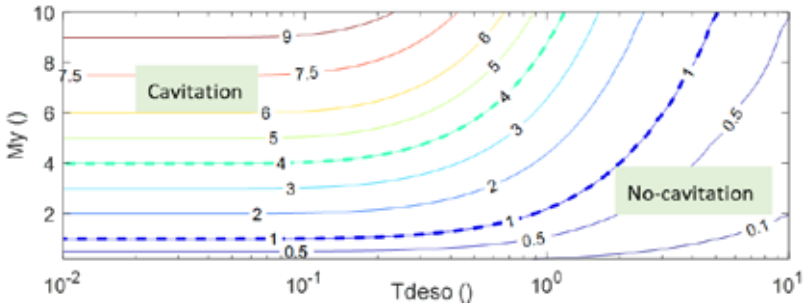

Figure 2: non-dimensional results for cavitation estimation, NDCav abacus.

Comparison between experiment and modelling

In order to compare experimental results with numerical prediction, we identified NDCav values corresponding to present experiments. Parameters retained are D=1.6E-10 m²/s; l=0.005 m; ΔP=185 bars; t_{deso}=10 s; μ=2 MPa. From eq. (4) et (5), we obtain: $M_y = 3.7$ and $T_{deso} = 6.4E-5$. From Fig. 2 we see that for present experimental configuration, $NDCav = 3.7 > 1$. As NDCav is higher than 1, degradations are likely to occur in our material.

Indeed, experiments have shown degradations of EPDM samples under fast depressurisation, increasing towards the centre of the sample. In terms of NDCav equations, the proximity of the surface can be interpreted as a lower l parameter, which implies a lesser cavitation risk. Full validation of NDCav abacus to elastomer materials requires further experimentation with other materials and experimental conditions, which is out of the scope of present work.

CONCLUSIONS

Degradations in elastomers exposed to high-pressure hydrogen is a relevant topic in hydrogen technologies, especially in the case of a fast depressurisation condition. We developed a model allowing to predict degradations due to hydrogen. This model was assessed by comparing its prediction with experimental results on EPDM samples after a sudden depressurisation. Cavities were highlighted with tomography technique, confirming model predictions by direct comparison of material before and after hydrogen exposure.

ABSTRACT

Chemical hydrides show promise in solving the storage challenge, which is one of the important problems in the widespread use of hydrogen. An important issue that needs to be developed regarding chemical hydride storage is the high speed of hydrogen release. For this reason, this study focuses on hydrogen release rates of alkaline sodium borohydride with different prepared catalysts. Different amounts of surfactant as Triton X-100 including CoB catalysts have been prepared and hydrogen release rates (HGR) have been compared. Results indicate that Triton addition has different effects, but optimum ratio improves catalyst performance. 150 µl Triton addition (CoB-T150) raises HGR from 12.61 $L_{H2}*g^{-1}_{cat}*min^{-1}$ to 17.69 $L_{H2}*g^{-1}_{cat}*min^{-1}$, as 40.2% increase compared to pure CoB catalyst. As a result, surfactants offer alternative to enhance catalyst performance and need further research.

Keywords: CoB catalyst, $NaBH_4$ hydrolysis, surfactant, Triton X-100, hydrogen storage.

INTRODUCTION

Cobalt is effective transition metal in regard of chemical hydride hydrolysis. Its abundancy, low cost [1] and relatively high hydrolysis performance [2] are significant advantageous but it still needs an improvement considering its tendency to agglomeration during exothermic hydrolysis reaction [3]. This agglomeration leads to a reduction of the area where the interaction takes place [4]. Various stabilizing agents are used in the literature for stabilization [5][6]. One of them is surfactant as “surface active agent”. It is effective on the crystal formation, determining shape of material [7] and thus it may be a solution in the research for a catalyst with high catalytic activity for the hydrolysis reaction. For this reason, this study investigates that different amount of Triton X-100 -as nonionic surfactant- usage during cobalt boride catalyst preparation and activation of prepared catalysts within NaOH stabilized sodium borohydride solution.

MATERIALS AND METHODS

In this section, details of catalyst preparation and hydrogen releasing processes have been summarized.

Catalyst Preparation

Pure CoB and surfactant as Triton X-100 added CoB-Triton catalysts have been prepared using chemical reduction method. First of all, cobalt(II) chloride hexahydrate (Merck) and ethanol were mixed in a volumetric flask and 0.02 mole solution was formed. Certain amounts of prepared solution and ethanol were mixed in a beaker. Triton X-100 was added by micropipette as microliter level. Last pH was regulated with benchtop pH meter (Orion Star A111) to 4 for all catalysts with HCl or NaOH addition. Then, pH regulated solutions were cooled down 6 ºC in the circulating water bath (Heidolph Rotachill) and reduction was carried out injecting sodium borohydride (Alfa Aesar)-distilled water solution with constant 5 ml/min flow ratio by syringe pump (Chemyx-Fusion 6000), during 500 rpm stirring conditions. Mud like black stack was separated and washed with one time ethanol and two-time distillated water to eliminate contamination. Afterthat, extracted catalyst particles were dried in oven (Nuve EV 018) at 110 ºC, under 75% vacuum at least 2 hours. The flocculated catalysts removed from the oven were crushed by pressing in a mortar. Table 1 represents abbreviations of catalysts, according to Triton amount.

Table 1. Abbreviations of prepared catalysts.

Amount of Triton X-100, µl	Abbreviation
0	CoB
25	CoB-T25
50	CoB-T50
100	CoB-T100
150	CoB-T150
200	CoB-T200
250	CoB-T250

Hydrogen Releasing Tests

Experimental studies of hydrogen releasing rate determination have been carried out in Yildiz Technical University, Faculty of Chemical and Metallurgical Engineering Laboratory. Figure 1 illustrates test stand. First of all, sodium borohydride (Alfa Aesar), sodium hydroxide pellets (Merck, 99-100%) and distilled water are mixed in a small beaker. Prepared fuel in beaker is placed in a water bath (JSRC-13C) adjusted to the 65 ºC temperature. 10 mg weighed catalyst with analytical balance (Radwag-AS 220.R2) and heated fuel is poured into volumetric flask and the flask is closed with flexible hose which connected to bubbler and gas burette. Released hydrogen gas from hydrolysis reaction passess from bubbler and replaces the water in the gas burette. During all reaction, circulating water bath keeps the temperature constant and magnetic stirrer ensures 500 rpm.

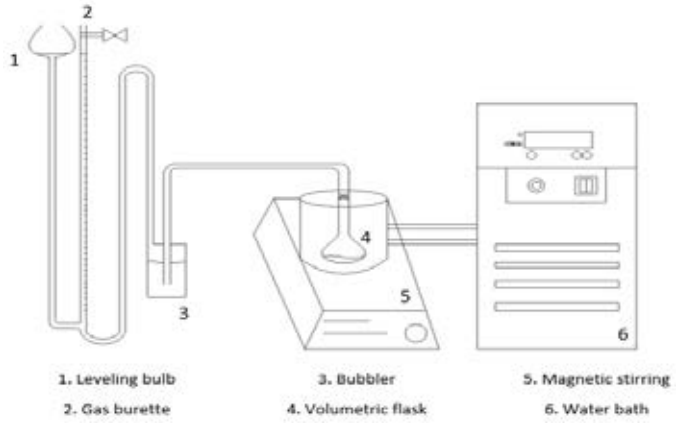

Fig. 1. Experimental setup of hydrogen release tests.

Total released hydrogen per gram catalyst and minute ($L*g^{-1}*min^{-1}$) is defined as hydrogen generation rate:

$$HGR = \frac{L_{H2}}{g_{cat}*min} \quad (1)$$

RESULTS AND DISCUSSION

In this section, performance of pure CoB and Triton added CoB catalysts were compared according to hydrogen release rates. Fig. 2 presents HGR results. It was observed that small amount (25 µl and 50 µl) of Triton addition reduces HGR and afterthat continuous increment raises HGR value until peak point as 150 µl. At this point, HGR rate is 17.69 $L_{H2}*g^{-1}_{cat}*min^{-1}$, 40.2% higher than pure CoB value. This may be attributed to anti-agglomeration effect of the surfactant [8]. Thus, raising surface area/mass ratio enhances catalytic activity. Moreover, decreased tension between fuel and catalyst may enhance wettability and result as higher interaction [9]. Also, Figure 3. represents emitted total hydrogen volume -against time- from 500 mg sodium borohydride, 500 mg NaOH and 10 ml distillated water solution, in the presence of 10 mg catalyst. It is clearly observed that Triton 150 releases maximum hydrogen volume in a short time, whereas Triton 50 releases less hydrogen with long time as parallel to HGR result. In addition to this, Triton 150 is obviously advantageous compared to pure CoB catalyst. Therefore, optimum amount of surfactant is 150 µl which indicates that further research like characterization and optimum conditions finding will be carried out with this catalyst.

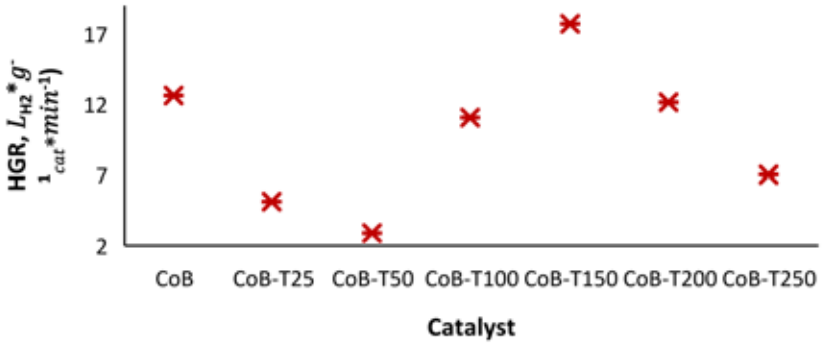

Fig. 2. HGR results of different catalysts.

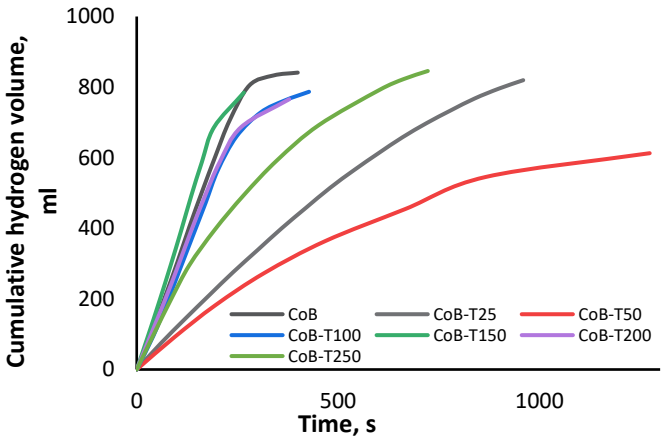

Figure 3. Released H_2 volume against time.

CONCLUSIONS

In this study, hydrolysis experiments of alkaline $NaBH_4$ in the presence of prepared CoB-Triton catalysts were carried out. According to HGR results, CoB-Triton 150 (150 µl Triton) is optimum catalyst that increases HGR as 40.2% compared to pure CoB. Our further research will be investigation of reaction temperature effect, optimum fuel concentration and SEM analysis.

ABSTRACT

Ammonia borane is a material with high hydrogen content, so it receives a lot of attention. Its handling and operating conditions are of great importance for technological applications. For this reason, in this work a study was carried out using high resolution Raman spectroscopy on the behavior of ammonium borane with four different heating ramps, in the first step of hydrogen release. With the data obtained, a principal component analysis (PCA) was made, in which the stability of AB in the release process can be noted. Stability is important in the release process, as it can be related to the formation of by-products.

Keywords: ammonia borane, Raman spectroscopy, principal analysis component, heating rates

INTRODUCTION

Ammonia borane (NH_3BH_3, AB) is one of the materials with high hydrogen content (19.6 wt. %), it was synthesized in 1955 [1], to which multiple studies have been carried out in the release process. Three steps of hydrogen release from AB by thermolysis are known. The temperature ranges in which this release occurs depend on the experimental conditions applied: the heating rate, pressure, purity, etc. [2]. AB releases about 1mol of H_2 in each release step and loses approximately 6.5 wt.% [3]. The first release step takes place between 100 and 130°C; at this point, mainly hydrogen and a few gaseous residues are released such as diborane (B_2H_6), borazine ($B_3N_3H_6$), and NH_2BH_2 [4, 5]. The second release step occurs between 130 and 200°C, in which a little more than one equivalent of H_2 is released per mole of AB, the main residue in this step is borazine; complex solid residues of type $[BNH_x]_n$ (with $x < 2$) is also formed [6]. And above 500°C, the last release step is observed, which is characterized by the residual loss of hydrogen and the formation of hexagonal boron nitride [7]. Five vibrational regions of borane ammonium are reported and defined: (i) a low-frequency region (100−500 cm^{-1}), which contains the lattice modes; a medium-low spectral region (500−900 cm^{-1}), containing the B-N stretching modes; (ii) an intermediate region (900−1300 cm^{-1}), which contains the BH_3 deformations; (iii) a medium-high spectral region (1300−1700 cm^{-1}), where the NH_3 deformations are observed; (iv) a high-frequency region (2200−2500 cm^{-1}), containing the B−H stretching modes; and (v) a very high-frequency region (3100−3400 cm^{-1}), containing the N−H stretching modes [8, 9]. In this work Raman spectra were obtaining in four regions: R1 (from 40 to 937 cm^{-1}), (from 966 to 1670 cm^{-1}), R3 (from 2180 to 2770 cm^{-1}) and R4 (from 3100 to 3400 cm^{-1}). The PCA was used to discriminate the Raman signals and show their differences, being registered in the main components (PCs), to which a statistical weight was associated.

MATERIALS AND METHODS

Ammonia borane, 97%, was purchased from Sigma-Aldrich and stored in a vacuum chamber. To carry out the analysis, a pellet of AB (16 mg) was prepared, subsequently it was heated in a THMS600 cell (Linkam Scientific Instruments), at a controlled temperature and with a precision of 0.01°C, to obtain Raman spectra as a function of temperature. The heating rates used were of 1, 2, 10 and 30°C/min. Raman spectra were obtained with backscatter geometry using a micro-Raman TriVista 557 spectrometer (Princeton Instrument) in a mono view configuration (1200 lines / mm grating and 700 mm optical path). The excitation line was 532 nm, double frequency of a Nd:YVO_4 laser and the instrument resolution was 1.9 cm^{-1}. Data acquisition of 10 s with an average of 15 times was used in all measurements.

For data analysis, a developed program in the MATLAB platform, based on the principal component analysis (princomp) was used. In this work, the PCA program used the covariance matrix in the four spectral regions. The changes between the shapes of the Raman spectra were recorded in the PCs with the highest percentage weight and plotted for their analysis.

RESULTS AND DISCUSSION

The Raman shift of spectra for the four heating rates in four regions is shown in Fig. 1; the bands that indicate the formation of species with NH_2 and $(BHNH)_n$ are observed. The hydrogen release temperature in the first step, for each heating rate, occurred in the range of 95-100°C.

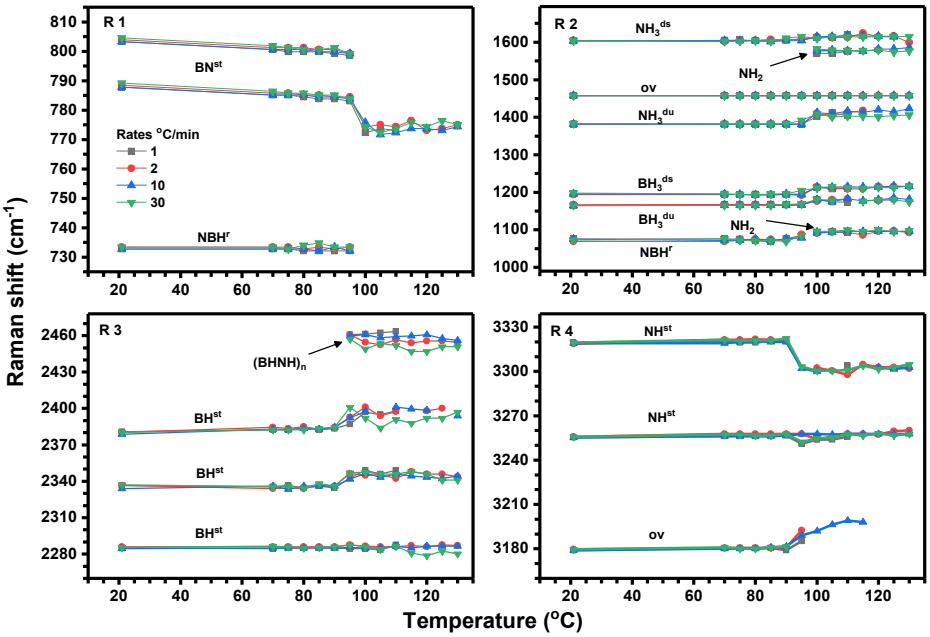

Figure 1. The shift of the AB bands, as a function of temperature, for the first release step, in the four AB spectral regions. The appearance of new bands for species with NH_2 and the formation of $(BHNH)_n$ are indicated with arrows.

In the spectra, a decrease in intensity is observed with increasing temperature; under these conditions, the material approaches the first step of hydrogen release. In region two, Fig 1, corresponding to the NH_3 modes, the appearance of two bands, located at 1576 and 1611 cm^{-1}, was observed after the first release step. With increasing temperature, the intensities of the bands changed; the intensity at 1611 cm^{-1} decreased and at 1576 cm^{-1} it increased.

The 1611 cm^{-1} band is the result of the 1604 cm^{-1} band shift. The 1604 cm^{-1} (NH_3ds) band is divided into two bands, 1576 cm^{-1} and 1090 cm^{-1} (which are also observed in the spectra for rates of 1, 2 and 10°C/min. These bands correspond to species with NH_2 and may correspond to polyaminoborane ((NH_2BH_2) PAB) formed at a temperature lower than 120°C [10, 11]. In region three, a new band also appeared after hydrogen release at 2460 cm^{-1}. This band is characteristic of stretching of the BH mode in polyiminoborane ((BHNH)n, PIB), formed at temperatures above 120ºC, which suggests the formation of this by-product [11]. These bands agree with what was observed by MJ Valero et al in Raman Spectra Obtained as a Function of Temperature [12].

According to the PCA analysis, PCA1 is related to intensities, which are associated with several molecules that provide the signal for each band. PCA2 is related to the position of bands (shift, disappearance, or appearance). In this sense, we can determine that in Fig 2 a dispersion of points (spectra) for a heating rate is associated with irregular intensity changes and shifting of the bands in a large interval of PCA 2. We can associate this with the instability of the AB when approaching the point of hydrogen release. According to Fig 2, when comparing the intervals of PCA 1 and 2, between the four heating rates, for the four regions, a large dispersion of points is observed for the rates 1, 2 and 10°C/min, and for the heating rate of 30°C/min, the points cover smaller intervals of PCA 1 and 2, for which it is considered that for this rate the release is under a more stable path and more directed to the release.

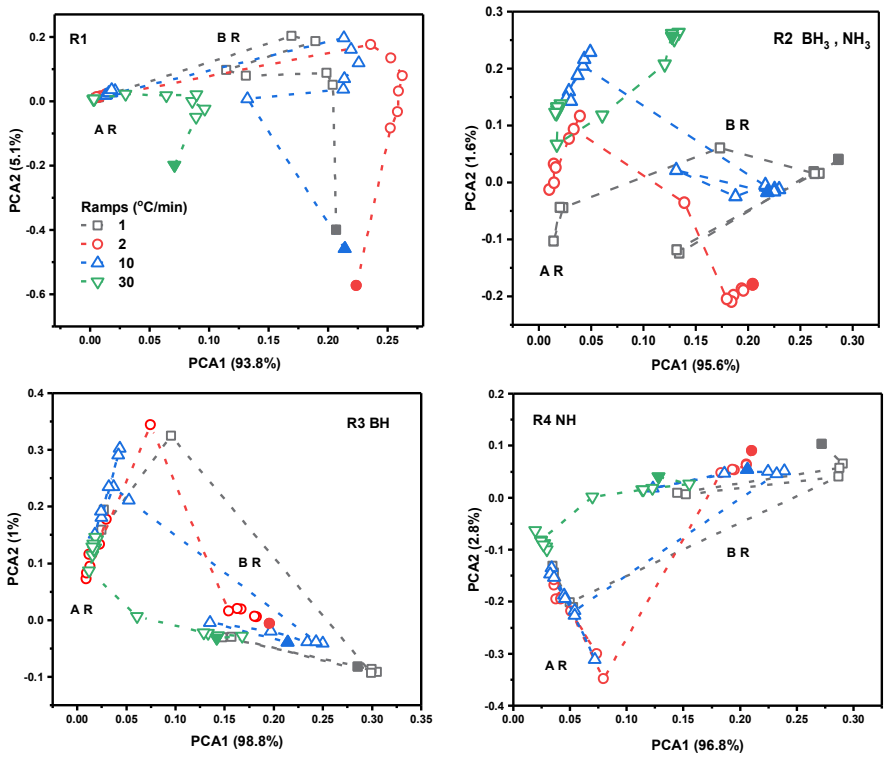

Figure 2. PCA analysis of different spectral regions of AB, in the first release step with different heating ramps. For each region, points within the dotted ellipse indicate spectra after release (AR) and the points outside (BR, before release) represent the Raman spectra obtained from room temperature (RT, full points) until the moment when the hydrogen release begins (95 °C).

CONCLUSIONS

The first release step took place between 95 and 100°C. It was observed that the formation of by-products was more evident in the spectra for the heating rates of 1, 2 and 10°C/min. PCA1 was associated with changes in intensity and PCA 2 with changes in bands. The release process for the heating rate of 30°C/min shows more stability. For this reason, a high heating rate was considered more convenient to improve the hydrogen release process.

ABSTRACT

Kawasaki Heavy Industries, Ltd. has established the Hydrogen Energy Supply Chain (HESC) which aims to introduce a large amount of liquid hydrogen (LH2) to Japan. LH2 will be produced from brown coal in Australia and then shipped to Japan with LH2 Carrier. After a long transportation, LH2 inside the tanks of the Carrier will be pressurized and saturated by heat leakage from outside. Therefore, reducing the pressure to 1 atmosphere will be required for the safe tank operation. However, decreasing pressure will cause flashing, which will cause an excess of the venting capacity or liquid leakage because of an increase of vent mass. Hence, the purpose of this research is to reveal the pressure reduction rate and liquid behaviour through experimental and numerical approaches. Pressure reduction experiments were conducted by using 30 m^3 tank whose around 80% volume was filled with saturated LH2. The experiments showed that the pressure undershoot occurred at the beginning, and then the pressure decreased based on the Clausius-Clapeyron equation. From numerical analysis by VOF based in-house CFD code, it was found that the pressure undershoot was caused by the boiling delay, and the tank pressure followed the saturation pressure after the liquid fully stirred.

Keywords: HESC, Liquid hydrogen, Large-scale liquid hydrogen tank, Flashing, Pressure undershoot

INTRODUCTION

The Japanese government established the Basic Hydrogen Strategy which aimed to realize hydrogen-based society [1]. In this strategy, the Hydrogen Energy Supply Chain (HESC) was one of the main projects to develop international hydrogen supply chain. As Fig.1 showed, liquid hydrogen would be produced in Australia and delivered to Japanese users [2]. This is the world's first project to transport a large amount of liquid hydrogen over a long distance, thus our research focused on the issues of this transportation, especially related to pressure reduction phenomenon. Considering the situation unloading LH2 at a Japanese terminal, the liquid inside the tanks will be fully saturated under the high pressure and filled up to 98% liquid level because of heat input during a long transportation. Although the tank pressure had to be decreased to 1 atmosphere for the safe tank operation, flashing or flash evaporation would occur when saturated liquid undergoes pressure drop as Fig.2 showed. This would lead to exceeding the venting capacity or a liquid leakage because of a large amount of the boiling gas. The flashing phenomenon, particularly inside large-scale tank, was not examined sufficiently, thus the purpose of our research was to examine the pressure reduction phenomenon of saturated liquid in terms of pressure reduction rate and liquid behaviour. Our previous study pointed out that the pressure reduction rate in the case of low liquid level and saturated liquid followed the Clausius-equation during depressurizing from the thermodynamic analysis [4]. However, it was clear that the ullage gas volume had a great impact on the pressure reduction rate, thus the case of the high liquid level and saturated liquid also had to be considered. In this paper, this high filling level case would be discussed.

Fig. 1. Overview of the Hydrogen Energy Supply Chain

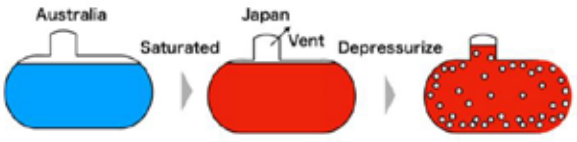

Fig. 2. Schematic of LH2 tanker operation

EXPERIMENT ON PRESSURE REDUCTION

The purpose of the experiment was to obtain the data of pressure reduction with high filling level and verify the results by using the thermodynamic model. 30 m^3 LH2 tank (Fig. 3) was used for this research. As Fig.4 showed, pressure gauge and 16 thermometers (named TIE-01~16 from top to bottom) were located inside LH2 tank, and LH2 pressurizing evaporator, thermometers, pressure gauges, and flowmeters were equipped on the vent line. To do the high liquid level and saturated liquid experiment by using only valve operation, the bubble vaporized by LH2 pressurizing evaporator was repeatedly introduced from the bottom of the tank by using the red line in Fig.4(a), and the large amount of liquid hydrogen was made saturated at 323 kPaG. After this procedure, GH2 vent valve was released, and tank pressure reduction started.

Results and discussion

The experimental results were shown in Fig. 5-7. As the time variation of pressure (Fig. 5) showed, the pressure under-shoot occurred around the beginning of the experiment, and then the pressure gradually decreased to 1 atmosphere. Figure 6 showed comparing the experimental result and the thermodynamic analysis we developed in previous research [4]. Since the both results matched well, it was found that the tank pressure obeyed the Clausius-Clapeyron equation during the pressure reduction experiment except pressure undershoot phase. Next, considering the pressure undershoot, this phenomenon was caused by the delay of the boiling. However, the question was that the thermometers' values inside liquid phase (TIE-05-16 in Fig. 7) always followed the fluctuation of the saturation temperature because of boiling. It was explained that many bubbles on the solid wall made easy to boil and the liquid around the wall boiled with decline of saturation temperature, on the other hand, the saturated bulk liquid was hard to boil and didn't boil with the pressure reduction. Consequently, this difference made the pressure undershoot. Moreover, the boiling difficulty of the bulk liquid led to the rise of the temperatures from 6 sec to 15 sec. After the pressure undershoot phase, it was clear that the whole liquid was uniformly stirred by the bubbles and boiled for keeping the thermal equilibrium state.

CFD ANALYSIS ON PRESSURE UNDERSHOOT

The CFD research with the VOF based in-house code (CIP based Level Set & MARS [5], [6]) was conducted for clarifying liquid behaviour during pressure undershoot. The CFD method employed TCUP (Temperature-based CIP-CUP) to solve hydrodynamic equations for free-surface flow and HLSM (Hybrid Level Set method and MARS) for the tracking of surface position on the fixed grid system. This numerical model could also deal with phase change phenomenon on sub-grid and grid scale [7].

Results and discussion

The time variation of pressure and the 2-D visualized results were shown in Fig.8. It was found that the pressure declined sharply, and the large amount of the boiling bubble emerged by overheating. After that, the pressure increased up to the saturation pressure and the liquid was stirred by the bubbles from the tank wall. Finally, the tank pressure declined following the Clausius-Clapeyron equation as we mentioned in the experimental analysis. The phenomenon was qualitatively understood, however, there remained problems with the quantitative analysis related to the boiling model.

CONCLUSIONS

1. The data of pressure reduction experiment in the case of high filling level with saturated liquid was obtained.
2. The pressure undershoots occurred at the beginning of the experiment, and then the tank pressure followed the Clausius-Clapeyron equation.
3. From CFD analysis, it was found that the pressure undershoot was caused by the delay of boiling. After the pressure undershoot, the tank pressure declined following the equilibrium state, because the boiled bubble stirred the liquid.

MACHINE LEARNING AS A TOOL FOR INTERPRETING VARIABLES IN HYDROGEN SORPTION DATA

ABSTRACT

To realize the hydrogen economy, it is important to develop methods of storing hydrogen that are cost-effective, safe, and compact. One method of storing hydrogen which shows a lot of potential is through physisorption on high surface area carbon. However, the scientific literature offers conflicting information on which properties of the carbons are important to hydrogen storage and to what extent. This is chiefly because each experimental study on carbon materials only analyzes results on an incredibly small subset of carbon materials. To remedy this, we conducted an integrative data analysis wherein we collected experimental data from many studies in the literature to construct a large dataset. We then used this dataset to develop a machine learning model which can predict the hydrogen adsorption isotherm at 77K based on the porosity and chemical composition of the carbon. By analyzing this model using a post-hoc explanation method called Shapley Additive Explanations, we can analyze the structure-property relationships clearly.

Keywords: Hydrogen storage, porous carbon, machine learning

INTRODUCTION

Hydrogen shows great potential as an energy carrier due to its large gravimetric energy density, and efficient utilization in fuel cells. However, one issue with hydrogen is it has a low volumetric energy density, i.e., it takes up a lot of space. To counter this issue, hydrogen is usually compressed to high pressures of up to 70 MPa, but that comes with its own set of problems such as energy losses during compression and stringent materials requirements due to hydrogen embrittlement of storage tanks at higher pressures. One way to get around this problem is by storing hydrogen through physisorption on a material with large surface area, which allows more hydrogen to be stored at lower pressures. This is because the weak van der Waals interaction between the surface of the material and the hydrogen molecules result in hydrogen being stored at a higher density near the surface. For this application, many different materials have been suggested, such as zeolites, metal organic frameworks (MOFs), and porous carbon materials. Porous carbon materials have the advantages of being relatively cheaper and being already scalable as it is a mature technology. For example, in our recent work we synthesized a carbon foam material which is able to store >10 wt% in total at 9.5 MPa and 77K, as well as >2 wt% at 9.5 MPa and 298K, which is competitive with MOFs and zeolites but requiring only very simple synthesis steps and common precursors such as ethanol [1].

However, porous carbon materials are relatively unpopular in the scientific literature due to our limited understanding of how the properties of the carbons affect adsorption. This issue is largely a limitation of the experimental design that we use in materials science. In each experimental study of porous carbon materials, we typically study a small group (5-10 samples at most) of carbon materials which are made using incredibly similar precursors and synthesis method. Although using this data to analyze the synthesis-structure or synthesis-property relationships for that particular synthesis method is possible, anything beyond that would be difficult. First, since the data is only limited to that one synthesis method, the generalizability of those conclusions to other carbon materials made with other methods is questionable. In addition, since we are considering only a very small number of samples in each study, any quantitative conclusions we make will be highly biased.

To solve this issue, we conducted an integrative data analysis. We collected studies from the scientific literature to construct a dataset containing the porosity and chemical composition of various carbon materials and their hydrogen adsorption isotherm at 77K. Then, we fitted and evaluated several different machine learning models. The best model was then explained using a method called Shapley Additive Explanations (SHAP), which allows us to visualize the relationships as well as interaction effects in the form of dependence plots [2].

METHODS

Data Collection

We collected data from 14 experimental studies in the literature which fulfill our search criteria. Our criteria for inclusion are:

- The study includes chemical composition analysis

- The study conducted hydrogen adsorption experiments at 77K
- The study measured nitrogen sorption at 77K and/or CO_2 sorption at 273K and used them to calculate the pore size distribution using Non-Local Density Functional Theory (NLDFT) up to the ultramicropore range (pore diameter < 0.7 nm) in addition to the Brunauer-Emmett-Teller (BET) specific surface area and pore volume

A majority of the studies do not include their data in tabular format, in which case we convert them from the graphs using a software called Plot Digitizer.

Model Fitting and Evaluation

We fitted five different predictive models which use the porosity and chemical composition as inputs to predict the hydrogen adsorption isotherm at 77K. Those models are: (1) least squares linear regression (LR); (2) support vector regressor with linear kernel (SVR(L)); (3) SVR with radial basis function kernel (SVR (RBF)); (4) extreme gradient boosted trees (XGBT, implemented using the XGBoost library); and (5) random forest (RF).

To evaluate their performance, we conducted 5-fold group cross validation. Here, 1\5 of the dataset is used as a validation set while the others are used as training, and the process is repeated five times. We used group cross validation with the sample names as a group identifier instead of completely randomizing it to ensure that the models have to predict a new isotherm from a completely unseen material rather than just interpolating the isotherm between pressure points for known materials.

Finally, after choosing the model with the best predictive performance, the model is refit with the entire dataset. Then, we use an algorithm developed by Lundberg et al. [2] to calculate Shapley values for each prediction. Shapley values are the measure of a contribution of a feature to the predicted value. Simply, they are the difference between expected prediction when the feature is included in the predictor vs when the feature is missing averaged over different orderings of feature inclusion in the model. We calculate the Shapley values for each prediction, and then plot them over all the predictions to visualize the overall trends in a dependence plot.

RESULTS AND DISCUSSION

From the cross-validation, we found that RF has the best out-of-sample predictive performance with an R^2 of 0.910. We then fitted it to the full dataset and explained it with SHAP (Fig. 1A). From this, we found that BET surface area is the most important carbon property in determining hydrogen uptake, although the strength of this relationship is not as strong as is implied by the empirical Chahine's rule. This is due to the fact that this model includes both pore volume and surface area, resulting in the attribution being split between them. We found that there was a correlation between oxygen content and uptake, which supports some suggestions from early experimental data [3]. The pore size distribution of the carbons also has some effect on uptake, with ultramicropore volume (pore diameter < 0.7 nm) contributing significantly more than micropore volume (pore diameter < 2 nm) alone (Fig. 1B). Although, this relationship is not nearly as strong as the effect of surface area and total pore volume on uptake and the effect of an improved pore size distribution is diminished at larger pressures. We also conducted some sensitivity analyses and found that the conclusions are generally robust to model selection and dataset size.

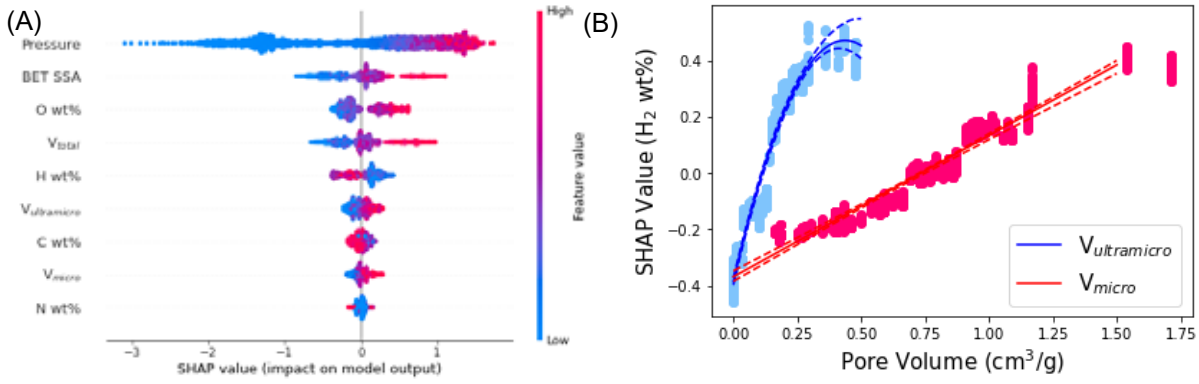

Fig. 1. (A) Plot showing relative importance of the different variables which predict hydrogen uptake and (B) plot showing that ultramicropore volume affects hydrogen uptake more strongly than micropore volume.

CONCLUSIONS

In summary, we have a developed a model which can predict the hydrogen sorption isotherm of various porous carbon materials based on their chemical composition and porosity parameters. We then used a post-hoc explanation method

to then understand and analyze the quantitative structure-property relationships governing hydrogen uptake on porous carbon materials, which led to some important insights on which variables are important to hydrogen uptake.

ABSTRACT

Hydrogen release units from Liquid Organic Hydrogen Carriers suffer from two main drawback: high energy demand at high temperature, and inefficient H_2 release due to the viscosity of both the hydrogen gas produced and the liquid carrier. In this work, we present the CFD-assisted design of a centrifugal dehydrogenation reactor for the H_2 release from perhydro-dibenzyl toluene. Our proposed technology allows to negligibly affect the required residence required for the slow dehydrogenation of perhydro dibenzyl toluene, while allowing an extensive degassing of the LOHC by a combination of applied shear stress and radial pressure drop in the reactor. Reactive simulations are underway, in addition to experimental validation of the degassing rates.

Keywords: Liquid Organic Hydrogen Carriers (LOHC), Reactor design, Centrifugal fields

INTRODUCTION

H_2 is a crucial energy carrier and critical chemicals to the chemical industry, but its storage is one of the current bottleneck for the H_2 economy due to its low density. State-of-the-art in H_2 storage is highly energy intensive: Liquified H_2 (i.e. LH_2, at -253 °C) can require as much as 36-45% of the H_2 energy content in actual plants (between 12 and 15 kWh kg^{-1} H2) [1], while compressed gas H_2 (CGH_2) at 350-700 bar up to 10-20% [2-4]. Fortunately, it is possible to store H_2 at milder process conditions, making use of the Liquid Organic Hydrogen Carrier (LOHC) concept: H_2 is reversibly stored at 30-50 bars and 150-300 °C via a catalytic exothermic reaction by saturating the double bonds of organic molecules. H_2 is then released on-demand at atmospheric pressure in an endothermic catalytic reaction occurring at 250-300 °C. LOHC represents an interesting compromise between a high storage of energy (up to 2.05 kWh/l [5]) and required energy (8.9 kWh/kg H_2, i.e. representing 27% of the LHV of the H_2 stored [6]).

The main impediment to the commercial deployment of LOHC is the heat requirements at high temperature for H_2 release. The dehydrogenation of LOHC is typically performed in packed bed reactors that are optimized for optimal heat input and product gas removal [7, 8]. To avoid perturbing the fluid flow and the required long residence time for dehydrogenation, a degassing volume is planned. However, due to the high viscosity of some LOHCs (e.g., ranging from 0.04 to 0.22 Pa*s for dibenzyl toluene (H0-DBT) and perhydro-dibenzyl toluene (H18-DBT), respectively), the H_2 bubbles produced during the dehydrogenation tend to stay in the bed in the interstices between the catalyst particles.

Considering the critical requirements for lower energy, we designed an electrified unit for the dehydrogenation of the H18-DBT (induction heating). In addition, in order to improve the removal of H_2 bubbles during dehydrogenation, we further intensified the unit by generating a swirling flow pattern of the LOHC via tangential injection. In this work, we present the results of the computational fluid dynamics (CFD) simulation that lead to the design of the continuous experimental setup including the 21 litres centrifugal reactor.

COMPUTATIONAL METHODS

Multiphase turbulent gas-liquid bubbly flows simulations were carried out following the Eulerian-Eulerian framework implemented in OpenFoam v8. Turbulence was accounted for using the k - Omega Shear Stress Transport model, i.e., a two equation model solving for the turbulence kinetic energy (k) and specific dissipation rate (ω), a blended model shifting to the well-known standard k – Epsilon model in free-stream regions. The reactor's geometry was drawn using Salome 9.7, and the CFD simulation domain was meshed with the OpenFOAM's native snappyHexMesh meshing tool. The reactor (now built and ready to be used to gather experimental data for validation) has two 25 mmID inlets positioned at the bottom of the reactor at a 10% angle with respect to the horizontal plane, a lower 0.150 mID diameter cylindrical section (0.150 m high), followed by an expansion zone, and a 0.300 mID diameter larger section (0.200 m high) where two outlets are positioned tangentially (Fig. 1 a).

As the development of the chemistry solver is still underway in our group for the heterogeneous catalytic reaction yielding H_2 and H_2-poor LOHC from a H_2-rich LOHC, we designed the current unit by generating 1 mm bubbles using a source term applied to the bottom part of the reactor. The thermophysical properties of perhydro dibenzyl toluene and hydrogen at 300 °C were used for the continuous and dispersed phase, respectively. Velocity fields and the residence time distribution were monitored using OpenFOAM native functions.

RESULTS AND DISCUSSION

The required long resistance time in packed bed dehydrogenation unit results in low LOHC superficial velocity, and a low flow axial pattern limiting the removal of the small H_2 bubbles generated at the surface of the catalyst particles. Our proposed configuration with tangential inlets creates a strong swirl and has the advantage of completely removing the bubbles from the bed without affecting the liquid residence time. We calculated the F-curve from a step change in tracer concentration using the scalar passive transport approach: the residence time for the liquid phase reduced only from 25 to 19 s (equivalent packed bed reactor volume and swirling unit, respectively). However, the striking difference with the conventional packed bed configuration is the combination of strong shear rates due to strong swirl of the liquid phase (Fig. 2 b) resulting in an annulus-type gas-phase distribution (Fig. 2 c).

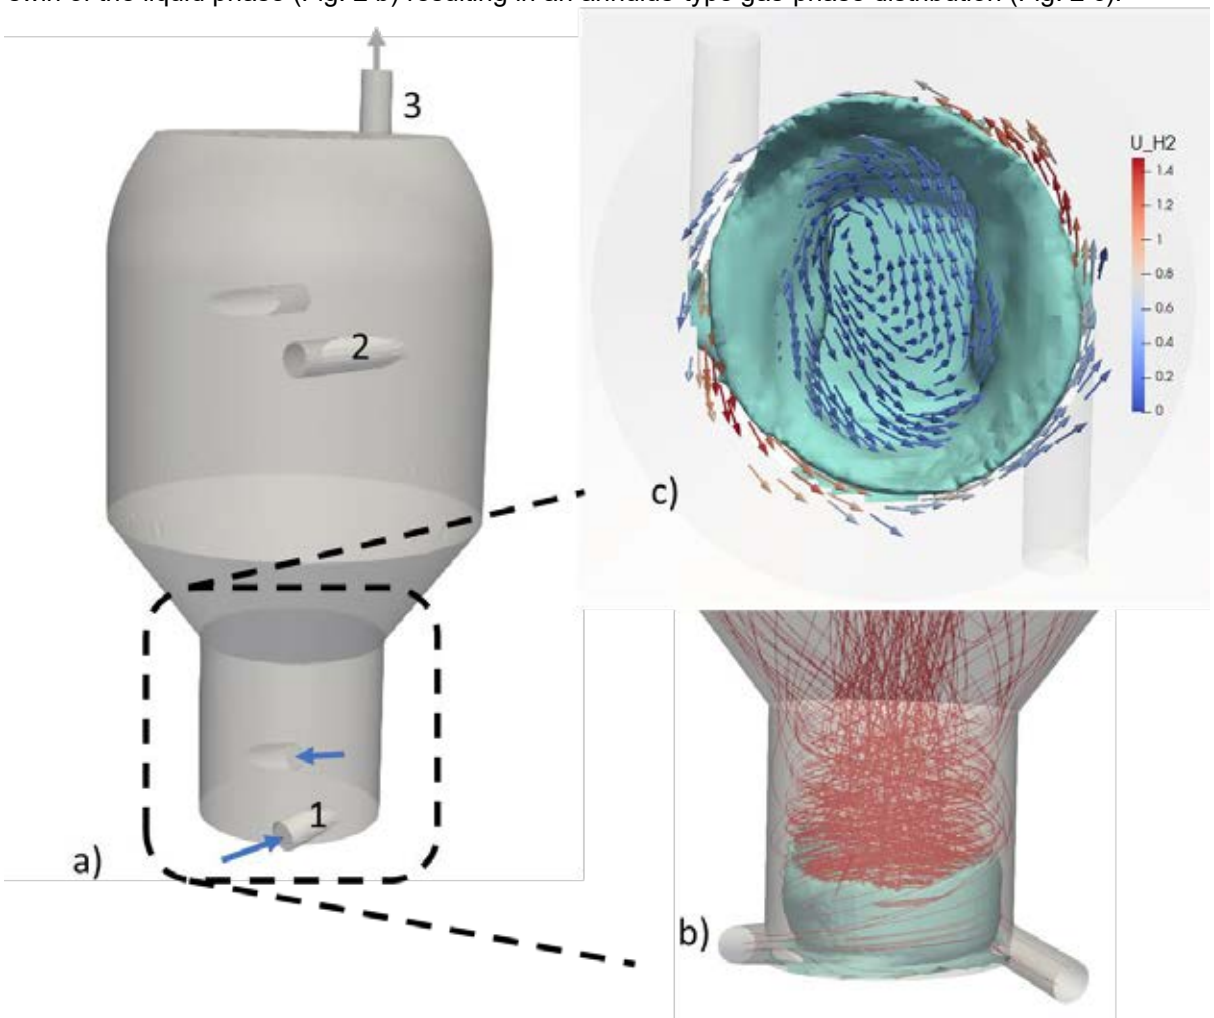

Fig. 1. Overview of the a) centrifugal 21 l dehydrogenation unit highlighting the (1) two LOHC inlets and (2) outlets, and (3) H_2 outlet; b) streamlines for the LOHC (red) and contour plot of the hydrogen generated during 0.5 s of reaction (light turquoise); and c) top view of the contour plot and vector field for the hydrogen generated.

Even though the liquid velocity can exceed 2.5 m/s in the vicinity of the circumferential wall near the bottom of the reactor, we expect the global conversion of perhydro dibenzyl toluene to be substantial due to the high number of turns that the liquid passes in the catalyst bed. Reactive simulations and experimental validations underway will allow to confirm this assumption. In addition, we can observe that most of the hydrogen produced in the packed bed is pushed towards the outer circumferential wall, thanks to the strong swirl and resulting shear stress enhancing degassing of the centre-part of the bed. The swirling motion of the LOHC also creates a 0.2 kPa pressure drop in the radial direction (lowest pressure in the centre of the bed), thus further contributing to the enhanced degassing of the

bed. Interestingly, as theoretically demonstrated by Tsori and Leibler [9], the sharp separation of miscible liquids is possible in a centrifuge as the rotation exceeds a critical threshold. If this is the case, our centrifugal unit would allow to circumvent another disadvantage of the state-of-the-art packed bed technology. Catalyst deactivation by the liquid products is a known issues in dehydrogenation of LOHC. The rotational flow could lead to perhydro dibenzyl toluene enriched regions towards the centre of the unit (the density of plain dibenzyl toluene being higher than that of perhydro dibenzyl toluene), in which case, by circumscribing the location of the catalyst towards the centre of the unit, our unit would allow selective contact between perhydro dibenzyl toluene and the catalyst.

CONCLUSIONS

The centrifugal dehydrogenation unit designed in our laboratory was numerically characterized for its hydrodynamic: we were able to show that despite a depreciable decrease in the required residence time for dehydrogenation reactions to take place, we are able to achieve a complete degassing of the bulk of the packed bed. Hydrogen bubbles generated during the dehydrogenation reaction are pushed towards the circumferential walls, thanks to the combination of strong shear stress and radial pressure drop contributing to enhanced degassing of the LOHC. This technology could circumvent thus both the degassing issues observed in state-of-the-art packed technology, as well as selective contact between the H2-rich LOHC and the catalyst particles. Experimental validation and reactive simulations underway will allow to confirm these observations.

ACKNOWLEDGEMENT

We thank the Industrial Research Fund (Industrieel Onderzoeksfonds, IOF) of the University of Antwerp, as well as the Port of Antwerp for the financial support for this project. We also sincerely thank Hydrogenious LOHC Technologies for supplying the dehydrogenation catalyst and perhydro-dibenzyl toluene which will be used for the experimental validation of the centrifugal dehydrogenation unit.

ABSTRACT

Low temperature waste heat (e.g., 100°C) can be utilized for hydrogen compression with hydride forming materials. In order to increase productivity and to decrease cycle time of a metal hydride-based hydrogen compressor, it is necessary to face heat transport limitations and to accelerate the overall rate of reaction. The compression cycle time can be significantly decreased by using metal hydride composite materials (MHC) with increased thermal conductivity. In this contribution, the use of composite materials is compared with conventional metal hydride (MH) materials with low thermal conductivity. A dual stage hydrogen compressor was built in laboratory scale and demonstrated with MH and innovative MHC. MHC increase the productivity of a MH compressor by up to 500%.

Keywords: *Hydrogen compression, Metal hydride, Metal hydride composite, thermo-chemical compression*

INTRODUCTION

Solid hydrogen carriers like metal hydrides can fulfill various applications for industrial hydrogen technologies such as storage, compression, purification, and isotope separation. Hydrides operate at moderate temperatures (25 °C to 300°C) and enable highest volumetric storage densities (100 g_{H2}/l) [1]. During exothermal hydrogen absorption, i.e., the formation of MH, heat of reaction is released. The technical reaction speed depends on the heat dissipation or heat supply for hydride decomposition. Rapid hydrogen absorption or release cannot be guaranteed in the event of heat accumulation. Thus, the low thermal conductivity of MH powders represents an obstacle to its applicability in fast-operating technical systems. However, the heat transport can be significantly increased by adding a second material with a high intrinsic thermal conductivity, such as graphite, aluminum, or copper, forming MHC [2,3].

MATERIALS AND METHODS

In this contribution, we report about a dual-stage MH compressor using MH or MHC to estimate the impact on productivity. For this purpose, a powdered AB_5 alloy (La-Ni based) and an AB_2 alloy (Ti-Mn-based, Hydralloy C5) were used with and without expanded natural graphite (ENG) and compacted between 50 and 300 MPa in inert gas atmosphere, respectively. The materials were filled into two double-walled pressure vessels and cycled between 20 and 100°C. The supply and release of hydrogen into the pressure vessels was realized using a lab-scale hydrogen compression test rig.

RESULTS AND DISCUSSION

For MH based compression systems hydrogen is absorbed at low temperature and released at higher temperature and thus higher pressure [4]. By using metal hydrides, low temperature waste heat (e.g. 100 °C) can be used to realize high purity hydrogen compression. In comparison to loose MH powder beds, the use of MHC with high thermal conductivity decreases the compression cycle time drastically. Thus, the productivity of the thermochemical compressor increases.
Figure 1 depicts manufactured MHC with high thermal conductivity (A), the double-walled pressure vessels for hydrogen compression (B) and the laboratory test rig for hydrogen compression (C). After integration of the materials into the pressure vessels and into test rig, the materials were activated and cycled individually (1.5 bar/20-40 bar, 20°C/50°C). The results were compared to pressure-composition-isotherms of the hydride forming materials to maximize the compression ratio. By using MHC with high thermal conductivity, the productivity of the individual stages of the compressor could be increased by up to 500 %. The two-stage compressor realized hydrogen compression

with simulated waste heat between 20°C and 100°C from 5 to 70 bar. In comparison to loose MH powder beds, the use of MHC with high thermal conductivity decreases the compression cycle time by up to a factor of 5.

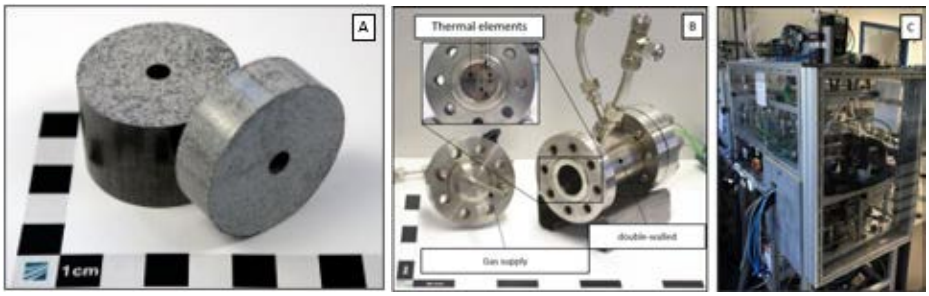

Figure 1: Metal hydride composites (MHC, A) were filled in a double-walled pressure vessel (B, [5]) to perform a thermo-chemical compression in a test rig (C).

CONCLUSION

Metal hydride forming materials can serve as innovative hydrogen compression materials. MHC have an increased thermal conductivity and can realize hydrogen absorption/desorption and temperature changes in a few minutes. By using MHC with highest thermal conductivity, the productivity of the two-stage compressor was increased by up to 500 % compared to loose MH powder beds.

REACTION PROCESS OF AMMONIA PRODUCTION FROM IRON NITRIDE AND CARBONATED WATER

*Hiromi Eba, Tian Liu, Keiichi Fukami
Faculty and Graduate School of Science and Engineering, Tokyo City University, Tamazutsumi 1-28-1, Setagaya, Tokyo, Japan

*Corresponding author e-mail: heba@tcu.ac.jp

ABSTRACT

The interstitial compounds, Fe_3N and Fe_4N, reacted with water to generate NH_3 and H_2. The reaction proceeded under normal temperature and pressure when carbon dioxide was added to the reaction system. The product ratio, NH_3/H_2, was larger than the value calculated from the reaction formula when iron nitride had reacted completely. The NH_3 formation proceeded easily because the activation energy calculated from the Arrhenius plot of temperature vs. reaction rate was lower for NH_3 formation than for H_2. As the reaction progressed, the lattice constant of iron nitride decreased, suggesting that N diffused between the lattices and moved to the surface to produce ammonia. Fe_3N, which has a crystal structure in which N readily diffuses between lattices, had a higher ammonia production rate than Fe_4N. Adding carbonate to the system accelerated the reaction. The elementary reaction involving carbonic acid was the rate-determining step: the reduction of H^+ in carbonic acid by reacting with Fe or removing Fe^{2+} from the reaction system by forming a soluble Fe^{2+} carbonate complex was the slowest reaction step.

Keywords: Ammonia production, Carbon dioxide, Carbonic acid, Iron and steel, Iron nitride

INTRODUCTION

Ammonia (NH_3) is an essential raw material for nitrogen fertilizers used in agriculture, and has been identified as a potential hydrogen carrier in recent years. However, NH_3 is mainly synthesized through the Haber–Bosch process, requiring high temperature and pressure. To reduce this environmental burden, it is necessary to achieve NH_3 synthesis under milder conditions. We have investigated NH_3 generation from iron nitride (Fe_3N and Fe_4N) and carbonated water at ambient temperatures and pressures [1]. In this study, the activation energies and amounts of NH_3 and H_2 produced were determined and compared.

MATERIALS AND METHODS

Iron nitride (Fe_3N or Fe_4N) powders and a small amount of carbonated water were sealed in a bottle under 101.3 kPa CO_2. The bottle was stirred at a constant temperature between 298 and 328 K. The gas-phase H_2 and CO_2 and liquid-phase NH_3 were quantified by gas chromatography every 30 min. After the reaction, the bottle contents were dried, and qualitative and quantitative analyses were performed using X-ray diffraction (XRD). Additionally, an Na_2CO_3 aqueous solution was prepared and used instead of carbonated water, repeating the same measurements.

RESULTS AND DISCUSSION

NH_3 and H_2 generation

Fig. 1 shows the changes in the amounts of H_2 and NH_3 with time at each temperature. For both NH_3 and H_2, the production rate and final production amount increased as the reaction temperature increased. The ratio of NH_3 produced to H_2 was always higher than that of NH_3/H_2 described in Eq. (1). In Eq. (1), 1 mol of Fe_4N produces 1 mol of NH_3, and 4 mol of Fe in Fe_4N provides eight electrons. Hence, 5 mol of H was expected to be produced in addition to 1 mol of NH_3, i.e., 2.5 mol of H_2 would be produced. We presumed that N escaped from the lattice of Fe_4N, an interstitial compound, and reacted preferentially with H on the Fe_4N surface.

$$Fe_4N + 4H_2O + 4CO_2 \rightarrow 4FeCO_3 + NH_3 + 2.5H_2 \quad (1)$$

Confirming the reaction progress by XRD

The XRD measurements of the solid phase after the reaction revealed unreacted Fe_4N and $FeCO_3$ production. The amount of substance of each crystal phase was quantified from the XRD pattern by the powder pattern fitting method. Consequently, the amount of Fe_4N consumed and the amount of $FeCO_3$ produced were determined. Theoretically, consuming 1 mol of Fe corresponds to producing 2 mol of H ($Fe + 2H^+ \rightarrow Fe^{2+} + 2H$). The amount of Fe_4N consumed, as determined from XRD analysis, corresponded well with the amounts of NH_3 and H_2 produced. On the other hand,

regarding the amount of substance of N, the amount of NH_3 produced was higher than the amount of Fe_4N consumed. The higher amount NH_3 can be explained by assuming that N escaped from the lattice of Fe_4N by interstitial diffusion to generate NH_3, as described above. The lattice constant of Fe_4N decreased slightly as the reaction progressed, suggesting N escaped.

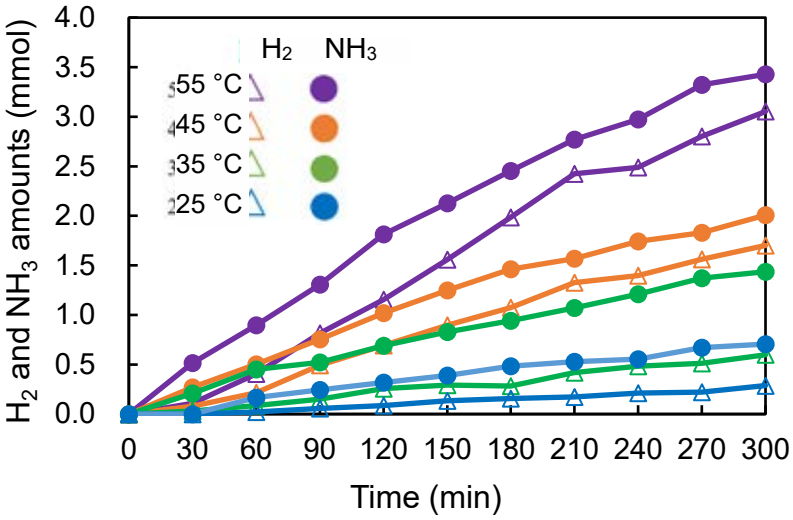

Fig. 1. Changes in the amounts of NH_3 and H_2 with time in the reaction between Fe_4N and carbonated water.

Activation energy estimation

The activation energies, ΔE_a, calculated using the Arrhenius plot of the reaction rate constants obtained at different temperatures were 27 and 50 kJ/mol for NH_3 and H_2 formation, respectively. A small ΔE_a value indicated that NH_3 production was advantageous.

Comparison of NH_3 production activity of Fe_3N and Fe_4N

Fe_3N showed a higher reaction rate for NH_3 production than Fe_4N did because of differences in their crystal structures. As shown in Fig. 2, Fe_3N is based on the hexagonal close-packed structure of ε-Fe, in which N regularly occupies one-third of its octahedral sites. In contrast, in Fe_4N, N regularly occupies a quarter of the octahedral sites of the face-centered cubic lattice (γ-Fe, austenite phase) of Fe. In this structure, Fe occupies both the Ca and O sites of the perovskite-type structure ($CaTiO_3$), and N occupies the Ti site. In Fe_4N, the Fe octahedra share edges; therefore, N must move via a small tetrahedral site. However, in Fe_3N, N can move between octahedral sites through faces and easily move and diffuse between lattices because Fe octahedra share faces.

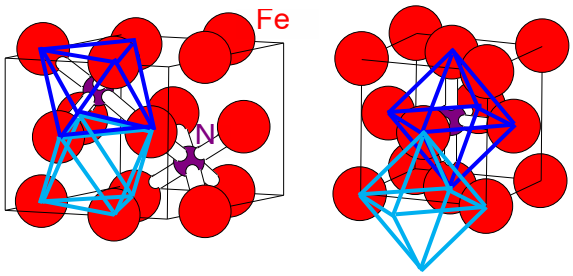

Fig. 2. The crystal structure of Fe_3N (left) and Fe_4N (right) and the connection of Fe octahedra.

Addition of water-soluble carbonate

Adding Na_2CO_3 increased the NH_3 formation rate and total NH_3 amount. Adding carbonate increased both the pH and HCO_3^- concentration, improving the rate of the redox reaction involving HCO_3^- and the formation of the Fe^{2+} carbonato complex. Therefore, one of these processes was expected to be the rate-determining step.

CONCLUSIONS

Experiments on generating NH_3 by reacting iron nitride and carbonated water were conducted, and the following results were obtained.

- The NH_3/H_2 ratio was higher than that produced when Fe_4N reacted completely. Because the lattice constant of Fe_4N in the solid phase decreased as the reaction proceeded, it was understood that N atoms diffused between the iron nitride lattices, moved to the surface, and combined with the H atoms. The activation energy of the formation reaction was smaller in NH_3 than in H_2, and the generation of NH_3 was more advantageous.
- Fe_3N was superior to Fe_4N in terms of the rate and amount of NH_3 produced. The crystal structure in which N diffuses easily is advantageous for NH_3 formation.
- Adding alkali metal carbonates to the reaction increased both the rate and amount of NH_3 produced. While N in iron nitride was ready to combine with H immediately, one of the elementary reactions involving carbonic acid was the rate-determining step. Carbonic acid was thought to be involved in decomposing water to provide H for N and removal of Fe ions from the iron nitride surface by carbonato complex ion formation after the reaction.

EFFECT OF IRON PARTICLE SHAPE AND ALLOY COMPOSITION ON HYDROGEN PRODUCTION EFFICIENCY IN THE WATER-IRON REACTION

*Hayao Yagi, *Hiromi Eba*

ABSTRACT

The relationship between the properties and reactivity of iron particles was investigated to develop a hydrogen production process from scrap iron using carbonated water. To evaluate the effect of alloy composition, Ni was selected from the range of alloy elements commonly present in steel that constitute scrap iron. A Ni salt was added to pure iron powder, stirred in an organic solvent, and dried. Subsequently, the redox reaction using the iron powder for hydrogen generation from water was analyzed. The final amount of hydrogen produced increased, which suggested that Ni may have penetrated the iron crystals. The hydrogen production efficiencies of pure iron powder and alloyed steel powders from the manufacturer were also compared. Ni partially alloyed steel powder (SIGMALOY2010) generated more hydrogen than pure iron powder of the same particle size. Moreover, a clear correlation between the particle size and hydrogen production was observed for SIGMALOY2010; the smaller the particle size, the higher the hydrogen production, which suggested that the reaction rate corresponds to the specific surface area. However, for other alloyed steel, no clear correlation exists with particle size. It was found that shape, porosity, and specific surface area also need to be analyzed and discussed.

Keywords: Hydrogen generation, Carbon dioxide, Iron and steel, Scrap iron, Ni alloyed steel

INTRODUCTION

The demand for clean and sustainable hydrogen energy is expected to increase in the near future as the utilization of fuel cells increases. Furthermore, because the amount of scrap iron generated is increasing in Japan, we focused on hydrogen gas (H_2) production through the reaction of Fe metal obtained from scrap iron with carbon dioxide (CO_2) in Eq. (1). Carbon dioxide is used to accelerate the reaction, and can simultaneously be immobilized in the form of a carbonate.

$$Fe + H_2O + CO_2 \rightarrow FeCO_3 + H_2,\ \Delta H(298K) = -69\ kJ/mol \quad (1)$$

In this study, Ni was selected from various alloy elements commonly present in steel that constitute scrap iron, and the effect of Ni addition to pure iron on hydrogen production was evaluated. The obtained results were compared with the effects of pure iron and alloy steel powders.

MATERIALS AND METHODS

Ni addition to pure iron powder

First, 0.9 g of $Ni(NO_3)_2{\cdot}6H_2O$ (99.9%) was dissolved in 15 mL of acetone (99%) in a bottle, to which 3.0 g of pure iron powder (99.9%, particle size 3–5 μm) was added. Subsequently, the mixture was stirred at room temperature at 2000 rpm (rotations per minutes) for 4 d using a constant-temperature shaker. The mixture was then placed into a vacuum dryer and dried at 80°C for 5 h. Excess $Ni(NO_3)_2$ was removed by adding 15 mL of acetone, and the resultant solid-liquid mixture was separated using a centrifuge at 5000 rpm for 15 min. The recovered solid phase was designated as Sample A. The Fe powder was recovered by stirring in acetone under the same conditions, without $Ni(NO_3)_2{\cdot}6H_2O$, and was designated as Sample B.

Evaluation of hydrogen production reaction

Reagent pure iron powder and samples A and B were used as reactants. Pure iron powders (KB-90, K-100T, 303A-60) and alloy steel powders (SIGMALOY2010, 4100V, 20CRV, 30CRV) manufactured by JFE Steel Corporation were also used as reactants. Table 1 lists the compositions of seven JFE steel samples. The JFE steel samples were screened using sieves to classify particles with sizes of <45 μm, 45–106 μm, and 106–180 μm. Each sample (2.0g) was sealed in a 295-mL bottle and filled with 101.3 kPa CO_2. Carbonated water (5mL), prepared by bubbling 101.3 kPa of CO_2 until equilibrium was reached, was added to the sample, and the mixture was stirred in a constant-temperature shaker at 50°C and 2000 rpm. The gas phase in the bottle was analyzed by gas chromatography at regular intervals after the reaction initiated, and changes in H_2 and CO_2 concentrations over time were analyzed.

Table 1 Composition of iron and steel manufacturing powders

Types	Designation	Chemical composition
Pure iron powder	KB-90	87.0% ≤ M.Fe
	K-100T	90.0% ≤ M.Fe
	303A-60	99.0% ≤ T.Fe
Alloyed steel powder	SIGMALOY2010	Fe – 2%Ni – 1%Mo
	4100V	Fe – 1%Cr – 0.8%Mn – 0.3%Mo
	20CRV	Fe – 2%Cr – 0.8%Mn– 0.2%Mo – 0.2%S
	30CRV	Fe – 3%Cr – 0.3%Mo – 0.3%V

RESULTS AND DISCUSSION

Evaluation of Ni-doped Samples

Fig.1 shows the time variation of H_2 concentration when pure iron powder and samples A and B were used as reactants. The H_2 concentration of the pure iron powder after 300 min was approximately 50%, whereas those of samples A and B were approximately 80% and 60%, respectively. Ni is known to be an austenite-forming element in stainless steel; hence, Ni addition probably altered the atomic arrangement of Fe and enhanced its reactivity. Meanwhile, NO_3^- anions may have remained in Sample A and coordinate with Fe^{2+} ions that are generated by the redox reaction with carbonated water to form soluble complex ions. When $FeCO_3$ generated by the reaction precipitates on the surface of raw iron particles, the reaction is inhibited; however, the precipitation can be suppressed by solubilizing Fe^{2+}, and the surface reaction of iron particles can continue.

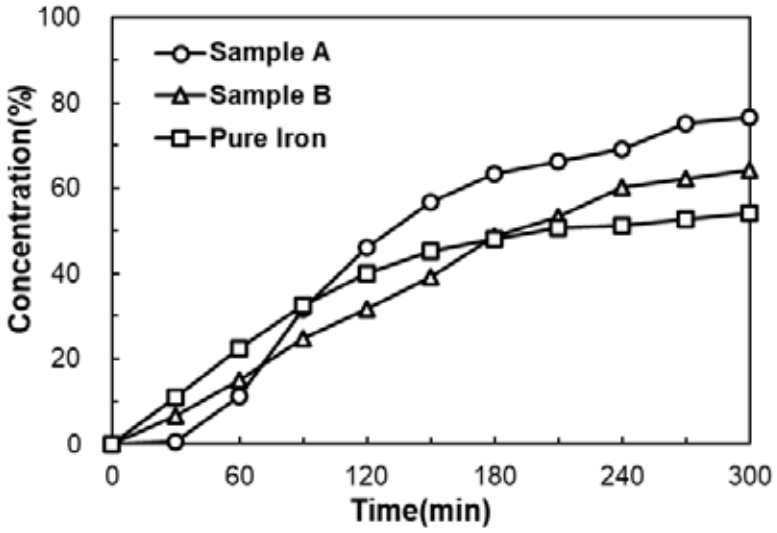

Fig.1 Time variation of H_2 concentration generated by Ni-doped iron

Evaluation of Hydrogen Production Reaction using JFE Steel Samples

Fig.2 shows the H_2 concentration of the JFE steel samples after 300 min of reaction. The H_2 concentrations of KB-90 and K-100T, which are reduced iron powders, were higher than those of 303A-60, which is an atomized iron powder. This is proposed to be because the former samples are porous, whereas the latter sample has spherical particle shape with a smaller specific surface area and relatively lower reaction rate. The H_2 concentration of the alloyed steel powders were higher than that of pure iron powder 303A-60, which is possibly owing to the change in particle shape during alloy treatment that may have increased the specific surface area. Generally, the smaller the particle size, the higher the reactivity and specific surface area. It is also possible that fine particles may become more reactive as they are dispersed during the reaction. The trend was particularly clear in SIGMALOY2010

containing Ni; however, the overall trend remains unclear. When particles aggregate into clusters and form larger particles, the specific surface area is large, even if the aggregated particle size is large, and the reactivity is high.

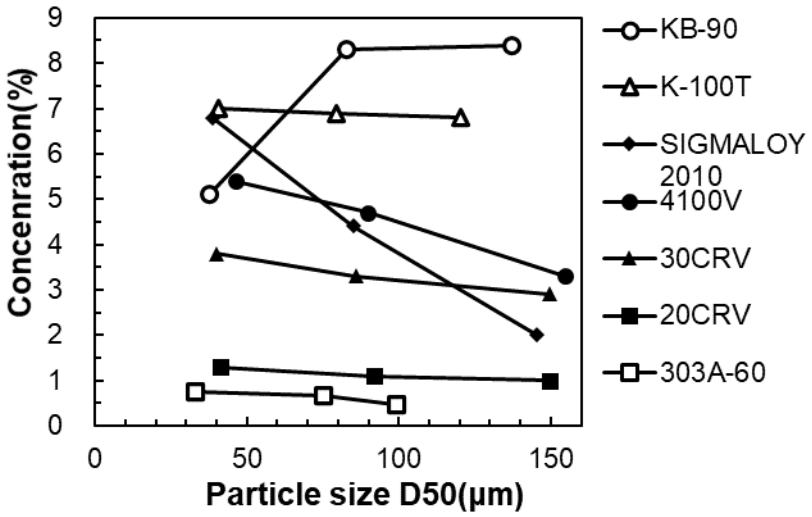

Fig.2 Concentrations of H_2 produced from iron and steel manufacturing powders after 300 min

CONCLUSIONS

The addition of $Ni(NO_3)_2$ to the pure iron powder resulted in higher hydrogen production. The Ni-containing steel powder SIGMALOY 2010 produced more hydrogen than pure iron powder, and a clear correlation between particle size and hydrogen production was observed. However, for other steel powders, it is necessary to confirm and discuss not only the particle size but also the shape, porosity, and specific surface area. In the future, the complex ion-forming ability of NO_3^- and the solubility of $FeCO_3$ will be evaluated to elucidate the effect of counterions. The conditions for improving the reactivity may be investigated by measuring the specific surface area and evaluating other properties.

ABSTRACT

This study analyzes the viability of a metal hydride–phase change material (MH-PCM) onboard storage system. Additionally, the effect of natural convection and thermal enhancements on the absorption time and gravimetric capacity are studied. To this study's knowledge, no studies have been performed on MH-PCM configurations while including natural convection. No significant attempts to include thermal enhancements were neither found in the literature. The results show that natural convection plays a significant role during the melting of PCM and absorption of hydrogen by the MH. The addition of natural convection causes a reduction of 68.9% in absorption time. Introducing thermal enhancements to the MH-PCM tank, the absorption is reduced by 92.4% while seeing a decrease of the gravimetric capacity of 30.42% compared to the case not including thermal enhancements. Performance indicators are gathered by having a defined car and the currently defined storage subjected to different driving cycles. From comparing these performance indicators with the targets set by the Department of Energy, it is concluded that an MH-PCM onboard storage system is not viable. The cause is contributed to the PCM mass required to store the released heat during absorption.

Keywords: Hydrogen storage, Metal hydride, Phase change material, Heat transfer, Thermal management

INTRODUCTION

New challenges are revealed as the energy sector must move towards sustainable energy. These challenges include transforming fossil-based fuels into green alternatives such as green electricity and hydrogen (H_2) for the automotive industry. Metal hydrides (MHs) are a potential storage medium of H_2 for automotive applications. During the absorption of H_2 by the metal, heat is released as this said reaction is exothermic. In an ideal case, the heat required for the desorption of H_2 is equal to that of the heat released during absorption. Therefore, multiple researchers have proposed to combine the MH with phase change material (PCM). The downside of an MH-PCM configuration is the poor heat transfer capability, thus resulting in high absorption times. Multiple studies have already discussed the application of an MH-PCM tank and numerically simulated such a system [1]. However, these papers did not include natural convection (NC) and applied barely any thermal enhancements (TE). Therefore, this study first focuses on numerically implementing these subjects into a numerical model describing the thermal behavior of an MH-PCM configuration to study the effect of NC and TE on the AT and GC. Second, this study performs a sensitivity analysis to determine the influence of a selected group of parameters on the AT and GC. Third, this study determines the viability of an MH-PCM configuration as an onboard storage system. Last, this study also answers whether simultaneously achieving an AT and GC of 5 minutes and 4.5 wt.% is possible.

METHODOLOGY

Different designs are formulated to determine the NC and TE effect on the AT and GC, and their thermal behavior is numerically solved in COMSOL Multiphysics. A few selected designs are mentioned. The first design is denoted as BD and is based on the findings of Alqahtani et al. [1]. The second design is proposed to manipulate the PCM flow beneficially to lower the AT. This design, denoted as 4C, sees the addition of fins within the PCM, extending outwards from the origin. The final two designs include a PCM-foam composite where the foam has a porosity of 85%. This design also includes fins. These designs are denoted by F-fins and F85, respectively. Schematics of these designs are displayed in Figure 1.

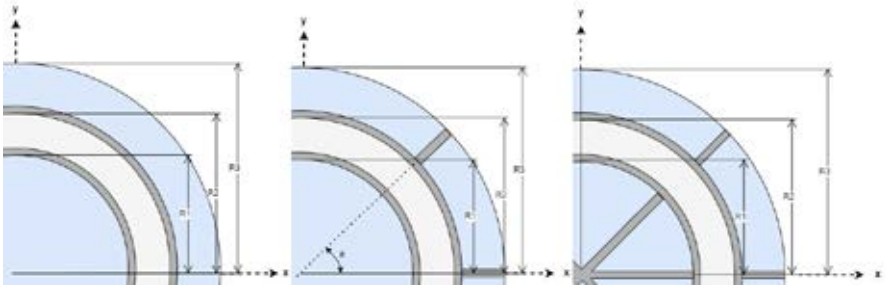

Figure 1. Schematic overview of the BD and F85 (left), 4C (middle) and F-fins (right). The PCM, MH-bed and wall or fins are represented by blue, white and grey respectively.

The following simplistic design is proposed to check the viability of an MH-PCM onboard storage system, as presented in Figure 2. The storage system in this design includes an MH-PCM tank, expansion valve, heat exchanger (HE), and heater. The decision is to rely on the pressure difference between the MH-PCM tank and fuel cell to deliver the required H_2 mass. Performance indicators are collected to check the current MH-PCM onboard storage system's viability. This is done by having a defined automobile go through selected driving cycles. This gives a required power profile from which a required H_2 can be obtained. This required H_2 profile is then applied to the storage system, from which then performance indicator values are collected. Comparing the obtained performance indicators with the targets set by the DOE and other hydrogen onboard storage systems, the viability of an MH-PCM onboard storage system is checked.

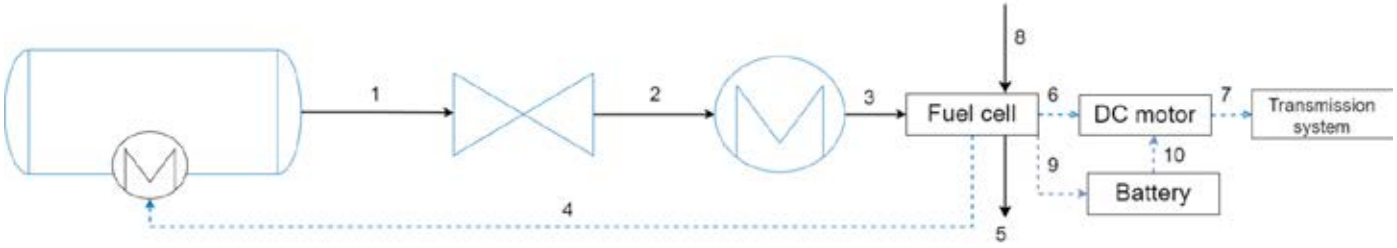

Figure 2. Schematic overview of a simplistic MH-PCM storage system.

MH selection

The MH that is selected for this study is based on $LaNi_5$. However, for this study, $LaNi_5$ is altered. The GC of this MH is increased to 10 wt.%, which makes this MH non-existent. A non-existing MH is selected to be still able to reach the set target of 4.5 wt.% by the DOE. Due to this alteration, the saturation density of the MH also changes to 7960 kg/m^3.

Validation of the numerical model

The developed numerical model is validated with experimental results. The equations governing the behavior of the MH-bed are validated with experimental results from Jemni et al. [2]. The equations describing the PCM are validated with experimental results from Jones et al. [3]. The governing equations regarding a PCM-foam application are validated with the experimental results from Zhao et al. [4]. All numerical results show a good agreement with the experimental data.

RESULTS AND DISCUSSION

This section presents the thermal behavior of the different proposed designs. This is followed by an analysis of the viability of MH-PCM configuration as an onboard storage system.

Designs and Sensitivity analysis

Figure 1 shows the temperature and velocity profile of the BD during the absorption process. Within the melted PCM, NC sets in. Hot fluidized PCM moves upwards, forming a thermal bottleneck that significantly slows down the absorption of H_2 in the upper section of the MH-bed. However, due to the transport of hot PCM away from the lower half of the cylinder, the absorption of H_2 is accelerated within that area. Table 1 shows the AT and GC of designs mentioned within this short paper. The lowest AT is obtained by conduction only in the BD (Cond) case and is significantly slower in case NC is included. This shows that NC is an important aspect when simulating MH-PCM configurations and can thus not be neglected. The 4C case shows a decrease in AT of 25% while seeing a decrease in the GC no higher than 2%. The fastest AT is observed by F-fins, which can be expected as the effective thermal conductivity of the PCM-foam composite is significantly increased. The results show that adding fins that block the flow of liquid PCM effectively decreases the AT while having a very low decrease in the GC.

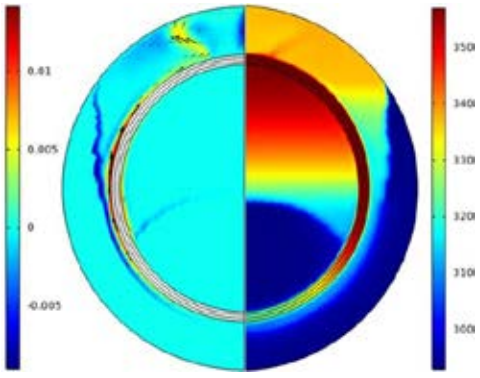

Figure 3. The temperature profile in Kelvin and velocity profile in m/s of the BD at 840 seconds after the start of the absorption process.

Sensitivity analysis

During the sensitivity analysis, the latent heat, pressure of the H_2, thermal conductivity, standard enthalpy of formation, and stored H_2 mass. To quickly summarize, the effects of these parameters diminish or grow stronger as the MH-PCM tank's size increases or decreases. An interesting result is an increase in AT when the latent heat increases. This is unsatisfactory as selecting a PCM with a higher latent heat would result in a higher AT and GC.

Table 1. Absorption times and gravimetric capacities of the mentioned designs.

	Absorption time (s)	**Gravimetric capacity (wt.%)**
Cond	12650	0.996
BD	3940	0.996
4C	2920	0.982
F85	460	0.705
F-fins	300	0.693

Storage system performances

The performances are compared in Table 2 with the targets set by the DOE. The term “opt” represents the case where all the H_2 is extracted, whereas the others represent cases where not all the H_2 can be extracted due to limitations of the system. The cases that end with an “S” represent constant velocity cases where the number in front dictates the velocity in km/h. The FUDC and WLTC represent cases developed by organizations and/or countries to determine, for example, emissions from the engine of a car. It can be seen that all values are significantly lower than the target values. Due to the highly required PCM mass, the currently defined MH-PCM configuration is not viable as an onboard storage system to store the exothermic heat. However, the ranges the car can travel do look promising. If the weight of the PCM could be reduced, the viability of an MH-PCM onboard storage system would increase.

CONCLUSIONS

The influence of natural convection (NC) and thermal enhancements (TE) on the absorption time (AT) and gravimetric capacity (GC) are studied. It can be concluded that NC has a significant and satisfactory impact on the AT of a metal hydride-phase change material (MH-PCM) configuration and should be considered when simulating such a case. TE reduces the AT even further, where the combination of separating the PCM into chambers and imbed them in foam showed the lowest AT among the different designs. The sensitivity analysis showed that if the latent heat increases, it decreases the GC but increases the AT for the range in which it was varied. A simplistic storage system is proposed from which performance indicators are gathered by applying different driving cycles to the defined vehicle. From the retrieved data, it can be concluded that an MH-PCM storage system is not a viable option for an onboard application. The main drawback of such a system is the weight of the required PCM, which is too high.

Table 2. Values of the targets set by the DOE and the values of the performance indicators retrieved after applying a certain driving cycle.

ABSTRACT

Boron-hydrogen (B-H) materials are used as hydrogen and heat sources, due to their reducing potential. It has been shown again with the COVID-19 pandemic that greenhouse gas activities are anthropogenic in origin. In particular, the conversion of carbon dioxide (CO_2) into valuable chemicals has an important place in the fight against the climate crisis. The conversion of anthropogenic CO_2 into valuable chemicals has important implications for a habitable world. In many studies in the literature, boron hydrides have been used to produce, hydrogen and convert carbon dioxide into valuable chemicals. Formic acid and methanol obtained by hydrogenation can be seen as the clean energy movement of the future with its value in hydrogen storage. The type of valuable chemicals that will be formed by the hydrogenation of CO_2 is directly related to the method to be followed. The type of catalyst used, or how much hydrogen molecule interacts with CO_2, determines the valuable chemical that will form. Disturbances in the thermodynamics of the hydrogenation of CO_2 have been tried to be eliminated by various types of catalysts and necessary condition optimizations. Many catalysts and methods developed for the hydrogenation of CO_2 were examined. This study discusses the use of B-H materials via catalytic conversion of CO_2 into valuable chemicals in terms of critical factors such as reaction conditions, selection of catalyst, and solvent.

Keywords: Hydrogenation, Decarbonization, Borane-Hydrogen Materials, Carbon dioxide reduction

INTRODUCTION

The existence of human beings on earth and their increasing demands appear as CO_2 and global warming in nature. One of the important steps taken for a clean and livable world is the European Union's goal of transitioning to a carbon-free economy by 2050, within the scope of the "Green Deal". To keep global warming below 2°C, which is also the target of the Paris Agreement, many sectors have become obligated to make investments to reduce environmental impact based on their product portfolio [1]. Despite the political measures taken by the countries, the inability to reduce the amount of CO_2 in industrial flue gases necessitated the implementation of carbon capture technologies. One of the most practical solutions in the face of increasing global warming data is to see CO_2 in nature as a source and to carry out studies for this purpose. The main goal is to see harmful and waste CO_2 as a production potential. It is a field of work that has important effects on many industrial organizations that have determined environmentally friendly, innovative, and sustainable working principles at home and abroad. This aim means that research in this area will create a direct supply on the industrial platforms.

CO_2 HYDROGENATION STRATEGIES

Chemical boron hydrides produce hydrogen by hydrolysis in the aqueous medium. Hydrogen is a high-energy substance that can be used as a reagent for the conversion of CO_2. As a result of the hydrogenation of CO_2, fuels such as methane (CH_4), hydrocarbons with high added value, and chemicals such as methanol (CH_3OH), formic acid (HCOOH), CH_4, and carboxylic acids (-COOH) are formed. The species that may occur after hydrogenation are shown in Fig.1 in the cycle. In the CBH cycle in the figure, the commercially important $MB(OR)_4$ product is obtained after hydrogenation. It is predicted that the approach of detecting the $MB(OR)_4$ structured product and converting the CO_2 retained in the structure into a valuable chemical as a result of its hydrolysis, can enable a single CO_2 source to turn into two different valuable chemicals.

There are many studies examining the production and structural properties of catalysts used to increase hydrogenation efficiency. Studies in which biomass is added to HCOOH by using hydrolysis, wet and catalytic oxidation, and CO_2 is reduced to COOH by various methods have been investigated in the literature. In addition, research has been carried out in which an artificial photosynthesis mechanism is considered with the photoelectrochemical conversion of CO_2 [2]. In studies examining the hydrogenation mechanism, it has been reported that the CO_2 hydrogenation efficiency is in the range of %40-50 [3].

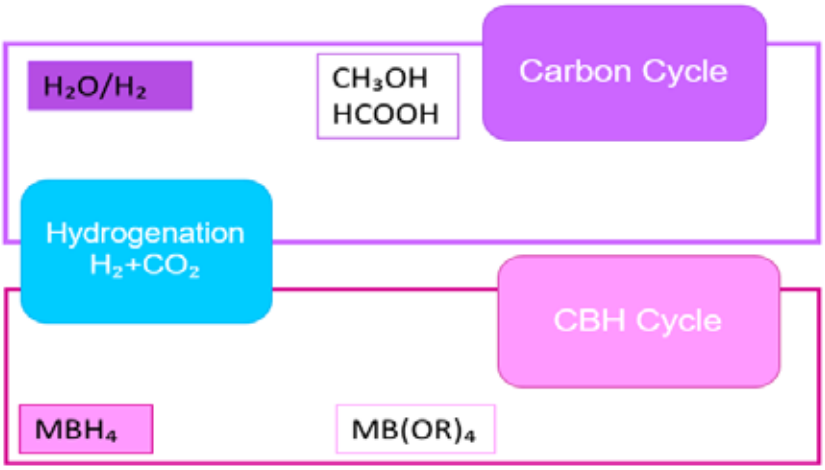

Figure 1 B-H compounds and carbon cycle

B-H materials have been investigated for the production of HCOOH and CH_3OH by the hydrogenation of CO_2 gas. Researches in this field aim to convert the pollution source CO_2 into valuable chemicals via CO_2 hydrogenation. In general, the interaction of sodium borohydride ($NaBH_4$) with CO_2 is directly dependent on the reaction conditions. Studies on the use of various B compounds for the hydrogenation of pure CO_2 have focused on B-containing metal hydrides and organic compounds [4, 5]. As a result of the reaction of B-H compounds with water, the molecular hydrogen (H_2) in its structure becomes free and the borate compound is formed as a by-product. With the presence of CO_2 in the reaction medium, H_2 released from the B-H compound during the reaction interacts with the CO_2, forming HCOOH, and CH_3OH according to the H/C stoichiometry. As seen in Figure 2, the CO_2 is reduced by H_2 to the released one from the B-H materials.

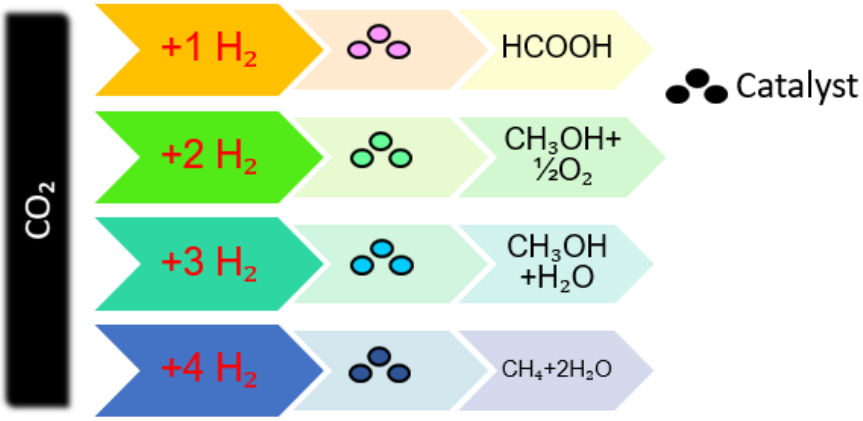

Figure 2 Synthesis of valuable products via catalytic CO_2 hydrogenation

CONCLUSION

In the literature, they investigated the reduction of the CO_2 they produced under in-situ conditions with $NaBH_4$ using $(NH_4)_2CO_3$ as a CO_2 source and determined that the compound formed as a result of the reaction carried out under microwave conditions was sodium formate [6]. In another study, $NaBH_4$ was used as a hydrogen source, and they determined that they produce formic acid when pure CO_2 and bicarbonate are used as a CO_2 source [7]. In studies on the use of $NaBH_4$, one of the B-H compounds, $Na[HB(OCHO)_3]$ and $Na[H_2B(OCHO)_2]$ were obtained as a result of the reaction of $NaBH_4$ with CO_2 in an acetonitrile environment [8].

In the studies in the literature, solvents such as water, ethanol (C_2H_5OH), and acetonitrile (CH_3CN) were used, as well as in solvent-free conditions. In a study on the conversion of CO_2 with a borohydride in solvent-free conditions, formate and alkoxide-like compounds are formed as a result of the rapid reaction between porous γ-$Mg(BH_4)_2$ and CO_2 under 30°C and 1 bar conditions [9]. In a study, HCOOH was obtained with a 24% yield as a result of the reaction of aqueous potassium borohydride (KBH_4) solution with CO_2 under ambient conditions [10]. In addition to this, in another research, potassium formylhydroborates $K[H_xB(OCHO)_{4-x}]$ (x =1-3) was synthesized as the main product as a result of the reaction between KBH_4 and CO_2 under mechanochemical and thermal conditions [11]. As a result, it

has been stated that the reaction conditions should be optimized and studies should be continued for this purpose to realize the conversion of CO_2 into valuable organic chemicals with the use of complex hydrides with high selectivity and sustainability.

ABSTRACT

Achieving net-zero emissions in the atmosphere is one of the most critical challenges faced by society. Thus, the research efforts should be intended to develop and implement new green sources to substitute the traditional fossil fuels avoiding carbon dioxide emissions. Among others, hydrogen energy is positioned as promising renewable energy but still requires overcoming the disadvantages of storage. In this context, ensuring a safe process employing reasonable volumes and pressures is one of the hotspots which are needed to address. Sodium borohydrides with significant advantages such as low vapor pressure, stability, or high hydrogen storage capacity have been largely studied in the last years. Catalysts and the different operating conditions are well known in this field. This work intends to demonstrate the benefits of the employment of additives to improve process control in terms of yield. Specifically, sodium carboxymethyl cellulose additive in 1 wt %, provides performance of 85 %, concluding that although further efforts are required, this approach could improve the hydrolysis of borohydrides for hydrogen storage.

Keywords: hydrogen storage, sodium borohydrides, additives, hydrogen generation rate.

INTRODUCTION

One of the key aspects that must be addressed to mitigate climate change is carrying out innovative renewable sources of energy which can compete with conventional sources based on fossil fuels. Nevertheless, the most currently developed green energies, solar and wind have major drawbacks such as low performance or their intermittent character. In this context, hydrogen-based energy presents itself as a promising alternative. However, this type of H_2 energy technologies still have some limitations that need to be approached, especially regarding storage for onboard applications [1]. At present, traditional systems are based on i) gaseous form, which, in addition to working at 273 K, requires the use of high pressures or ii) in liquid form, which, although works at ambient conditions of pressure, demands cryogenic temperatures, below 25 K [2]. The US Department of Energy (DOE) recommends searching for new systems capable of achieving high storage capacity targets, high regeneration capacities, and lower costs [3]. In this framework, hydrogen storage in solid materials could constitute a step forward in developing this energy source. Concretely, the chemical hydride sodium borohydride (NaBH4) has been widely studied in the last years due to its inherent advantages, i) stability under inert conditions and wide range of temperature, ii) low work pressures, iii) high purity, iv) high hydrogen storage capacity (10.8 wt. %), v) exothermic reaction (ΔH= -210 kJ·mol-1), vi) capacity of simultaneous generation and storage, vii) H_2 released can be directly fed to a PEM fuel cell to generate electric energy and viii) is a non-toxic compound [4–6]. Moreover, its main limitations, the hydrogen release rate and the stabilization of the kinetics, can be overcome by using enhanced catalysts and additives, respectively [7]. In this regard, additives are introduced to optimize the $NaBH_4$ hydrolysis because of, apart from the stabilization, the improvement on the hydrogen rates and, consequently, the higher yields and better performance of the process. Thus, this work aims to optimize the hydrolysis of sodium borohydride through the study of different additives to improve the hydrogen generation. Consequently, 4 different non-toxic and environmentally friendly additives, sodium carboxymethyl cellulose (CMC), polyacrylamide (PAM), sodium dodecyl sulfate (SDS), and β-cyclodextrin (BCD), were chosen to progress in the understanding of storage and release of hydrogen using $NaBH_4$.

MATERIALS AND METHODS

Hydrogen is released by the $NaBH_4$ hydrolysis at moderate temperature, according to the following equation (ec. 1.) Excess of water, x, is required to increase the H_2 yield due to by-product's water retention. In the case of this work, an x = 15 was considered.

$$NaBH_4 + (2 + x)\, H_2O \rightarrow NaBO_2 \bullet x H_2O + 4\, H_2 \qquad (1)$$

Four additives have been tested (1 wt. %) to study their influence on hydrogen release and kinetics stabilization. Sodium carboxymethyl cellulose (CMC, Sigma Aldrich, average Mw≈700,000), Polyacrylamide (PAM, Polysciences. Inc, Mw=18,000,000), sodium dodecyl sulfate (SDS, Sigma Aldrich, ≥98.5 %) and β-cyclodextrin (BCD, Sigma Aldrich, ≥97.0 %. CMC is a derivative of cellulose, non-toxic and generally non-allergenic which dissolves rapidly in cold water. Its viscosity drops during heating, which could promote the improvement of hydrogen release rate. PAM is often used as a viscosity modifier, and friction reducer and consequently could also help control the hydrogen release. However, its high molecular weight could impede the formation of a homogenous aqueous solution. In the case of SDS, this additive has widely used to improve the storage capacity and induction time of multiple compounds. Finally, BCD is a non-toxic, green, and cyclic oligosaccharide and has proven to be suitable support due to its potentiality to construct strong interaction between the metal, in this case the catalyst, and the solution, which is beneficial for the enhancement of performances.

The catalyst is composed of Ni-Ru based in powder form and was prepared from a mixture of precursors in the deionized water. The synthesis procedure is extensively described in previous works [8]. All the experiments were carried out in a stainless-steel batch reactor with a free internal volume of 229 cm3 [7], and the tests were performed at room temperature (26 ± 1 ºC), without stirring, and at least in duplicate under the same conditions to ensure the reproducibility of the system.

RESULTS AND DISCUSSION

One of the critical parameters in a process is the H_2 yield because it is intimately related to the overall performance of the process. Thus, this section discusses the different yields achieved in the hydrolysis of sodium borohydride using the CMC, PAM, SDS, and BCD additives.

Figure 1 illustrates the mean value reached employing each of the four additives and compared with the conventional process without additives, as well as the deviation standard for each case. It is important to remark that the yields were calculated considering the real and theoretical pressure of the system. In all cases, the additives were added to the aqueous solution in a proportion of 1 wt. %.

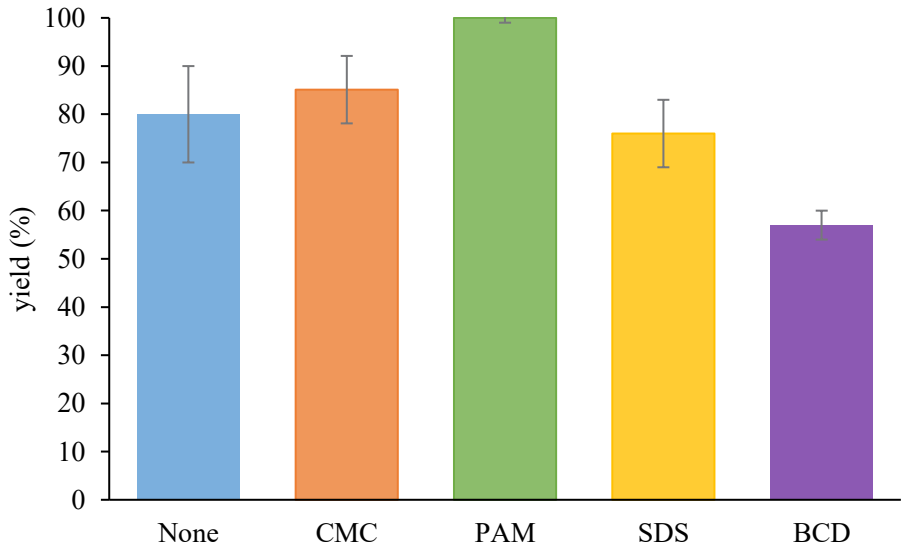

Figure 1: Hydrogen generation yield (%) achieved in a batch reactor using different additives.

Polyacrylamide additive (PAM) is presented as the most promising precursor since it allows H_2 yields close to 100 %, and the standard deviations are under 1.5 %. In contrast, the compound β-cyclodextrin (BCD) offers the worst outcomes. In this case, the performance is about 57 %, far from the desirable values for $NaBH_4$ hydrolysis. Moreover, BCD had even lower values than the system when no admixtures were added. However, the method without a precursor has the most variability, although the average yield is over 80 %, the standard deviation is about 10 %. Finally, CMC and SDS meet yields of 85 % and 80 %, respectively and standard deviations are in the range of 5-7 %, which could be considered admissible and therefore the use of these admixtures could stabilize the process. In addition, the Hydrogen generation rates (HGR) have been calculated, resulting in values as high as 1374±40 H_2 $mL \cdot min^{-1} \cdot gcat^{-1}$ for the CMC additive. However, only a generation rate of 788±120 $mL \cdot min^{-1} \cdot gcat^{-1}$ has been reached using the SDS precursor.

CONCLUSIONS

This manuscript contributes to giving a step forward employing precursors in low quantity, specifically 1 wt. %, identifying and describing the most variables that affect the process of the $NaBH_4$ hydrolysis in comparison with the conventional system where no additives are used. For this purpose, four additives based on different viscosities and nature have been evaluated, analyzing the yields obtained.

The results show that Polyacrylamide additive presents the most yields, close to 100 %. In the case of sodium carboxymethyl cellulose provides reasonable yield values (85 %). Finally, the other two additives studied, β-cyclodextrin and sodium dodecyl sulfate achieving lower values in terms of H_2 release or yield but, in both cases, offer higher replicability with respect to blank-case (without additive).

ACKNOWLEDGEMENT

This work has been conducted with financial support from the Spanish Ministry of Economy and Competitiveness (project RTI2018-093310-B-100). This research is also being supported by the Projects “HYLANTIC”-EAPA_204/2016” & ENERGY PUSH SOE3/P3/E0865, which are co-financed by the European Regional Development Fund in the framework of the Interreg Atlantic and Interreg Sudoe Programmes.

ABSTRACT

In the present work, $Ca(BH_4)_2$ is synthesized by ball milling MgB_2 with CaF_2 and thereafter applying H_2 pressures of 1000 bar and temperatures of 350°C. Formation of α,β and γ-$Ca(BH_4)_2$ phases are confirmed, using in-situ synchrotron powder X-ray diffraction (SR-PXD). Volumetric measurements with a Sieverts' apparatus and mass spectrometry results indicate that 3.5 wt.% of H_2 can be stored reversibly. During hydrogenation, boron-fluoride exchange between MgB_2 and CaF_2 occurs. As a result, $Ca(BH_4)_2$ and MgF_2 are formed. During dehydrogenation, starting materials MgB_2 and CaF_2 are formed back, together with the H_2 release. Applying high pressures of H_2 can be helpful to investigate hydrogen storage systems that were reported to be partially reversible previously in the literature.

Keywords: High pressure, Hydrogen storage, Complex hydrides

INTRODUCTION

Light metal borohydrides ($Ca(BH_4)_2$, $Mg(BH_4)_2$, $LiBH_4$, etc.) are interesting hydrogen storage materials due to their high gravimetric capacities [1]. For example, $Ca(BH_4)_2$ has a theoretical H_2 storage capacity of 11.6 wt.% with a dehydrogenation enthalpy of 36 kJ/mol. Possible dehydrogenation reactions of $Ca(BH_4)_2$ are presented as in Eq. 1-3.

$$Ca(BH_4)_2 \rightarrow Ca + 2B + 4H_2 \ (11.6\,wt.\%) \quad (1)$$

$$Ca(BH_4)_2 \rightarrow 1/3CaB_6 + 2/3CaH_2 + 10/3H_2 \ (9.6\,wt.\%) \quad (2)$$

$$Ca(BH_4)_2 \rightarrow CaH_2 + 2B + 3H_2 \ (8.7\,wt.\%) \quad (3)$$

Significant hydrogen amount is released from reactions in Eq.1-3. However, poor rehydrogenation of the dehydrogenation products; CaB_6, amorphous boron or CaH_2 hinders the practical use of $Ca(BH_4)_2$. Rönnebro *et al*. reported that hydrogenation of CaB_6 and CaH_2 to produce $Ca(BH_4)_2$ was not successful even at high temperature and pressure conditions (T= 400-440°C and $p(H_2)$ = 700 bar) [2]. In the present work, an alternative path is proposed to synthesize $Ca(BH_4)_2$. MgB_2 - CaF_2 mixture was ball milled and high hydrogen pressure (1000 bar) and temperature (350°C) was applied. In-situ dehydrogenation with SR-PXD was carried out to identify the desorption products. Hydrogen capacity was determined via in-house made Sieverts apparatus.

MATERIALS AND METHODS

Appropriate amount (1/1 molar ratio) of starting materials MgB_2 and CaF_2 (purchased from Sigma Aldrich, ≥ 99% purity) were ball milled for 40 hours using Spex 8000M shaker mill under Ar atmosphere. In order to prevent contaminations, sample preparation and milling were carried out in a dedicated Ar-filled glovebox (O_2 and H_2O below 10 ppm).

Hydrogenation reactions were carried out at an in-house made Sieverts apparatus (rated to max. 2000 bar of H_2 pressure), using absolute pressure method. 1000 bar of H_2 was loaded into the sample reactor (sample amount ~ 400 mg) and data was collected starting from room temperature until 350°C. Total measurement volume is ~ 15 ml, which allows obtaining sufficient pressure difference due to hydrogen absorption. An in-house made Sieverts apparatus was utilized to determine the released hydrogen amount, using differential pressure method. 50 mg of sample was loaded into the sample holder. Desorption kinetic data was collected starting from room temperature until 400°C with 10°C/min heating rate, under 1 bar of H_2 backpressure. In-situ SR-PXD measurements were carried out at Desy P02.1-Powder diffraction and total scattering beamline (wavelength λ ~ 0.2 Å, sample to detector distance: 160 cm). Small amount of powder was loaded into the measuring cell, which is later connected to a stage in the beamline. Diffraction data was collected every 10 seconds, while the sample is heated from room temperature to 400°C with 10°C/min heating rate.

RESULTS AND DISCUSSION

Hydrogen absorption trial was carried out for the ball-milled MgB_2-CaF_2 mixture, as seen in Figure 1. 1000 bar of H_2 was loaded into the reactor with 400 mg of sample at room temperature. Following, sample temperature was raised

to 350°C. As temperature rises, hydrogen pressure is also rising as expected. At temperatures of ~300°C, hydrogen pressure is decreasing sharply, due to hydrogen absorption.

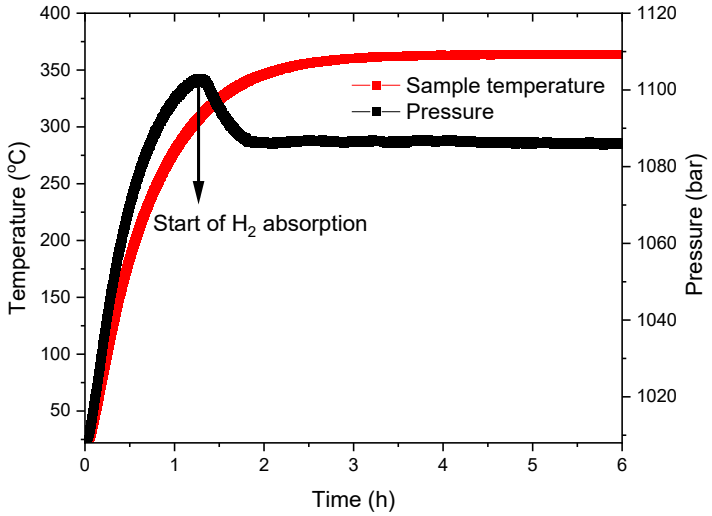

Figure 1: Hydrogen absorption of ball milled MgB_2-CaF_2 mixture. Corresponding data for sample temperature and pressure in red and black colour, respectively.

Structural characterization on the hydrogenated sample was carried out with in-situ SR-PXD, as seen in Figure 2. Hydrogenated sample at room temperature is composed of α, β and γ-$Ca(BH_4)_2$. Additionally starting materials MgB_2 and CaF_2 are identified, together with MgF_2. Presence of MgB_2 and CaF_2 indicate that sample is not fully hydrogenated, which means, ball milled composite doesn't have a homogenous mixture of starting materials. Boron-fluoride exchange between MgB_2 and CaF_2 during hydrogenation results with formation of MgF_2 in addition to $Ca(BH_4)_2$. At temperatures of ~ 120°C, diffraction peaks related to α and γ-$Ca(BH_4)_2$ disappear, β-$Ca(BH_4)_2$ becomes the main phase. Desorption of β-$Ca(BH_4)_2$ starts at 300°C, since diffraction intensity of $Ca(BH_4)_2$ decreases and intensity of CaF_2 increases. 3.5 wt.% of gas is released from its desorption, as seen in Figure 3. It is confirmed with mass-spectroscopy that desorbed gas is purely hydrogen.

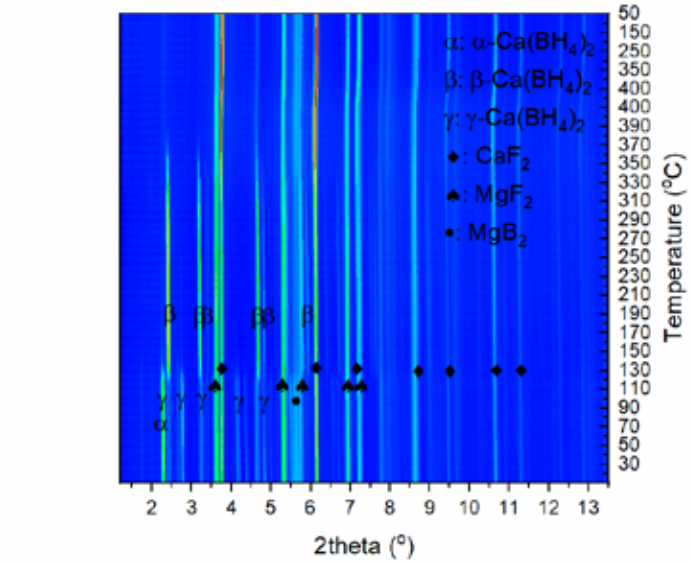

Figure 2: In-situ dehydrogenation of hydrogenated sample with SR-PXD, starting from room temperature until 400°C (10°C/min heating rate) under 1 bar of Ar pressure.

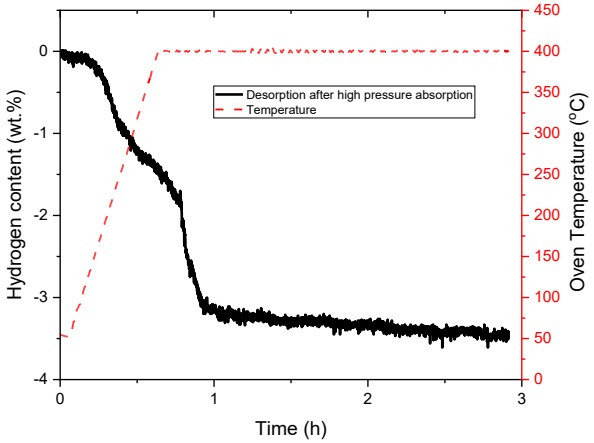

Figure 3: Dehydrogenation kinetics of hydrogenated MgB_2 - CaF_2 mixture. Sample was heated from room temperature to 400°C with 10°C/min heating rate.

CONCLUSIONS

Application of high pressure of hydrogen (1000 bar) on the MgB_2 - CaF_2 results in $Ca(BH_4)_2$ formation. During dehydrogenation, boron-flouride exchange between $Ca(BH_4)_2$ and MgF_2 results in formation of desorption products CaF_2 and MgB_2. Desorbed gas amount is calculated as 3.5 wt.%, and it is purely hydrogen according to the mass-spectroscopy result. Reactions are expected to be fully reversible, cycling experiments are still ongoing. Application of high-pressure hydrogen allows investigating H_2 storage systems that are reported to be partially reversible in the literature.

ABSTRACT

With its high capacity (7.6 wt%), magnesium is a promising material for high temperature hydrogen storage applications [1]. To date, few studies have systematically tracked the morphological evolution of a material over a large number of hydrogen (de)sorption cycles. A Mg-C composite was prepared and exposed to 1000 hydrogen (de)sorption cycles. The experiment was interrupted at several points during cycling to retrieve a small aliquot of powder in order to characterize the crystallographic and morphological changes that were taking place in the material. The material demonstrated good capacity retention until about 700 cycles had been completed, at which point the kinetics of hydrogen (de)sorption began to slow. This could be explained by grain growth and particle densification observed in the material on extended cycling.

Keywords: Magnesium, Magnesium Hydride, Hydrogen Storage, Long-term Cycling, Structural Evolution

INTRODUCTION

To realize a functional hydrogen economy, hydrogen storage applications are required which are suited to various scales and end uses. Mg/MgH_2 has been studied for decades owing to its low cost, high abundance, and high gravimetric hydrogen capacity [1]. Due to the thermodynamic stability of the Mg-H bond, Mg is limited in terms of its usefulness in low temperature applications, however, applications are being sought which either require frequent hydrogen (de)sorption or where a suitable waste heat stream is available to offset heat requirements.

This study aimed to elucidate the structural evolution of Mg-C on extended cycling and its effect on performance.

To that end, the results of a long-term hydrogen (de)sorption cycling study on a magnesium-carbon composite material are presented herein. The study started with two grams of material cycled in a custom rig at in the Hydrogen Laboratory Complex at Canadian Nuclear Laboratories (CNL). At predetermined intervals, aliquots of the material were removed to characterize the crystallographic and morphological changes in the material. The study concluded after 1000 cycles which demonstrates the cycling stability of this magnesium-carbon composite for solid-state hydrogen storage.

EXPERIMENTAL

A composite material, comprised of Mg and C powders was prepared by high energy ball milling. All material handling was performed in an ultra-high purity (UHP) argon atmosphere glovebox containing <0.1 ppm each of O_2 and H_2O. Mg powder (98%, Sigma Aldrich) and C powder (used as received from CNL) were sealed in WC milling tools with a ball-to-powder weight ratio of 19.4:1 under argon before being moved to a ball mill and milled to produce a powder. 2 g of the resulting material were placed in a borosilicate test tube and plugged with glass wool. Hydrogen (de)sorption cycling was performed in a custom-built Sievert's apparatus at CNL. All cycles in this work were carried out isothermally at 330 °C using UHP H_2.

Sampling of the powder material was performed at various stages of the experiment. Sampling was performed by cooling the reactor and returning it to the glovebox for material retrieval. A 50 mg aliquot of the material was removed from the reactor at each sampling point and the remainder was returned to the Sievert's apparatus to continue cycling. X-ray diffraction (XRD) was performed using a Bruker D2 Phaser at CNL. Scanning electron microscopy (SEM) was performed using an FEI Nova NanoSEM 450 at the Reactor Materials Testing Laboratory (RMTL) at Queen's University.

RESULTS AND DISCUSSION

The SEM images shown in Figure 1 show the progression of the morphology of the Mg-C material over the first 50 cycles. The morphology of the material changed drastically during activation. After one cycle, the material was observed growing in pristine, faceted hexagonal pillars. This results from growth of Mg at the surface of the bulk material on the phase transformation from magnesium hydride to magnesium metal during desorption. XRD data suggests that growth occurs preferentially in the 'c' crystallographic direction. As cycling continued, the pillars began to deform and quickly covered the entire surface of the particles. They continued to grow from the particle surface as the bulk material was slowly transformed entirely into a branching, ligamented structure we observed as the activated structure. Each cycle

results in a lattice expansion and contraction of about 30%, which imparts significant stress on the material; it is also known that the hydride phase (α-MgH_2) is brittle, and fractures easily [2]. Between cycles 10 and 50, the ligamented particles continued to grow in length, but did not appear to grow in diameter, which did not exceed 5 μm during this time. This is consistent with c-directional growth being preferred. As the particles break up and entangle, it was difficult to measure the particle lengths, but many appeared to be continuous in the tens of microns, and some exceeded 100 μm in length.

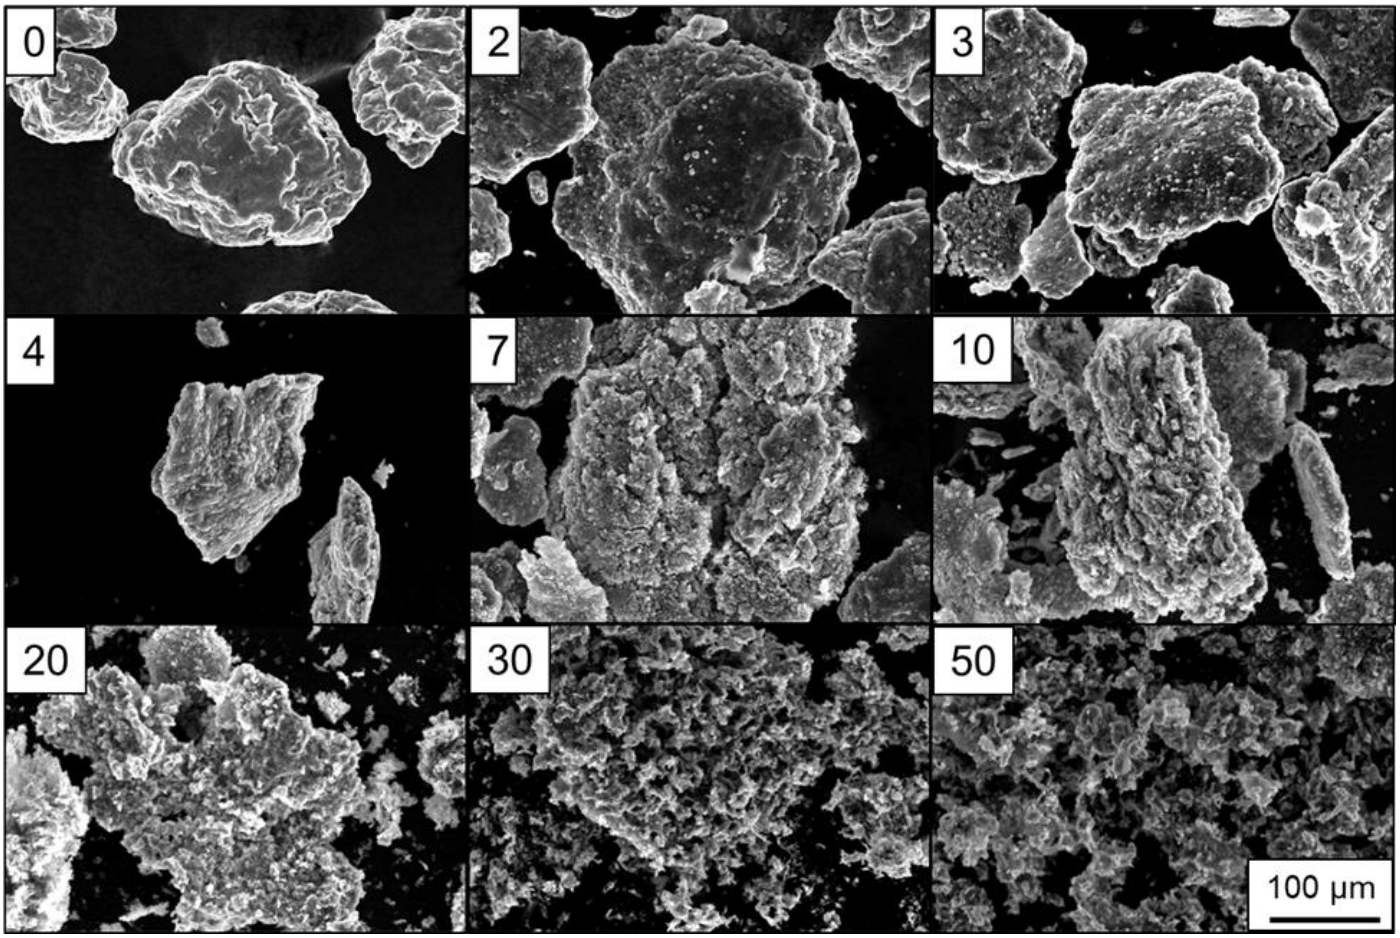

Fig. 1. SEM images showing the morphological evolution of the composite over the first 50 cycles. All images are shown at 500X magnification and the cycle count is shown in the top-left corner of each image.

Figure 2 shows the SEM images acquired after cycles 100, 200, and 300. These cycles show a slight increase in individual particle size. The individual branches of the ligamented structure had typical diameters between 2-5 μm by cycle 50. By cycle 100, these were typically between 2-10 μm. The samples obtained for cycles 200 and 300 had typical particle diameters ranging from 5-10 μm. All three of these samples had particle agglomerates comprised of sintered ligaments ranging from 50-1000 μm across; the agglomerates generally increased in size with increasing cycle count.

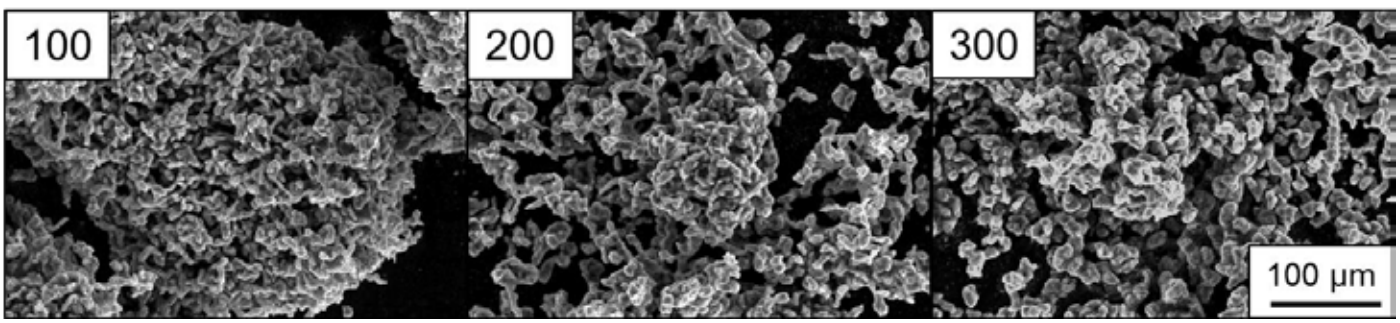

Fig. 2. SEM images showing the morphological evolution at cycles 100, 200, and 300. Images are shown at 500X magnification.

Figure 3 (Right) shows the amount of hydrogen desorbed during selected desorptions from cycles 301-1000. The hydrogen capacity experienced a slow decline from 6.3 wt% on cycle 330 to 4.7 wt% on cycle 917. Increasing the absorption time to 45 minutes (cycles 918+) increased the amount of hydrogen absorbed and, thus, the amount of

hydrogen that was desorbed (5.5 wt. %). The significant decline observed between cycles 725 and 917 was a result of the automated testing software which assigned a fixed time for hydrogen absorption of 30 minutes. As cycling progressed, the kinetics of hydrogen absorption decreased and, as a result, less hydrogen was absorbed during that fixed time. Thus, less hydrogen was available for desorption. This slowing of kinetics can be explained by the morphological evolution across the late cycles which showed the slow increase in both particle and agglomerate size. Figure 3 also shows SEM images of the material after cycles 500 and 1000. By cycle 500, typical ligament diameters fell between 10-20 µm, and by cycle 1000 it increased to 20-50 µm. Typical agglomerate sizes at cycle 500 fell between 50-1000 µm, and by cycle 1000 they were 100-1000 µm. We have also shown that the material had undergone significant densification by cycle 1000, which is typical of the late stage of the sintering processes. [3] The decrease in both high-diffusivity grain boundary area and surface area both contributed to the decline in (de)sorption kinetics as the required hydrogen diffusion depths increased and thicker hydrides were formed. This eventually led to the apparent loss of hydrogen capacity as the time required to form and decompose the hydride phase exceeded the cycle times allowed by the experiment.

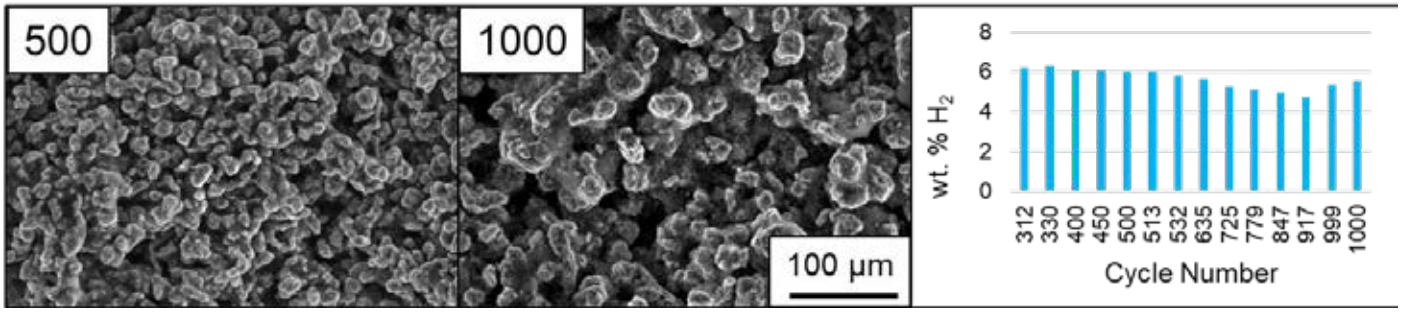

Fig. 3. (Left, center) SEM images showing the morphological evolution at cycles 500 and 1000. Images are shown at 500X magnification. (Right) Hydrogen desorbed at selected cycles between 300-1000.

CONCLUSIONS

In the early stage of structural evolution, magnesium undergoes significant morphological changes, this occurred over approximately the first 50 hydrogen storage cycles. Hydrogen absorption causes lattice expansion, atomic rearrangement and embrittlement of magnesium which comminuted into small particles on cycling. In the later stage of evolution (>cycle 50) the magnesium particles undergo a much slower process of sintering to form agglomerates and densification owing to the heat from their surroundings which reduces the kinetics of hydrogen (de)sorption. The agglomerate sizes generally increase with cycle count during this stage. At higher cycle counts (>cycle 200), particle growth becomes more apparent, and is accompanied by more severe kinetic limitations resulting from densification and associated diffusion limitations. ABSTRACT

Because of the evolving hydrogen economy, there is a growing interest in the development and commercialization of suitable hydrogen storage technologies like liquid organic hydrogen carriers (LOHCs). N-ethylcarbazole/dodecahydro –N-ethylcarbazole (NEC/12H-NEC) LOHC application, although not currently commercialized, requires relatively low temperatures for the dehydrogenation step when compared to other systems that have been commercialized. What is reported in this study are results from ongoing efforts to develop and scale-up the NEC/12H-NEC LOHC system at Canadian Nuclear Laboratories. Preliminary dehydrogenation results using an in-house catalyst show the achievement of a target hydrogen release rate of 1.4 x 10^{-5} m^3/s, clearing the way for further scale-up.

Keywords: Liquid organic hydrogen carrier, Catalysis, Dehydrogenation, N-ethylcarbazole, Hydrogenation

INTRODUCTION

Liquid organic hydrogen carriers (LOHCs) are liquids or low temperature melting solids that can be reversibly hydrogenated and dehydrogenated in the presence of a suitable catalyst and under appropriate conditions of temperature and pressure. On hydrogenation, these materials store a certain amount of hydrogen related to their structure and release the corresponding amount of hydrogen during the dehydrogenation step, making them an excellent choice for hydrogen storage and release. Such storage and release of hydrogen can be leveraged in situations where hydrogen production is variable (for example using renewable energy sources like wind and solar), or for the storage and subsequent release of hydrogen produced from nuclear energy. Fig. 1 shows a schematic of the NEC/12H-NEC LOHC.

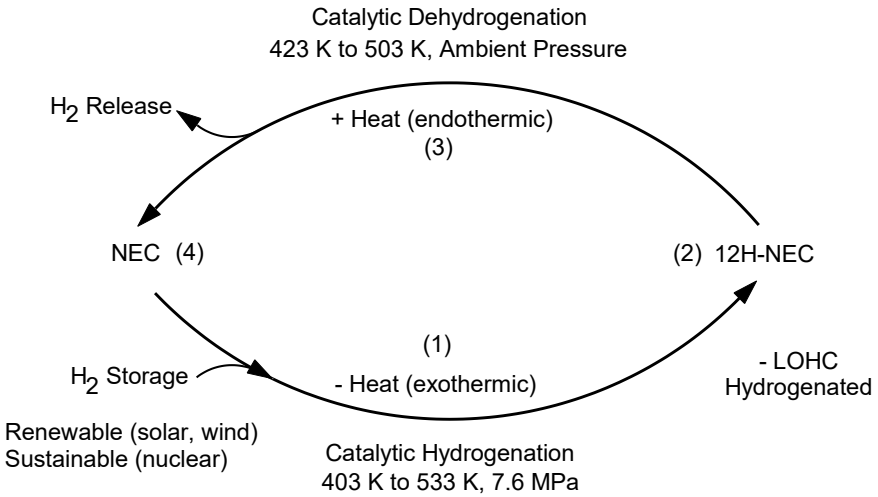

Fig. 1. Schematic of the NEC/12H-NEC LOHC system

Ongoing efforts have focused on the development of various LOHCs, mostly at laboratory scale [1-3]. However, there are a few systems that have been commercialized. For example, Hydrogenious has developed a commercially available LOHC based on dibenzyltoluene/perhydro-dibenzyltoluene (DBT/18H-DBT) [4]. Chiyoda has also successfully demonstrated a commercial scale LOHC based on toluene/methylcyclohexane (TOL/MCH) [5]. The dehydrogenation step of these two commercially available LOHCs require relatively high temperatures (563 to 623 K) compared to the N-ethylcarbazole/dodecahydro-N-ethylcarbazole (NEC/12H-NEC) which has low enthalpies of hydrogenation and dehydrogenation (50 - 54 kJ/mol) and dehydrogenation temperatures in the range of 453 K to 503 K only. To the best of the authors' knowledge, there is no commercially available LOHC system based on NEC/12H-NEC. Therefore, there is a need to develop and commercialize the NEC/12H-NEC LOHC system because it can operate at a lower temperature, and when compared to TOL/MCH system, is non-flammable and nontoxic.

Experimental investigations of the NEC/12H-NEC system as reported in the literature have focused on catalyst development [4], identification of intermediates [6], development of plausible mechanisms and kinetics [7-9], and operating conditions. With respect to catalyst development, efforts have been made to study different noble metals and supports [10-12]. The results of these studies indicate that the same noble metal can have a different activity towards 12H-NEC dehydrogenation when placed on a different support. Similarly, different noble metals can have different activities when placed on the same support. For example, Jiang et al. [10] investigated a series of noble metal catalysts using titanium dioxide (TiO_2) as the support and found that the activity of these catalysts decreased in the order Pt/TiO_2 > Pd/TiO_2 > Pd/Al_2O_3 > Rh/TiO_2 > Au/TiO_2 > Ru/TiO_2. While Feng et al. [11] studied the effect of Pd catalysts supported on different supports and found a sequence of decreasing activity as follows: Pd/C > Pd/Al_2O_3 > Pd/TiO_2 > Pd/SiO_2. The order observed for the Pd/Al_2O_3 and Pd/TiO_2 is reversed compared to the sequence given by Jiang et al. [12]. Incidentally, studies involving the use of zeolites as supports for the dehydrogenation of 12H-NEC are scarce. It is therefore important to investigate Pd on different supports (including zeolites) for the dehydrogenation of 12H-NEC. With respect to operating conditions, it has been reported that by reducing the pressure, the dehydrogenation reaction can be carried out at a temperature of 433 K with favourable kinetics [12].

For several decades, Canadian Nuclear Laboratories (CNL) has been developing noble metal based catalysts for nuclear applications. These catalysts were developed using a variety of supports including carbon and zeolites. Presently, CNL has an active hydrogen program for which hydrogen storage technologies is a component. The NEC/12HNEC LOHC system is one of the hydrogen storage technologies being developed at CNL for commercialization. Current efforts have led to the development and testing of a proprietary Pd based catalyst on a modified zeolite support for 12H-NEC dehydrogenation with comparable activity and selectivity as the commercially available Pd/Al_2O_3 catalyst. Scale up is in progress. Details of some of these experimental campaigns will be presented in this paper.

EXPERIMENTAL

Experimental work was carried out with the goal of demonstrating the LOHC system for 0.1 to 0.128 kg of NEC and 12H-NEC corresponding to hydrogen storage and release of at least 1.4 x 10^{-5} m^3/s of hydrogen during hydrogenation and dehydrogenation, respectively. For the chemicals used in this study, NEC (97 %) and 5 wt% Ru/Al_2O_3 (reduced) were purchased from Sigma Aldrich and were used as received without further purification. 12H-NEC, which is used as a starting material for all dehydrogenation reactions, was prepared by hydrogenating NEC. The commercial catalyst used in the present study for hydrogenation was the 5 wt% Ru/Al_2O_3 catalyst. A proprietary 5.5 wt% palladium/zeolite catalyst was prepared and used for the dehydrogenation reaction. The metal loading (wt% of metal) of this catalyst was determined using inductively coupled plasma - optical emission spectrometry (ICP-OES). All prepared catalysts were calcined in air and subsequently reduced in flowing hydrogen. Following reduction, the catalyst was purged with helium and subsequently kept in an inert (helium) atmosphere until use.

Experimental Setup

The reactor used for hydrogenation and dehydrogenation studies was a PARR Model 4561 Mini Bench-top reactor with a volume of 0.0003 m^3 equipped with a PARR Model 4848B Reactor Controller (PARR Instrument Company, Moline, IL). The NEC hydrogenation reaction was carried out at 423 K and 7.6 MPa. The 12H-NEC dehydrogenation reaction was carried out at 488 K and ambient pressure. For each hydrogenation reaction, 0.1 kg of NEC and 0.010 kg of 5 wt% Ru/Al_2O_3 corresponding to a 10:1 ratio was loaded into the PARR reactor. For dehydrogenation, a similar ratio was maintained, however, 0.128 kg of 12H-NEC and 0.0128 kg of catalyst were used. The hydrogen released during dehydrogenation was swept by nitrogen and measured on a volumetric basis. LabView (National Instruments) was used for data acquisition with ten seconds (10 s) set as the capture frequency (interval between two data points).

RESULTS AND DISCUSSION

Fig. 2 and Fig. 3 show the results from the hydrogenation of NEC (at 423 K) and dehydrogenation of 12H-NEC (at 488 K), respectively. Both experiments were carried out using a catalyst to reactant ratio of 1:10. From Fig.2, the two hydrogenation experiments performed show good reproducibility. Fig. 2 also indicates that more than 0.05 m^3 of hydrogen was stored in less than one hour. The results from the dehydrogenation experiment shown in Fig. 3 indicates that a hydrogen release rate of 1.88 x 10^{-5} m^3/s was achieved which is greater than the scaling-up target of 1.40 x 10^{-5} m^3/s.

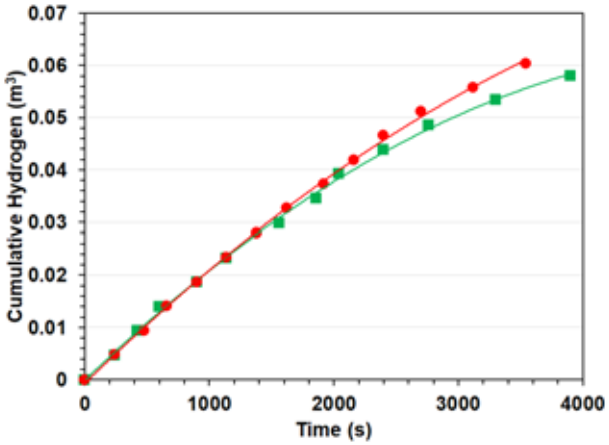

Fig. 2. Hydrogenation of NEC at 423 K

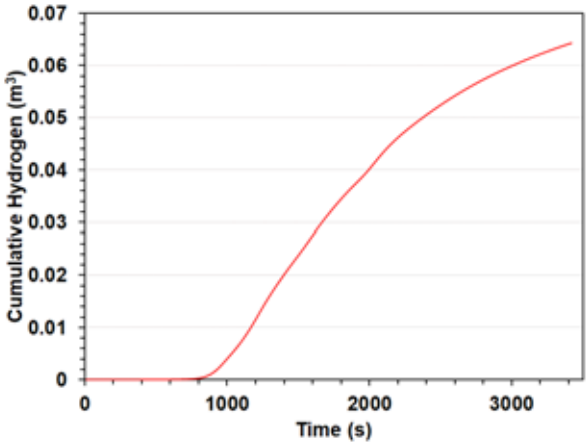

Fig. 3. Dehydrogenation of 12H-NEC at 488 K

CONCLUSIONS

The NEC/12H-NEC LOHC system is being developed at CNL for hydrogen storage and release. A proprietary Pd based catalyst has been developed for the dehydrogenation reaction. As part of our effort to scale-up the LOHC process, hydrogenation and dehydrogenation experiments were carried out with the goal of storing and releasing at least 1.4 x 10^{-5} m^3/s of hydrogen. The experimental data presented indicate that the initial target has been achieved with ongoing efforts focused on further scale-up as well as optimization of the catalyst performance.

ABSTRACT

Ammonia borane (AB: NH_3BH_3), as a potential hydrogen storage material, has been considered to be stored in different mediums for long-distance and safe transportation for practical usage. Three possible ways to store ammonia borane were parallelly considered: in the solid-state, liquid state of AB-NH_3 (NH_3 adducts or solution), and aqueous solution of AB. Among them, the liquid AB-NH_3 method shows promising advantages over other methods, In further, the basic properties of the AB-NH_3 system were studied in detail, such as absorption amount/pressure, temperature dependency of the density of the AB-NH_3 liquid, viscosity change when solved in liquid NH_3, and the thermal stability (shelf-life). The thermodynamical parameters of the reaction between AB and NH_3 were estimated and the enthalpy and entropy values were calculated to be -19.87kJ/mol and 67.76 J/mol·K respectively. In this way, the above basic properties were clarified.

Keywords: ammonia borane, liquid ammonia, viscosity, thermodynamics, storage density.

INTRODUCTION

With the depletion of traditional fossil fuels and relevant air pollution problems, seeking a sustainable and clean energy source has been an important task in the current now for all the people on our earth. Hydrogen energy attracts worldwide attention because it is a feasible solution and clean way to the environmental problems that are caused by the combustion of fossil energy. Furthermore, it can be renewable through many possible methods. The utilization of hydrogen storage materials is considered a priority means of storing hydrogen. Ammonia borane (AB: NH_3BH_3), a potential hydrogen storage material, attracts a lot of attention because of its high hydrogen content (19.6 wt.%), nontoxicity, and high stability under ambient conditions, as well as high solubility in common solvents such as water[1-3]. Additionally, hydrogen production from AB has been studied a lot and hydrogen can be released easily by thermolysis or hydrolysis [4-6]. To make it commercial and applicable, safe, stable, and easy storage and transportation are the crucial aspects. However, there are few studies related to the evaluation of the influence of storage medium and durability of AB. Therefore, in this study, the physical properties of AB-NH_3 system were investigated for a deeper understanding of handling and storing ammonia borane in liquid NH_3.

MATERIALS AND METHODS

As purchased AB with a purity of 97% (Sigma-Aldrich Japan) was used as the starting materials. The samples were stored in the glove box (Miwa MFG, MP-P60W) filled with a high purity Ar (99.9999%) to avoid the impact of air and moisture. The thermodynamic properties of the AB stored in liquid NH_3 were checked by the pressure composition isothermal (PCI) measurements of absorption/desorption processes by using BELSORP instruments. The structural and phase identification of samples before and after PCI was characterized by X-Ray diffraction (XRD) measurements using Rigaku RINT-2500. The density evaluation was conducted in a hyper glass cylinder with a homemade ammonia filling system equipped with a pressure gauge at room temperature. For kinematic viscosity analysis, stainless cells with glass windows were used and a magnetic stirrer was put in the cells, which was attached to an ammeter to measure the current density. The viscosity was calculated by a calibrated curve that was obtained by using standard solutions with different viscosities. Nuclear magnetic resonance (NMR) spectroscopy was performed to check the stability of ammonia borane in liquid NH_3.

RESULTS AND DISCUSSION

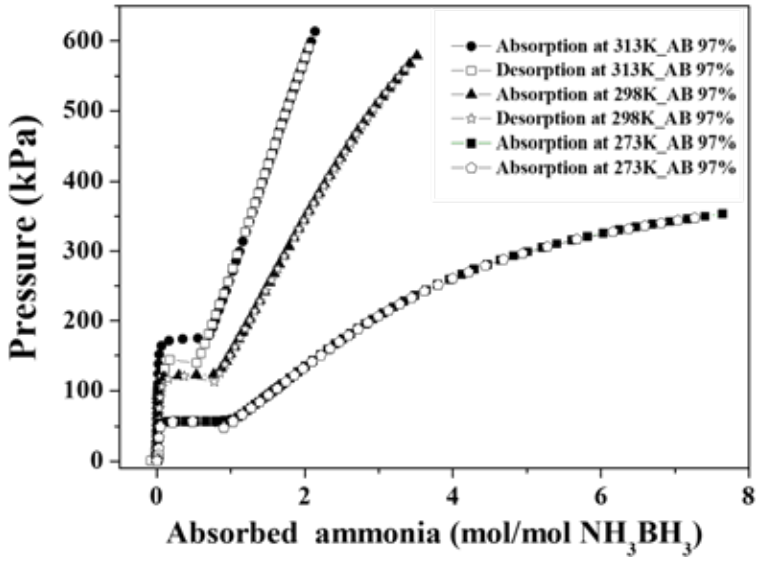

Fig.1 Pressure composition isotherm (PCI) measurements of ammonia borane for NH_3 absorption and desorption processes at different temperatures.

As the main thermodynamical properties of AB-NH_3 system, the pressure composition isotherm (PCI) measurements of ammonia borane for NH_3 absorption and desorption processes at three different temperatures of 273K, 298K as well as 313K were presented in Fig.1. At 273K, with the increase of NH_3 amount in the system, the pressure was increased to 53.78kPa, and a plateau region was observed. In this region, ammonia borane absorbed NH_3 and then formed a composite with the coexisting phase of solid and liquid. Totally 1 mol NH_3 was absorbed by AB at this temperature and then NH_3 was liquified continuously with the increasing NH_3 pressure. The plateau pressure of NH_3 absorption at different temperatures was measured and thus according to the Vant' hoff plot, the enthalpy and entropy values were calculated to be -19.87kJ/mol and 67.76 J/mol.K respectively. Other results such as density, viscosity, and shelf-life measurements will be discussed in detail in the online presentation.

CONCLUSIONS

The safe storage of AB was studied systematically in this work. NH_3 was used to store AB for the first time. The physical properties of ammonia borane stored in liquid ammonia were clarified. The thermodynamical parameters of the reaction between AB and NH_3 were estimated by measuring the pressure composition isotherm at different temperatures. the enthalpy and entropy values were calculated to be -19.87kJ/mol and 67.76 J/mol·K respectively. Other results like density and viscosity measurements as well as the durability test will be discussed in detail in the online presentation.

ABSTRACT

In this study, a dynamic model is developed for predicting the absorption and desorption characteristics of the MH systems. The accuracy of the developed dynamic model is compared with the actual model. Further, the effect of reactor size on the overall performances of the system is studied. The dynamic model predicted the average bed temperature during absorption with a maximum deviation of 3.0% for the considered operating conditions compared to the actual model. At the same time, a maximum deviation of 2.06% was observed during desorption. The dynamic model exactly predicted the reaction completion time during absorption and desorption processes. The dynamic model is 306 times faster than the actual model reported in the literature, which saves computational time and cost with appreciable accuracy. The dynamic model can also be used to compute coupled systems like heat pumps, energy storage systems, compressors, and heating and cooling systems, which will be presented in our future work.

Keywords: Metal hydride, dynamic model, absorption; desorption; $LaNi_5$

INTRODUCTION

Metal hydrides (MHs) find a wide range of applications, including hydrogen storage, hydrogen compression, thermal energy storage, heat pumps, and heat transformers [1]. The study of MH systems involves the selection of suitable alloys/ alloy pairs based on the application, design of an efficient reactor, selection of optimum process parameters, and energy-efficient operating strategy [2]. Thermodynamic studies have been performed to select the MH alloy pairs and evaluate the cycle performance of MH-based thermal machines [3]. However, the thermodynamic model doesn't consider the highly dynamic nature of the MH systems, which makes it not suitable for the accurate selection of metal hydride alloy pairs for several applications. On the other hand, complete thermal models solving for mass, momentum, and energy balances involve extremely high computational costs. In this perspective, researchers developed lumped/dynamic model for predicting the performance of the MH-based thermal machines [4]. The main advantage of the lumped model is its lower computational cost. However, the validity of such a model over a range of reactor sizes and operating conditions is seldomly presented.

The main objective of the present work is to develop a dynamic model (where the dependent variables are a function of time) for predicting the absorption and desorption characteristics of the MH systems. Also, the dynamic model results are compared with the actual model, where the dependent variables are functions of space and time. Further, the percentage deviation of the dynamic model from the actual model as a function of reactor size and supply hydrogen pressure is elucidated. Tubular reactors are selected for the analysis as they are simple, easy to construct, and involve comparatively lesser hydraulic losses among several reactor designs [5].

PHYSICAL SYSTEM AND NUMERICAL MODELING

Physical system

The present study is focused on predicting the absorption and desorption characteristics of MHs filled inside a tubular reactor using a dynamic model. In the case of tubular reactors, the MH alloy is filled inside the tube, and heat transfer fluid (HTF) flows over the tube [6]. The widely studied alloy, $LaNi_5$, is considered for the analysis, and the properties are obtained from the Sunku Prasad and Muthukumar [7]. Water is used as HTF for removing/ supplying the heat to the MH reactor. The primary purpose of the dynamic model is to quantify the performance (charging and discharging times, energy density, storage efficiency, etc.) of candidate MHs.

Governing equations and boundary conditions

The assumptions and governing equations for the dynamic and actual models are presented in Table 1. The numerical solution for the equations given in Table 1 has been obtained using the finite element-based simulation tool, COMSOL Multiphysics 5.3. The relative tolerance of 10^{-6} is used for both models.

RESULTS AND DISCUSSION

The comparison results of the dynamic model and the actual model for different sizes of the tubular reactors are shown in Fig. 1. The temperature variations show that the final absorption time predicted by the dynamic model is

almost the same as the actual model, despite marginal intermediate deviations. The maximum percentage of deviations for cases A and D are 1.06 % and 3%, respectively. The percentage deviations for cases B and C fall between 1.06 % and 3%, as shown in Fig. 1. It is observed that the percentage deviation increased with the reactor size. This is due to higher temperature gradients along the radial direction for larger reactors. During desorption (Figs. 3 and 4), it is seen that the reaction completion time and the minimum temperature predicted by the dynamic model are almost the same as the actual model. Like absorption, the percentage deviation between the models increased with the reactor size during desorption, and the maximum deviation for case D was found to be 2.06%.

From Figs 1-4, it is observed that the dynamic model predicts the transient absorption and desorption behavior with considerable accuracy. Further, the computational time for the developed dynamic model is 306 times lesser than the actual model. Hence, the dynamic model can be used to save the computational cost drastically without compromising accuracy.

CONCLUSIONS

In this study, a dynamic model is developed for predicting the absorption and desorption characteristics of the MH systems. The developed dynamic model predicts the absorption and desorption behavior with a maximum deviation of 3% for the considered operating conditions compared to the actual model. The developed model was over 300 times faster than the actual model. The developed model can be used to predict the transient absorption desorption behavior in single metal hydride and coupled MH reactor systems with reasonable accuracy which will be demonstrated in further studies.

ABSTRACT

Based on a multi-stage regenerator design of magnetic refrigeration hydrogen liquefaction device, a two-dimensional transient numerical magnetic refrigeration model in the temperature range of liquid hydrogen was constructed. Some various factors on the cooling performance of the high temperature active magnetic regenerator (60 K - 80 K) were focused on, including operating frequency, fluid flow time ratio and filling mass of the magnetocaloric material. The simulation results showed that, as the operating frequency increases from 0.25 Hz to 4.00 Hz, the active magnetic regenerator can obtain is larger cooling power. Especially, under the condition of higher frequency and lower utilization factor, the larger cooling power and COP could be obtained. For fluid flow time ratio, the cooling power and efficiency increases with the increase of fluid flow time ratio from 40% to 80%. There is an increasing trend of corresponding utilization factor of the maximum cooling power, as the fluid flow time ratio increase. For the filling mass, the maximum cooling power has a linear relationship with the filling mass of the magnetocaloric material.

Keywords: hydrogen Liquefaction, Multistage magnetic refrigeration, Active magnetic regenerator, Numerical simulation

INTRODUCTION

Since Ohira et al. [1] first proposed the use of magnetic refrigeration technology for hydrogen liquefaction in 1997, some magnetic refrigerators [2] in the temperature range of liquid hydrogen (TRLH) have been developed and tested recently. In 2017, Park et al. [3] successfully developed a two-stage magnetic refrigeration equipment based on liquid nitrogen pre-cooling, which reached a minimum no-load temperature of 25.4 K. At the same time, the numerical simulation research[4] have been done. In 2014, Numazawa [5] constructed a magnetic refrigeration hydrogen liquefaction process based on simulation calculations, which was composed of a multi-stage active magnetic refrigeration cycle for precooling and a magnetic Carnot cycle for condensation. By numerical optimization, the theoretical liquefaction efficiency of this process could reach 46.9%. In 2020, Feng et al. [6] developed a one-dimensional magnetic refrigeration model in the TRLH, using liquid nitrogen pre-cooling. The liquefaction efficiency of a 12-stage magnetic refrigeration liquefaction device could reach 76.9% of the Carnot efficiency.

In a word, the abovementioned research focus on the system performance, and there are few studies on performance impact factors in each active magnetic regenerator (AMR) in the multi-stage magnetic refrigeration system. In this paper, based on COMSOL Multiphysics, a two-dimensional transient AMR model was constructed. Helium was used as the heat transfer fluid. The effects of various factors on the cooling performance of AMR were investigated. It provided theoretical guidance for the overall optimization design and experimental research of the multi-stage magnetic refrigeration system.

SIMULATION METHOD

In the multi-stage regenerator design, taking high-temperature stage AMR (temperature range 60 K - 80 K) as an example, a two-dimensional axisymmetric model was developed, as shown in Fig. 1. The geometry and operating parameters of the AMR model were shown in Table 1.

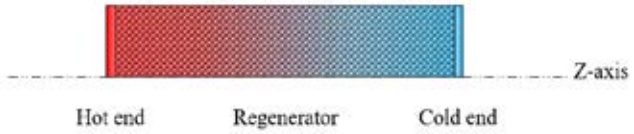

Fig. 1. Geometric model diagram of two-dimensional axisymmetric AMR

Table 1. Geometrical and operational parameters of AMR

Parameter	Value	Parameter	Value
Length of regenerator (*L*)	100 mm	Utilization factor (*U*)	0.0005 - 0.7
Diameter of regenerator (*D*)	20 mm	Frequency (*f*)	0.25 Hz - 4 Hz
Particle diameter of MCE material (*d*)	0.4 mm	Fluid flow time ratio (φ)	0.4 - 0.8
Porosity (ε)	0.36	Cold end temperature (T_C)	60 K
Magnetic induction intensity ($\mu_0 H$)	0.05 T – 1 T	Hot end temperature (T_H)	80 K

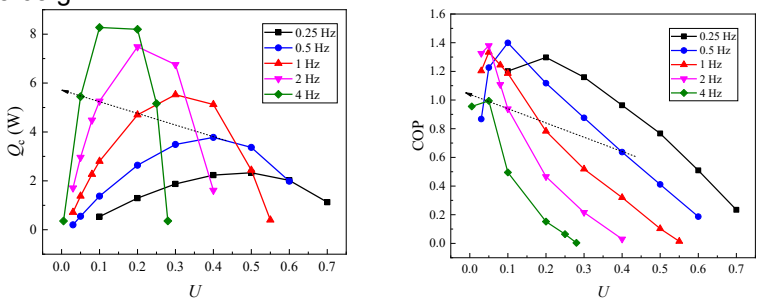
The governing conservation equations of the heat exchange fluid and the magnetocaloric material in AMR were established. For helium, the continuity equation, momentum equation and energy equation are as follows:

$$\frac{\partial \rho_f(T_f,p)}{\partial t}+\nabla\cdot\left(\rho_f(T_f,p)\mathbf{u}\right)=0 \tag{1}$$

$$\rho_f(T_f,p)\frac{\partial \mathbf{u}}{\partial t}+\rho_f(T_f,p)\mathbf{u}\cdot\nabla\mathbf{u}+\nabla p-\nabla^2\left(\mu_f(T_f,p)\mathbf{u}\right)=0 \tag{2}$$

$$\rho_f(T_f,p)c_{p,f}(T_f,p)\left(\frac{\partial T_f}{\partial t}+\mathbf{u}\cdot\nabla T_f\right)=\alpha_p T_f\left(\frac{\partial p}{\partial t}+\mathbf{u}\cdot\nabla p\right)+\nabla\cdot\left(k_f(T_f,p)\nabla T_f\right)+\frac{q_{sf}}{\varepsilon}(T_s-T_f) \tag{3}$$

The energy equation for magnetocaloric materials is as follows：



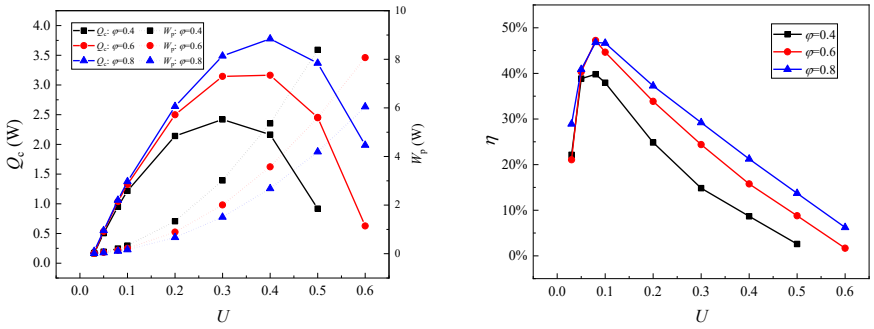
$$\rho_s c_{p,s}(T_s,\mu_0 H)\frac{\partial T_s}{\partial t}=\nabla\cdot\left(k_s(T_s)\nabla T_s\right)+\frac{q_{sf}}{1-\varepsilon}(T_f-T_s)+Q_{MCE} \tag{4}$$

The initial pressure of the magnetic refrigeration system was 1.6 MPa and the initial temperature was 80 K.

RESULTS AND DISCUSSION

Influence of operating frequency

Fig. 2 showed the variation of cooling power and COP of AMR with utilization factor under different operating frequencies *f* (0.25 Hz - 4 Hz). It could be seen that under the same frequency, the cooling power and COP of AMR first increase and then decrease with the increase of utilization factor. From Fig. 2 (a), it could be found that the cooling power has a significant improvement with the increase of frequency under the lower utilization factor. As the utilization factor was 0.1, the cooling power of the AMR increased from 0.54 W (0.25 Hz) to 8.28 W (4 Hz). This was because as the frequency increased, the mass flow rate of helium under the same utilization factor increased. Therefore, the convective heat transfer between the fluid and solid in the regenerator enhanced. Furthermore, the optimal utilization factor corresponding to the maximum cooling power of the AMR decreased as the frequency increased. For example, the optimal utilization factor was reduced from 0.5 (0.25 Hz) to 0.1 (4 Hz). At the same time, the dotted line in Fig. 2 showed that both the cooling power and COP of AMR increased with the increase of frequency at the helium flow rate of 5.65 g s^{-1}.

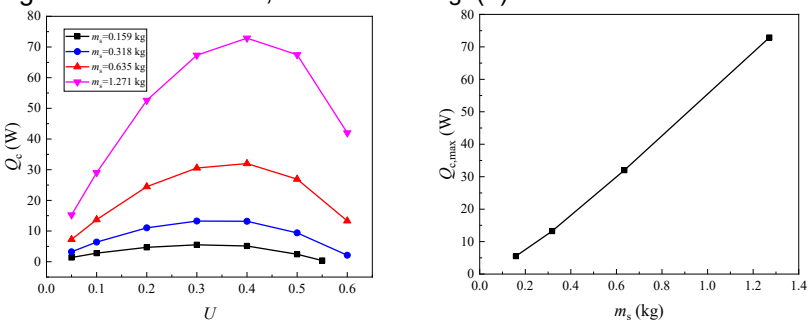


(a) cooling power (b) COP

Fig. 2. Cooling power (a) and COP (b) as a function of utilization factor at different frequencies (dotted line represents the same mass flow rate)

Influence of fluid flow time ratio

The flow time ratio φ of helium is defined as the ratio of the flow time of helium gas in the cycle, which is an important operating parameter. Fig. showed the cooling power, pump work and thermodynamic second efficiency of the AMR at 0.5 Hz when flow time ratio was 0.4, 0.6 and 0.8, respectively. It could be known that under the same utilization factor, with the increase of fluid flow time ratio, the AMR could have a longer heat exchange time per unit cycle. Meanwhile, it could be found that the maximum cooling power and the corresponding second thermodynamic efficiency of AMR both increased with the increase of the flow time ratio. For example, when the frequency was 0.5 Hz, the maximum cooling power of AMR increased from 2.42 W (φ=0.4, *U*=0.3) to 3.78 W (φ=0.8, *U*=0.4), and its corresponding thermodynamic second efficiency also increased from 14.83 % (φ=0.4, *U*=0.3) to 21.23% (φ=0.8, *U*=0.4).



(a) cooling power and pump power (b) thermodynamic second efficiency

Fig. 3. Cooling power, pump power (a) and efficiency (b) as a function of utilization factor at different fluid flow time ratios

Influence of filling mass of magnetocaloric materials

When the frequency *f* was 1 Hz and the flow time ratio *φ* was 0.8, the cooling performance of AMRs with different filling mass m_s (0.159 kg, 0.318 kg, 0.635 kg and 1.271 kg) of magnetocaloric materials was investigated. Fig. (a) shows the cooling power and thermodynamic secondary efficiency of AMR as a function of utilization factor. It could be known that the more the filling mass of the magnetocaloric material, the more the cooling power of the AMR. With the increase of utilization factor, the cooling power of AMR firstly increased and then decreased. Meanwhile, the AMRs with different filling mass had different maximum cooling power $Q_{c,max}$. which increased roughly linearly with the filling mass of the magnetocaloric material, as shown in Fig. (b).

(a) cooling power (b) maximum cooling power

Fig. 4. Cooling power (a) and maximum cooling power (b) at different filling qualities of magnetocaloric materials

CONCLUSIONS

The influence of various factors on refrigeration performance of AMR was investigated, including the operating frequency, fluid flow time ratio and filling mass of magnetocaloric materials.

- The higher the operating frequency of the system, the greater the maximum cooling power that the AMR could obtain.
- At the same frequency, as the utilization factor increases, the COP of AMR first increases and then decreases.
- At the same utilization factor, with the increase of the flow time ratio, the cooling power of the AMR gradually increases and the pumping power gradually decreases.
- The maximum cooling power of AMR has a linear relationship with the filling mass of the magnetocaloric material, which has important guiding significance for the size design of the magnetic refrigeration hydrogen liquefaction device.

ABSTRACT

With the increase in the importance of hydrogen energy, studies on storage for the use of hydrogen have also increased. Although metal hydride tanks have a higher hydrogen storage capacity in terms of volume, they are more inefficient in terms of weight and thermal management than the other storage systems. The bonding of hydrogen to the metal in MH tanks is exothermic during the absorption event, while the separation of hydrogen from the metal is endothermic during the desorption event. By incorporating phase change material (PCM) around the metal hydride tank, a 2D mathematical model is developed in this work. In terms of thermal management, this model is investigated both actively and passively.

Keywords: Metal-hydride hydrogen storage, PCM, Hydrogen energy, Hydrogen storage

INTRODUCTION

The use of fossil fuels is causing an increase in environmental challenges. As a result, governments have begun to contribute to the use of alternative energy sources like wind and wave, as well as energy carriers like hydrogen and batteries. Hydrogen has become more popular due to its high gravimetric energy density. However, in order to increase its volumetric density, research on hydrogen storage has increased. Metal hydrides have higher volumetric energy densities of any hydrogen storage technique, however, slow charging time is one of the main issues. Thermal management is another challenge as the metal hydride hydrogen storage tank heats up during absorption and cools down during desorption. A proper thermal management strategy should be selected to adjust the charging and discharging period of the metal-hydride tank.

Thermal management in metal hydride tanks can be accomplished in different ways. Askri et al. [3] investigated a cylindrical metal hydride tank with different cooling methods such as using external fins, and pumping cooling fluid through a 2D mathematical model. They validated their model experimentally, and examined the thermal interaction on the metal hydride tank surface and investigated the effect of different design on the duration of hydrogen hydration process. To understand how bed geometry affects the hydrogen absorption/desorption, Mellouli et al. [2] used PCM material as latent heat storage in a MgNi2-based metal hydride tank and performed heat and mass analyses in different bed designs (spherical shells, hexagonal tubes, and cylindrical tubes as phase change heat exchangers). Tong et al. [3] created a hydrogen storage system by integrating PCM and coiled tubes into an MH tank. To determine the acceptable hydrogen storage capacity and increase the heat and mass transfer performance, the design and production parameters of the hydrogen storage system were examined. They created a simple asymmetric model and compared the model with experimental data.

In this work, a 2D metal hydride hydrogen storage tank model with and without PCM was created, using a straight pipe integrated PCM. Pressure (5,8,12,20 and 30 bar) convection coefficient (5,10,20,100,500,1000 and 2000 W/m^{2}K), and temperature (278,283,288,298 and 313 K) for the case without PCM; whereas pressure (5,8,12,20 and 30 bar) and melting temperature (278,283,288,298,313 K) for the case with PCM were analyzed parametrically, and the cases, in which PCM becomes feasible according to the storage time and tank temperature, were examined.

MATHEMATICAL MODELING

In this section, the equations used for mathematical modeling of the metal hydride storage tank and PCM are given. Tank properties were listed in our previous study [4]. PCM specifications can be found in [3]. A schematic of the geometry of the model is given in Figure 1.

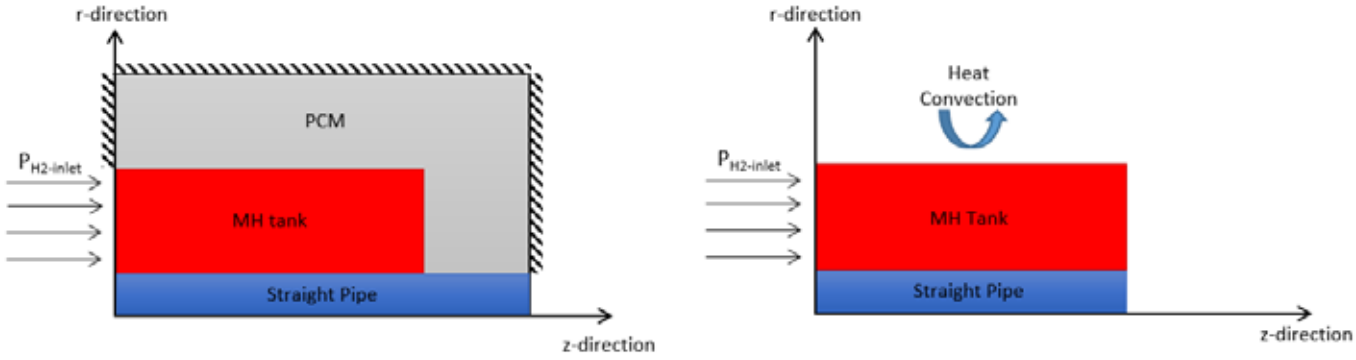

Fig 1. The geometry of MH tank (a) with PCM and (b) without PCM

Metal Hydride Hydrogen Storage Model

From the mass balance, $\dot{m}'''$ is the absorption reaction rate and can be calculated as follows,

$$\dot{m}''' = C_a \exp\left[-\frac{E_a}{R_g T}\right] \ln\left(\frac{P_g}{P_{eq}}\right) [\rho_{ss} - \rho_s] \tag{1}$$

where C_a is the heat capacity, E_a is the activation energy, R_g is the ideal gas constant, T is the hydride temperature, P_g is the gas pressure, ρ_{ss} is the hydride density at saturation state, and ρ_s is the gas pressure. P_{eq} is the equilibrium pressure and can be obtained from Van't Hoff equation [3]. The energy conservation of the metal hydride tank system can be calculated as follows,

$$\rho c_{eff} \frac{\partial T}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left[k_{eff} r \frac{\partial T}{\partial r}\right] + \frac{\partial}{\partial z}\left[k_{eff}\frac{\partial T}{\partial z}\right] + \dot{q}_{source} \tag{2}$$

where $(\rho c)_{eff}$ is the effective heat capacity, k_{eff} is the thermal conductivity, and $\dot{q}_{source}$ is the source term of the energy equation.

Phase Change Material Model

The temperature transform method was used and the equation for PCM can be obtained as follows,

$$\frac{\partial (C.T)}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(k_{en} r \frac{\partial T}{\partial r}\right) + \frac{\partial}{\partial z}\left[k_{en}\frac{\partial T}{\partial z}\right] - \frac{\partial S}{\partial t} \tag{3}$$

where C is the volumetric heat capacity, k_{en} is the enhanced thermal conductivity, and S is the source term. C and S can be calculated with the equations shown below [5],

$$C = C(T) = \begin{cases} C_s & T < T_m - \delta T_m \quad Solid\ Phase \\ C_m + \delta \dfrac{h_{sf}}{2\delta T_m} & T_m - \delta T_m \le T \le T_m + \delta T_m \quad Mushy\ Phase \\ C_l & T > T_m + \delta T_m \quad Liquid\ Phase \end{cases} \tag{4}$$

$$S = S(T) = \begin{cases} C_s(\delta T_m - T_m) & T < T_m - \delta T_m \quad Solid\ Phase \\ \left(C_m + \delta \dfrac{h_{sf}}{2\delta T_m}\right)(\delta T_m - T_m) & T_m - \delta T_m \le T \le T_m + \delta T_m \quad Mushy\ Phase \\ C_l \delta T_m - C_l T_m + \delta h_{sf} & T > T_m + \delta T_m \quad Liquid\ Phase \end{cases} \tag{5}$$

where T_m is melting temperature, δT_m is mushy range. Natural convection correlations inside annular cylindrical gaps are used to assess the liquid PCM's improved thermal conductivity [6].

RESULTS AND DISCUSSION

In this section, different parameters (convection coefficient, pressure, ambient temperature) are examined for metal hydride tank without PCM in order to examine the weight fraction and metal hydride temperature. In the PCM integrated metal hydride tank, the same outputs were examined for different pressures and melting temperatures.

The percentage filling rate of the tank for the case with and without PCM is shown in Fig 2a for a pressure of 20 bar.This figure shows that PCM is more feasible when the convection coefficient is less than 500 W/m^{2}K. Results show that, when the convective heat transfer coefficient around the MH tank exceeds 500 W/m^{2}K, the thermal resistance reduces significantly and the generated heat inside the MH tank extracted by the surrounding air. In contrast, inside the PCM, due to the low thermal conductivity of paraffin, the thermal resistance slows down the heat transfer process and adversely affects the heat extraction. It looks like that the PCM usage becomes unfeasible when the convective heat transfer coefficient is beyond a critical value. As a result, it can be seen that there are some instances where PCM is feasible. For 20 bar,no difference was observed in terms of weight fraction at melting temperatures of 5 ºC and 20 ºC. In the low pressure in the absorption process, the influence of PCM melting temperature is more effective.

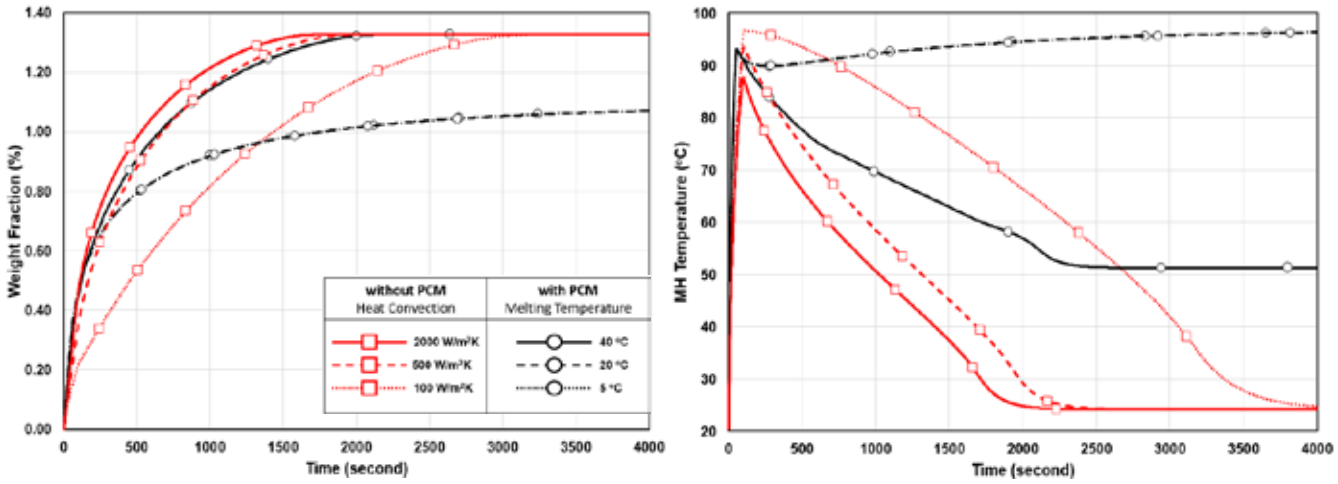

Fig. 2. Variations in (a) hydrogen weight fraction and (b) temperature under different heat convection coefficients and melting temperature at 20 bar

Fig 3a shows the metal hydride tank's percent hydrogen filling ratio. While the effect of melting temperature is studied in PCM analyses, the effect of convection coefficient is studied in non-PCM analyses. In comparison to other analyses, PCM-containing analyses have more efficient storage at a melting temperature of 20 ℃. This is because, PCM melts instantly at 5 ºC, but it can not change phase for the majority of the reaction time at 40 ℃. The influence of the convection coefficient on the percent hydrogen filling ratio is shown in Fig 3b. Since there is no increase in temperature during absorption, as the convection coefficient increases, the hydrogen filling rate of the tank increases.

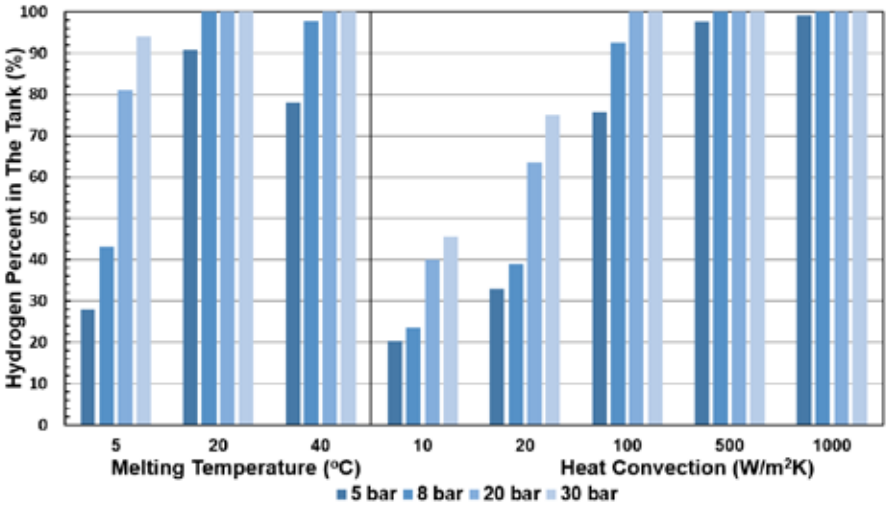

Fig. 3. Variations in hydrogen percent in the tank under different (a) melting temperature and (b) heat convection coefficient

CONCLUSIONS

In this study, 2D mathematical modeling of metal hydride hydrogen storage tank (with PCM and without PCM) was. It is observed that PCM is suitable for metal hydride hydrogen storage tanks with and without PCM by using different operating parameters. Weight fraction, tank temperature and major results were compared for two different models

in examining the effects of convection coefficient, pressure, melting temperature, and ambient temperature. The results of a tank with an active thermal management using the effect of the convection coefficient and a passive thermal management using PCM are shown. While the effect of PCM on weight fraction is higher at low convection coefficients used for active thermal management; It is not advantageous to use PCM in cases where the convection coefficient is high.

ABSTRACT

Nowadays, with the development of technology and the increase in energy demand, hydrogen has become one of the important energy carriers. Hydrogen must be stored before it can be used in hydrogen-based applications. Among the various storage options, metal hydride (MH) tanks can store more hydrogen in volume than the other ways. However, to realize the charging and discharging of hydrogen in MH tanks, thermal management must be done properly. For thermal management in MH tanks, many applications such as phase change material (PCM), heat exchangers, or fins can be used. In this study, a 1D mathematical model of a metal hydride tank and PCM is developed. Hydrogen weight fraction and PCM liquid fraction values were calculated for different values of PCM thickness (1 cm to 5 cm) and PCM melting temperature (27 ^{o}C to 35 ^{o}C) under different cases where MH radius (2.5, 3, 4, and 5 cm) and inlet pressure (8, 10, 12 bar) change. PCM thickness and melting temperature values have been optimized for cases where the weight fraction and liquid fraction are maximum for all cases.

Keywords: Metal-hydride hydrogen storage, PCM, Hydrogen energy, Optimization

INTRODUCTION

Due to the chemical structure of metal hydride (MH), hydrogen absorption is exothermic and desorption is endothermic. To have the desired hydrogen flow rate and shorter durations of charging and discharging processes, proper thermal management of the tank should be done. The tank's thermal management could be handled in a variety of methods. One of these methods is to use phase change material (PCM) that covers the tank.

There are several studies in the literature about PCM integrated MH tanks. Darzi et al. (2016) covered the outside of the $LaNi_5$-based MH tank with PCM material and performed a parametric analysis with different pressure and porosity values to examine the absorption and desorption characteristics of hydrogen. El Mghari et al. (2019) developed a 2D mathematical model to investigate the effect of PCM material on the MH tank and compared their model with the other numerical and experimental studies in the literature. They examined the effect of PCM on hydrogen absorption, desorption, and melting kinetics by varying the thermal conductivity and latent heat. Algahtani et al. (2020) investigated the effects of different designs on hydrogen absorption and desorption using two distinct PCMs. The charging and discharging times of hydrogen were investigated by parametric analysis using different PCMs. Nyamsi et al. (2020) developed a 2D mathematical model to examine the performance of the thermal energy storage (TES) system to recover the waste heat extracted from the two MH tanks ($Mg_2Ni/LaNi_5$). They employed a multi-objective optimization algorithm to optimize the characteristics of the PCM in this system, which included integrating paraffin-based PCM material to store the heat of reaction in the high temperature (HT) portion.

In this study, a 1D model of a metal hydride hydrogen storage tank covered with PCM was developed and the modeling equations were solved in MATLAB using the finite volume method. PCM thickness and melting temperature were optimized to find the optimum values of liquid fraction and weight fraction. Parametric analysis was conducted to evaluate the effects of inlet pressure of hydrogen (8,10, and 12 bar) and MH radius (2.5 cm, 4 cm, and 5 cm) on the time-wise variations for optimum values of PCM thickness (1cm to 5 cm) and melting temperature (27 ^{o}C to 35 ^{o}C).

MATHEMATICAL MODELLING

In this section, the mathematical modeling and solver algorithm of the metal hydride tank were given. The schematic of the MH tank can be shown in Fig. 1.

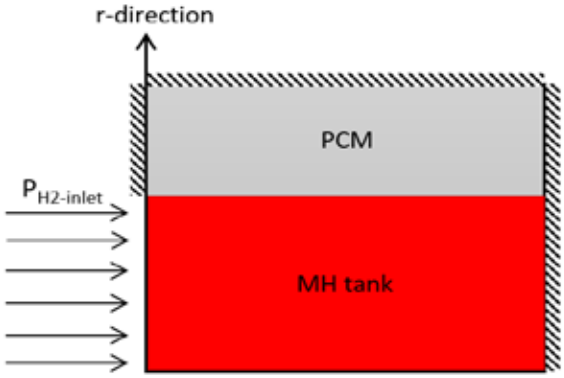

Fig. 1. The geometry of the MH tank

Metal Hydride Hydrogen Storage Model

The energy conservation of the MH tank system can be obtained as follows [5],

$$(\rho c)_{eff}\frac{\partial T}{\partial t}=\frac{1}{r}\frac{\partial}{\partial r}\left[k_{eff}r\frac{\partial T}{\partial r}\right]+\dot{q}_{source} \quad (1)$$

where $(\rho c)_{eff}$ is the effective heat capacity, k_{eff} is the thermal conductivity, and $\dot{q}_{source}$ is the heat generation within the MH tank due to the absorption reaction.

Phase Change Material Model

For PCM, the temperature transform method was used and the equation can be explained as follows [6],

$$\frac{\partial(CT)}{\partial t}=\frac{1}{r}\frac{\partial}{\partial r}\left(k_{en}r\frac{\partial T}{\partial r}\right)-\frac{\partial S}{\partial t} \quad (2)$$

where C is the volumetric heat capacity, k_{en} is the enhanced thermal conductivity, and S is the source term The C and S can be calculated using the equations given in [6]. The enhanced thermal conductivity of the liquid PCM is evaluated from the natural convection correlations inside the annular cylindrical gaps [7].

RESULTS AND DISCUSSION

The variation of weight fraction and liquid fraction for different PCM thickness (1 cm to 5 cm) and melting temperature (27 ºC to 35 ºC) values for cases where MH radius (2.5, 3, 4, and 5 cm) and inlet pressure (8, 10, 12 bar) change are examined in this section. PCM thickness and melting temperature values at maximum weight fraction and liquid fraction was determined by optimization. Optimizations were made using the Minitab program. For various MH radius and inlet pressure cases, Table 1 shows the ideal PCM thickness and melting temperature value for the maximum liquid fraction and weight fraction. It can be seen from this table that the melting temperature does not change in different cases and its optimum value is 27 ºC. Contrary to the melting temperature, it can be said that the PCM thickness takes different values in different situations, and it can be said that it is more effective than the melting temperature.

Table 1. Optimization results for different MH radius and inlet pressure values

MH Radius (cm)	Inlet Pressure (bar)	PCM thickness (cm)	Melting Temperature (ºC)	MH Radius (cm)	Inlet Pressure (bar)	PCM thickness (cm)	Melting Temperature (ºC)
2.5	8	3.22	27	4	8	3.38	27
	10	3.26	27		10	3.63	27
	12	3.43	27		12	3.90	27
3	8	3.26	27	5	8	3.47	27
	10	3.46	27		10	3.78	27
	12	3.58	27		12	3.99	27

In Table 2, MH temperature, PCM temperature, liquid fraction, and weight fraction values obtained using the values in Table 1 are given. It can be observed that in all cases, the liquid fraction achieves its maximum amount. When the

MH radius is 2.5 cm and the inlet pressure is 12 bar, the maximum weight fraction value can be obtained. According to this, the absorption rate of hydrogen is the highest in this case. In Fig. 2, the time-dependent changes in the weight and liquid fractions are shown for the PCM thickness and melting temperature calculated from the parameters obtained in Table 1. From this figure, it can be seen that a higher hydrogen absorption occurs when the MH radius is 2.5 cm and the inlet pressure is 12 bar. The change of MH radius and melting temperature does not cause any particular effect on the liquid fraction. In general, an increase in the pressure causes an increase in the liquid fraction and weight fraction, but increasing the MH radius causes these values to decrease.

Table 2. The results of the cases obtained as a result of optimization

MH radius (cm)	Inlet Pressure (bar)	MH Temperature (°C)	PCM Temperature (°C)	Liquid Fraction	Weight Fraction
2.5	8	57.75	45.36	1	1.061
	10	62.73	51.51	1	1.15
	12	63.64	51.60	1	1.22
3	8	61.005	49.18	1	0.89
	10	65.42	52.008	1	0.99
	12	68.96	54.75	1	1.06
4	8	63.23	51.51	1	0.68
	10	68.66	54.43	1	0.76
	12	72.26	54.64	1	0.84
5	8	64.06	52.23	1	0.55
	10	69.86	54.92	1	0.63
	12	74.75	57.21	1	0.69

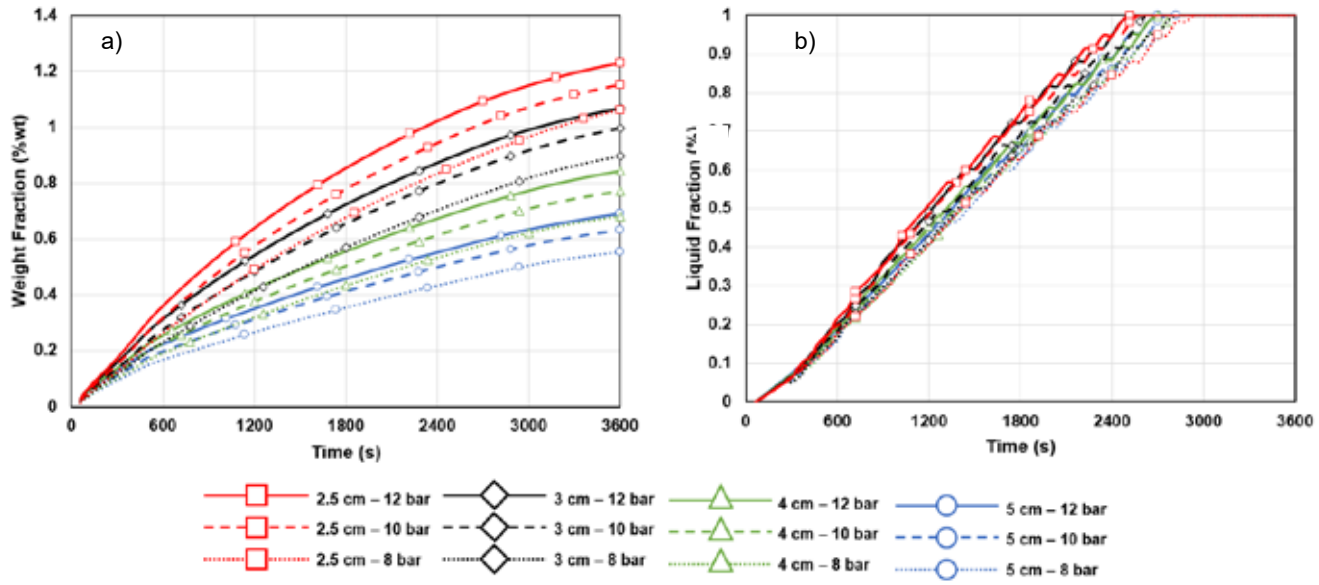

Fig. 2. Time-dependent change of (a) weight fraction and (b) liquid fraction for the best values of PCM thickness and melting temperature

For the maximum value of the weight fraction (2.5 cm MH radius and 12 bar inlet pressure), Fig. 3 shows the effect of inlet pressure on hydrogen percent in the tank at various PCM thicknesses. This figure shows that as the pressure increases, the weight fraction increases as well. In the case where the PCM thickness is 4 cm, the hydrogen percent is higher than that found for the other thicknesses. This is because PCM melts faster when it has 4 cm thickness compared to 5 cm thickness.

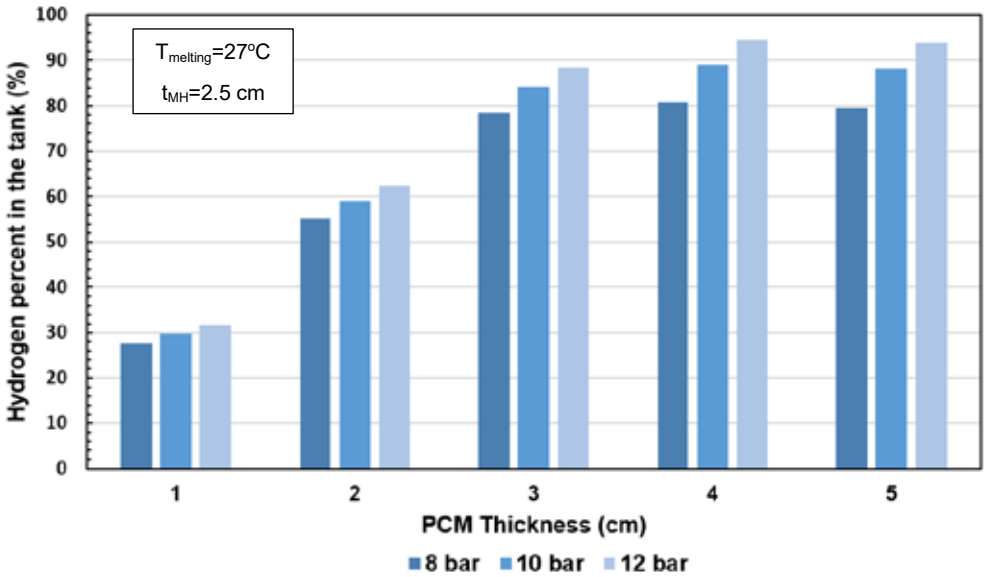

Fig. 3. Hydrogen percent in MH tank under different pressures

CONCLUSIONS

In this study, a 1D mathematical model of a PCM integrated metal hydride hydrogen storage tank is developed. For different MH tank diameter and inlet pressure values, the optimum PCM thickness and melting temperature values are obtained using the Minitab program when the weight fraction and liquid fraction are maximum. As a result, it is found that the weight fraction increases with the increase of the inlet pressure, on the contrary, the weight fraction decreases as the MH radius increases. Changing the inlet pressure and the MH radius does not have a specific effect on the liquid fraction.

ABSTRACT

In this study, infrastructure works and operation planning of underground hydrogen storage areas was examined. Important points to be considered in the feasibility study were determined in the creation of salt caverns to built in salt domes, which are an important underground storage area. As well as producing hydrogen with clean energy sources such as wind and sun, it is also very important to store it economically in very large volumes. It has been seen that infrastructure works and operational planning are of great importance for the hydrogen storage areas created in salt domes to be technically, economically and financially efficient and sustainable. It was determined that hydrogen could be stored efficiently and economically in well-planned salt caverns at low pressure and on a very large scale. For this purpose, it is found that the storage cost, which is one of the most important problems in front of the hydrogen economy in the future, can be reduced. At the same time, it is seen that very important effects on the development of hydrogen economy and technologies. As a result, it has been seen that operational planning plays a key role in the use of salt caverns for long-term safe and healthy hydrogen storage.

Keywords: Underground hydrogen storage, salt dome, salt cavern, hydrogen economy

INTRODUCTION

Nowadays, electricity and hydrogen fueled vehicles are the only solution to reduce the environmental effects caused by the transportation sector, both electricity generation and hydrogen production are provided from renewable energy sources. This will help to significantly reduce carbon dioxide emissions, especially for the transport sector. Various energy storage techniques seem to be a critical solution to overcome such challenges by increasing the availability of renewable resources or balancing energy supply demand and fluctuating processes in generation. Today, various energy storage methods are practically possible to integrate into engineering applications in various industries [1]. In particular, very large-scale safe and economical hydrogen storage methods should be developed. One of the most suitable methods for this purpose is to explore underground geological structures. Salt cavern is another underground storage medium that can be used as a high-pressure gas storage area in very large volumes under certain conditions and conditions [2-4].

It is one of the most suitable options for large-scale and long-term storage of hydrogen in underground (geological) salt caverns. With the increase in supply and demand for renewable energy sources, hydrogen storage, especially in underground salt caverns, will have even more strategic importance. In the future, hydrogen storage will be key, with hydrogen being used on massive scales as a fuel in cars and airplanes, as heating in buildings and residences, and as electrical power in industry and other fields. Therefore, In this study, it was tried to determine the prominent issues and methods in the operational planning and infrastructure studies of the underground salt caverns which have a key role in the economical storage of hydrogen produced with renewable energy sources. And also they have a key role maintain the supply-demand balance with a continuous supply flow and delivery to suppliers as liquid or gas. The fact that hydrogen, which is an important energy source of the future, can be stored in salt caverns in large volumes and economically at low pressures, and the insufficient lack of scientific studies in this field that has been an important source of my motivation.

MATERIALS AND METHODS

Underground storage caverns are used for large-scale production and distribution for Hydrogen Gas production and distribution business, and especially for the storage of surplus gas. Hydrogen is produced with the surplus of electricity produced on the basis of solar and wind energy. The gas is compressed by compressor units and transported to the storage facility by long-distance pipelines. The gas stored here is transported to hydrogen distribution stations by mobile tankers (Figure 1). The hydrogen produced flows through the pipelines to the storage facility.

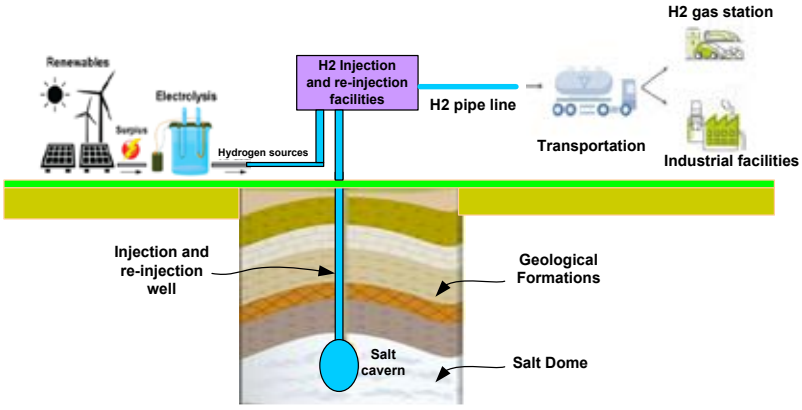

Figure 1. Hydrogen production and storage processes

There are important technical issues that should not be considered in underground hydrogen storage. Planning stages and well engineering studies are important in defining operations in underground projects. Here, it should be determined in which storage medium the hydrogen will be stored underground and the operation should be planned accordingly.

RESULTS AND DISCUSSION

Economic, technical and financial research of underground salt caverns should be carried out at the top of the issues to be considered in the feasibility study of underground hydrogen storage areas. In order to realize these, it is possible with the correct planning of infrastructure works and operational studies in the hydrogen storage area. Thus, it can be ensured that salt caverns are technically, economically and financially sustainable.

Infrastructure Works at the Hydrogen Storage Site:

- Inspection of the underground storage area, determination of existing or required new roads, legal permits to be obtained for all these and the cost of the investment are determined.
- Appropriate area is determined for the disposal of the salty water that comes out as a result of the construction of the caverns formed in the salt domes.
- The annual weather conditions of the underground storage area and the distance of the storage area to the residential areas are determined.
- In order to protect nature and the environment, necessary measures are taken to determine the negative effects of waste materials and to eliminate them.
- The operating mode of the facility built on the surface of the underground storage area is determined.
- The cost incurred in case of complete closure of the facility or temporary suspension of activities is calculated.
- For the safety of the facility, the presence of an emergency shutdown feature, taking the necessary precautions to prevent fire and explosions, and the establishment of a pressure relief system are taken into consideration.
- Materials used for hydrogen storage in underground salt domes and surface facilities must be of the best quality to avoid any problems.
- The technology and equipment to be used for underground cavern construction and for facilities located on the surface must be the latest, safest and most accepted by the authorities.
- Personnel to be employed in the underground storage facility should be experts, in-service training seminars should be given to the personnel at certain times, and maximum attention should be paid to the maintenance and repair needs of the facility over time.

Operational Planning in Underground Hydrogen Storage:

- Renewable energy resources of the region are determined.
- The geological and geophysical features of the region are examined.
- Suitable geological structures for underground storage are determined.
- The depth and dimensions of the salt domes are determined by geophysical methods.
- The physical and chemical properties of salt formation are analyzed.
- Architectural plans of the caverns planned to be built in salt domes are drawn up.
- The areas to be built in the salt domes and the size of the cavern to be built are determined.
- Well planning studies are created for the caverns where hydrogen will be stored.
- All risks that may occur in underground hydrogen storage are included in the technical well planning by providing the appropriate drilling site selection, and injection and re-injection well cost estimation is made.
- The hydrogen storage potential of the caverns is calculated.
- Optimum storage capacity and performance are determined.

- The ratio of working gas and pillow gas required for hydrogen storage in the cavern is determined.
- The flow and distribution of hydrogen injected and re-injected into salt caverns should be identified and evaluated.
- For long-term periods, the interaction of hydrogen with the salt cavern is evaluated.
- Possible underground risks for hydrogen operations are evaluated and risks are minimized.
- The interior structure and design of the cavern is constantly monitored by the underground ultrasonic imaging system.
- The maximum hydrogen storage and extraction capacity of each well is calculated.
- Presence, excess and transit time of hydrogen stored in salt caverns are determined.
- The mechanical effect of pressure changes caused by temporary or seasonal hydrogen storage in salt caverns is also evaluated.
- A management plan is created for the efficient operation of the cavern.

CONCLUSIONS

State Storage of hydrogen by compression in large volumes of high-pressure tubes or tanks increases the energy cost. In underground salt caverns, it can be stored in very large volumes with lower pressure. Hydrogen is produced with electricity produced in surplus from renewable sources such as solar and wind and stored in the salt cavern, providing a significant advantage in securing the energy supply chain for the next energy transition and in the hydrogen economy. It also has great potential to overcome the natural temporal fluctuations inherent in renewable energy generation. For this reason, it has been seen that structural planning is a necessity for the efficient storage and operation of hydrogen in salt caverns. By associating it with the feasibility of large-scale hydrogen storage, as well as operational planning and infrastructure studies, both structural uncertainties and the cost of the cavern can be reduced. Hydrogen production centers working with renewable energy systems and salt caverns can be safely and economically integrated. As a result, it has been seen that well-planned and safe underground salt caverns are a good alternative to ensure the continuity of the power supply, which is one of the most important parameters sought in renewable energy systems, and to store the excess power as hydrogen energy. An important part of the energy problem can be easily solved by storing hydrogen in caverns created in salt domes. Thus, it will be able to provide continuity in access to energy and the opportunity to have a clean and reliable energy source.

ABSTRACT

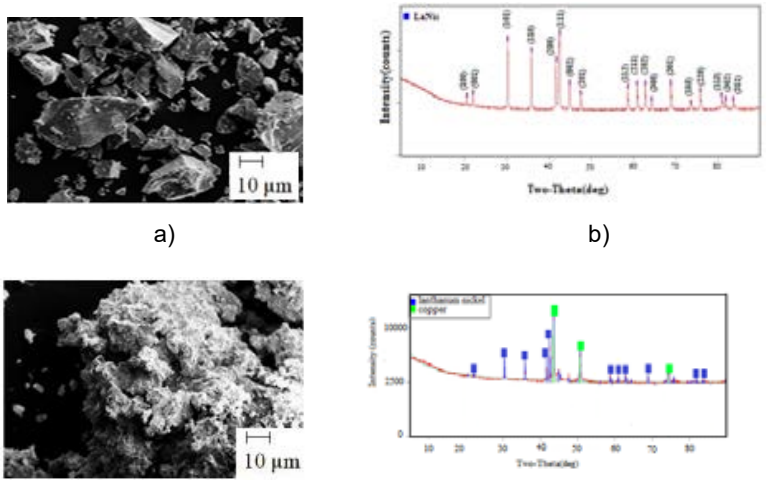
In this study, the hydrogen storage capabilities and thermal conductivity of the materials will be improved by applying both expanded natural graphite (ENG) addition and copper plating methods to the $LaNi_5$ alloy. The optimized $LaNi_5$-Cu alloy will be selected, ENG will be added at 1%, 5%, 10% and 20% ENG to this alloy and its application together with copper will be optimized. The obtained materials were characterized by XRD, SEM, BET and their thermal conductivity coefficients were measured with the Hot Disk Thermal Constants Analyzer device. In addition, the effect of storage materials with improved thermal conductivity on the hydrogen charging/discharging process in the metal hydride reactor will be experimentally investigated at the determined pressure.

Keywords: Hydrogen storage, Expanded natural graphite (ENG), Metal hydrides, Thermal conductivity

INTRODUCTION

Due to its high calorific value and being a clean fuel, hydrogen draws attention as the most studied energy carrier. However, the storage problems of hydrogen limit both its application areas and its commercialization. Recently, metal hydride reactors, which can store large amounts of hydrogen in small volumes and operate at high pressures, have attracted great interest. However, the biggest obstacle in the development of metal hydride reactors is the poor heat transfer properties of the alloys used [1]. As expected, this situation negatively affects the exothermic charge and endothermic discharge time and storage/release capacity. In this study, it is aimed to improve the heat transfer properties of hydrogen storage materials. One of the most effective methods for improving the thermal conductors of hydrogen storage materials is the method of coating the storage materials with copper. Recently, a lot of research has been done in this area. To improve the heat transfer of metal hydride reactors [2], they designed the reactor by using 10 kg of $LaNi_5$ alloy in their study and examined the system performance. With their work, they examined the effect of geometry and operational parameters and used them for reactor design and fabrication. They optimized the hydrogen charge and discharge at different pressures and flow rates. The results obtained from the experimental and numerical solutions show that the hydrogen storage rates of the reactors are significantly limited by the heat transfer between the metal alloy inside the reactors where the reactions take place and the external environment. Therefore, the improvement of heat transfer plays an important role in the design of reactors. In this context, researchers have proposed various designs to increase heat transfer in metal hydride reactors to reduce hydrogen charging time and increase stable discharge time. Pressing copper-coated metal alloy powders to increase the effective thermal conductivity of metal hydride reactors [3-5] are the process of producing metal hydride pellets by adding expanded natural graphite to metal alloy powders [6-7]. Lototskyy et al. [8] used C_{14} /$MgZn_2$ type AB_2 intermetallic metal hydride material and added 1% by mass of expanded natural graphite (ENG) to increase thermal conductivity during hydration. They reported that they reached a hydrogen storage capacity of 1.4% by mass when charged below 60 °C and above 50 bar pressure. The aim of this study; is to determine the main parameters to develop advanced hydrogen storage systems by improving the heat transfer coefficients and storage capacities of hydrogen storage materials with ENG and copper additives by forming metal hydride pellets to accelerate the hydrogen charge/discharge processes Fig. 1.

MATERIALS AND METHODS



$LaNi_5$, the hydrogen storage material, is available in powder form. Metal hydride pellets are obtained by coating this powder material with copper using additional chemical materials and pressing it at high pressure. The copper plating process starts with a solution of copper sulfate ($CuSO_4$), water (H_2O), and sulfuric acid (H_2SO_4). This solution is thoroughly stirred at room temperature until the copper sulfate powders are completely dissolved. Then $LaNi_5$ is added and mixed for the specified time. The dried powders are then pelletized Fig. 1. The sample powders are weighed out to approximately 40 g, poured into a stainless-steel die, and then compacted by a manually operated hydraulic press at 15x104 N.

Fig. 1. $LaNi_5$ pellet coated with copper

RESULTS AND DISCUSSION

SEM and XRD analysis of $LaNi_5$ nanoparticles coated with copper $LaNi_5$ are shown in Fig.2. The coated image of $LaNi_5$ powder is shown in Fig.2c. by scanning electron microscopy. The copper coating can be distinguished by its lighter color. The result of BET analysis showed $LaNi_5$ 0.114019 m^2/g, $LaNi_5$-Cu 2.56732 m^2/g.

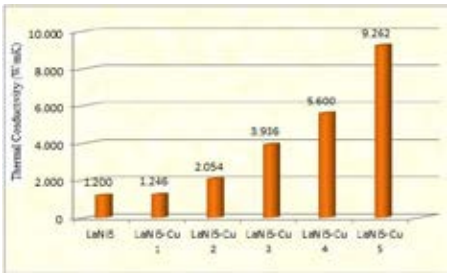

Fig. 3. Thermal conductivity analysis results of pellets optimized and prepared according to the amount of copper

The thermal conductivity of $LaNi_5$ powder was measured as 1.2 W/m-K (Fig.3). The thermal conductivity of the coating copper $LaNi_5$ metal hydride pellets were measured between 6 and 9 W/m-K. Within the scope of experimental studies, the thermal conductivity coefficients of $LaNi_5$ materials coated with copper have been increased by 500-750 %, and the copper coating ratios have been optimized.

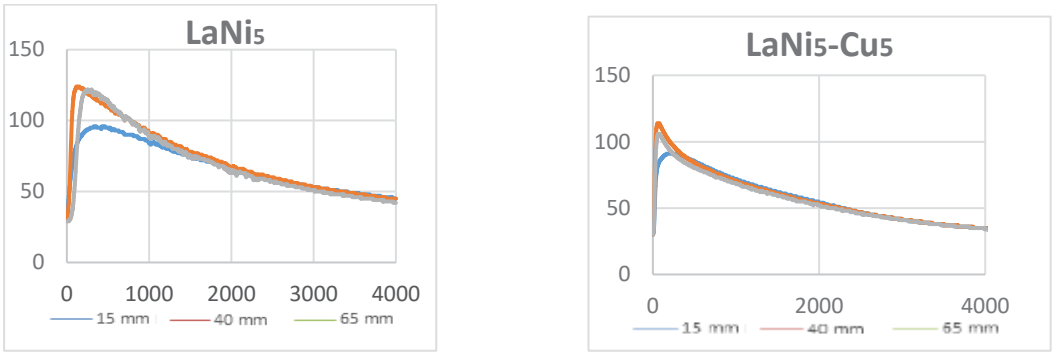

Fig. 4. Temperature development measured in the reactor at 10 bar a) $LaNi_5$ (standard) b) $LaNi_5$-Cu

To determine the effect of hydrogen charge pressure on storage kinetics in the study, experiments were carried out for 4000 s for a charge pressure of 10 bar. In these experiments, thermocouples were connected to 15 mm, 40mm and 65 mm points along the z-axis of the reactors, and time-dependent temperature change was measured.

CONCLUSIONS

To develop hydrogen storage materials, the main parameters were determined and the alloy was coated with copper. Thus, the heat transfer in metal hydride reactors is increased, the hydrogen charging time is reduced and the stable discharge time is increased. Coating the alloy with copper significantly increased the reaction kinetics and lowered the reactor temperature. As a result, hydrogen will be able to be stored in more reactors. The study determined the alloy with the most improved thermal conductivity. This alloy will be optimized with ENG and the results will be shared.

ABSTRACT

One of the most promising ways to store and reuse hydrogen is the usage of metal hydride tanks. During the charging process, i.e., absorption, heat is generated inside the hydride tank due to the exothermic nature of the absorption reaction. In contrast, the discharging process is endothermic, and heat should be supplied to the hydride tank. Thermal management is critical in metal hydride tanks (MHT), as overheating the tank during charging or supercooling during discharge significantly reduces the reaction rate and limits the amount of hydrogen stored/released to/from the tank.

This study aims to design a water jacket for the thermal management of a metal hydride tank. For this purpose, preliminary parametric flow analyses were conducted for a 3D water jacket design to determine the suitable geometrical configurations that provide uniform convective currents around the tank with lower pressure drops. $LaNi_5$ tank material is then implemented into the model, and the charging process was examined by varying the major hydrogen supply pressure from 10 to 25 bar. The model is developed in ANSYS-FLUENT software. A dedicated UDF code is implemented into the software to incorporate the reaction kinetics equation, the hydride's mass balance, and the hydride's energy source term. The validity of the developed procedure is assured by reproducing a recent numerical work from the literature, and comparative results showed a satisfactory agreement. The parametric analyses showed that increasing the hydrogen supply pressure from 10 to 25 bar reduces the charging time from 12 minutes to 6 minutes. In addition to the numerical survey, experiments are conducted for an HYDROSTIK metal hydride tank in water and air ambients. Based on the numerical simulations, a novel 4-port cooling jacket was produced with a 3D printer and the experiments were conducted under various hydrogen supply pressure. Results showed that in comparison to the reference condition inside stagnant air ambient, the implementation of a water jacket reduces the charging time from 6 hours to 30 minutes.

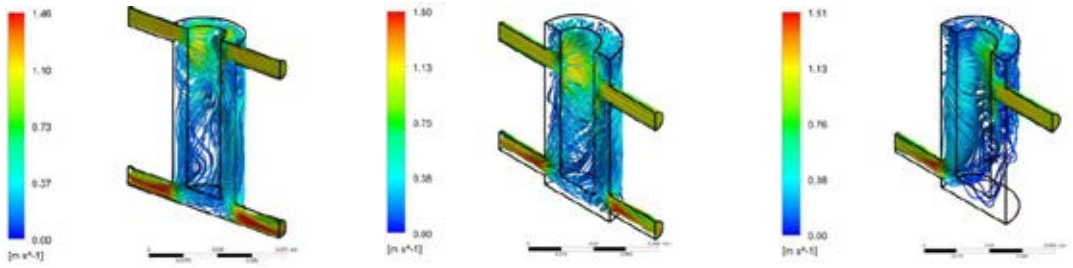
INTRODUCTION



As a renewable energy source, hydrogen can be stored in metal hydride tanks. The aim of this paper to develop of thermal management system for this storage method. As a result of the literature review, Ben Nasrallah et al. examined a thermal management system with a water jacket. In this study, they used the two-port water jacket design and carried out numerical and experimental studies [1-2]. Souahlia et al. also examined a thermal management system with a water jacket and helical heat exchanger [3]. In this paper, as a difference of these studies, three different water jacket geometries were designed and the one with the most suitable flow distribution was selected from these water jackets. In addition, the effect of different inlet/outlet port combinations on flow distrubition were examined.

NUMERICAL ANALYSES

In this study, the charging process of a cylindrical MHT with time dependent heat generation was investigated using commercial software ANSYS-Fluent. The tank, which is thermally managed with a water jacket, is modeled in 3D and the charging process is examined. In the study to examine the flow distributions of the water jacket geometry, 3D flow analyses were made and the geometry was determined. The geometry and MHT determined as a result of flow analysis were modeled together, thermal analyses were made and the effects of different parameters on the charging process were examined.

THREE DIMENSIONAL ANALYSES

The flow distribution on the tank surface and the manufacturability of the design were taken into account in determining the appropriate water jacket design and inlet/outlet port combinations. Three different designs were created. At Fig.1 (b), it is seen that the flow distribution is mostly uniform compared to Fig.1 (a) and Fig.1 (c). Therefore, all analyses were performed according to Fig.1 (b) geometry.

(a) 4PD1 (b) 4PD2 (c) 2PD

Fig.1. Flow Distributions for different geometries

Looking at Fig.2, increasing mass flow rate at the same pressure reduces the charging time of the MHT. At a constant flow rate, increased pressure has a similar effect and decreases the charging time. Looking at Fig.3, increasing mass flow rate at a constant pressure reduces the MHT temperature. While the flow rate is constant, increasing pressure increases the MHT temperature. Looking at Fig.4, while the pressure is constant, the increasing mass flow reduces the water outlet temperature.

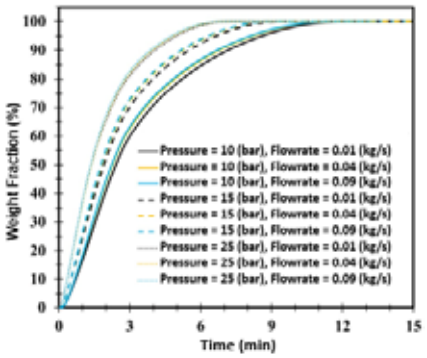


Fig.2. Weight fraction

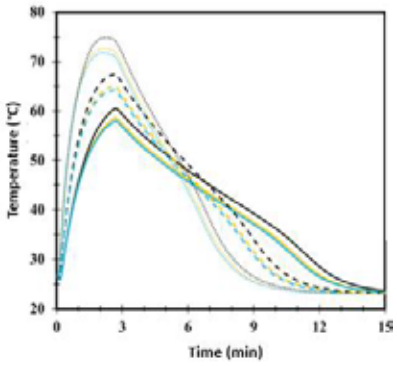

Fig.3. Average temperature of the tank

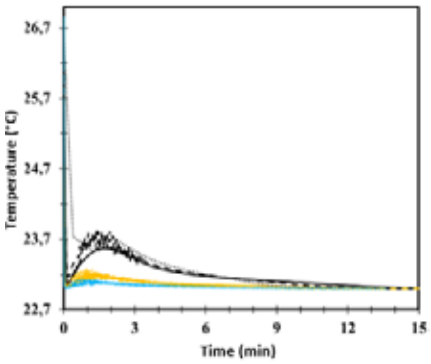

Fig.4. Outlet temperature of the water

EXPERIMENTAL STUDIES

Experiments were carried out to observe The effect of the water jacket on the discharge/charge processes. In Fig.5., it is seen that the charging and discharging processes of the MHT are carried out in a single experimental setup.

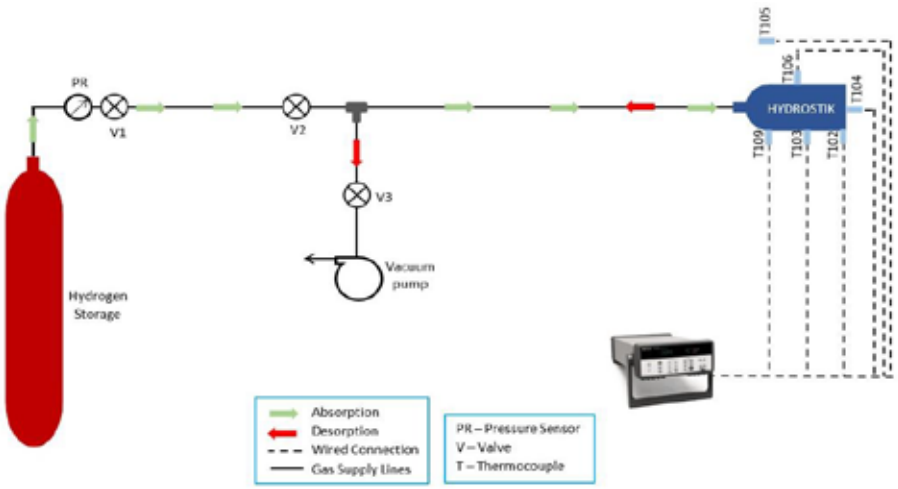

Fig.5. Experimental setup

Thermocouples numbered 102,103,104,106 and 109 were placed at different locations in order to measure the temperature changes on the surface of the MHT during the charging and discharging processes. In addition, thermocouples numbered 105,107, and 108 were used to measure ambient temperatures. In stagnant air ambient, the charging process took 6 hours and the discharging process took 3 hours, Fig.6.

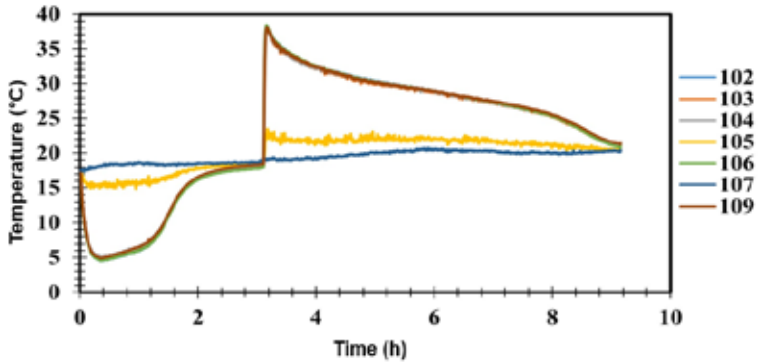

Fig.6. Charge and discharge process in stagnant air ambient

In experiments with the water jacket when water enters through the lower ports at Fig.7., the charging time took 30 minutes and the discharge time took 40 minutes, Fig.8. In the experiments using the water jacket, the total charging and discharging time was approximately 8 hours shorter than the stagnant air environment.

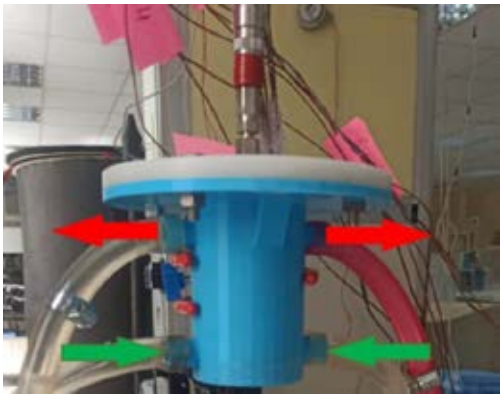

Fig.7. bottom-entry water jacket

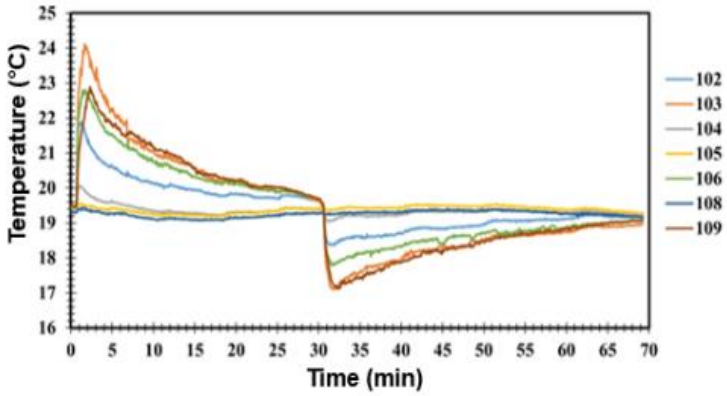

Fig.8. Charge and discharge process

CONCLUSIONS

As a result of flow analysis, it was decided to use 4PD2 which flow is uniformly distributed in the tank. It has been observed that hydrogen supply pressure is much more effective than mass flow rate in reducing the charging time. However, although the charging time decreases with the increase of hydrogen supply pressure, the maximum temperature in the MHT increases. In the experiments with the water jacket, it was observed that the charging and discharging times were shorter in the experiment with water inlet from the lower ports.

ABSTRACT

A compact auxiliary power unit in the 7.5 kW_e class was developed. The system is composed of two high-temperature PEFC stacks operated on reformate produced by a diesel fuel processor and the corresponding balance of plant components. In order to maximize the power density, each fuel processor component is designed as a multifunctional reactor. The stacks and the fuel processor are combined using manifolds applying additive manufacturing technology. Using the developed reactors, manifolds, as well as the selected fuel cell stacks and the balance of plant components, a compact system was designed and manufactured with a volume of 187.5 l. Preparatory experiments with the fuel processor focused on the validation of the system concept, aiming to maximize the fuel conversion while keeping the CO level in the fuel processor outlet below 1% for the ideal operation of the high-temperature PEFC. With various diesel and kerosene fuels, it was possible to identify the best operating parameters with each fuel at a very high fuel conversion of > 99.95% at full load of the fuel processor. In each experiment, the CO concentration remained stable and below the target value mentioned above.

Keywords: autothermal reforming, fuel cell system, fuel processor, HT-PEFC, jet fuel

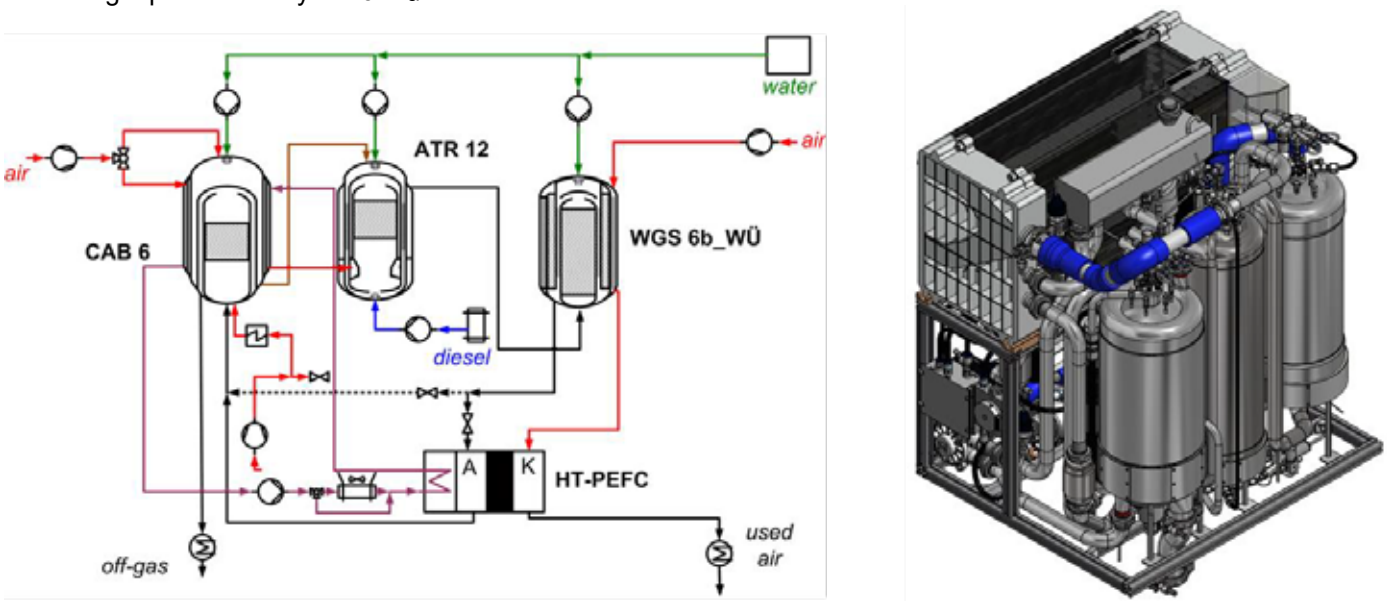
INTRODUCTION

This study focuses on the development process of a compact fuel cell system using a combination of autothermal diesel reforming and high-temperature PEFC technologies. The motivation for such a system is to extend the availability of the fuel cell technology for areas in which it is hard to realize a hydrogen infrastructure. Today, the wide availability of diesel and jet fuels makes such a system concept attractive for mobile and distributed power supply. In the future, synthetic fuels from biomass or hydrogen produced from renewable electricity can be utilized. The proof-of-concept was already demonstrated in a first generation with an integrated 5 kW_e system [1]. The current development, however aims to achieve the power density and start-up time targets of U.S. DOE for diesel-based fuel cell auxiliary power units (APU). According to these targets, the complete fuel cell APU must show a minimum power density of 40 W_e/l and 30 min start time [2]. Despite the big progress in diesel reforming in the recent years [3-6], a fuel cell operated on diesel reformate brings a high level of challenges on the systems level [7, 8]. The main issues are start-up, load change, shutdown as well as stability and the overall complexity of the process. Here, we firstly present the system layout and its final design. In the second part, we report on results from preparatory experiments from the fuel processing system.

SYSTEM LAYOUT AND DESIGN

To achieve a compact fuel cell system, multifunctional fuel processing reactors were developed. According to this approach, several system functions are integrated in the reactors of the fuel processing system. In addition to its main function of producing a hydrogen rich reformate, the reformer also includes a superheater, a mixer for producing a saturated steam for further heat exchange and an electrical heating wire for the start. The shift reactor can on one side reduce the CO content of the reformate to ideally 1% in two stages placed under a single reactor shell before the stack inlet. On the other side the reactor includes components such as evaporation cooling between stages, an electrical heating wire and a heat exchanger to cool the reformate and heat the cathode air before the stack inlets. Finally, the catalytic burner has the function of combusting the remaining H_2, CO and CH_4 present in the anode off-gas during normal operation and system start. In addition to its main function, this reactor also includes several heat exchangers in order to pre-heat the reforming air, superheat a big share of reforming water and heat up the heat transfer fluid to heat the fuel cell during start-up. Additionally, a glow plug is integrated in this reactor for start-up. The system layout presented in Fig. 1 (left side) shows the above-explained system design approach together with the conceptual design of the reactors. On the right hand side, Fig. 1 shows the 3D design of the system including the fuel processing system, the fuel cell stacks and the balance of plant components. Two HT-PEFC fuel cell stacks are used in the system, which are originally designed for commercial methanol-fueled systems [9]. In order to combine both stacks effectively, manifold plates were developed and optimized with CFD simulations, and finally produced via laser-additive manufacturing. The balance of plant components include turbo-compressors, pressure sensors, a micro diesel pump, diaphragm pumps, flow meters, check valves, relief valves, filters, coolers, a peripheral pump, fluid reservoirs and further valves. Following

a tight packaging approach analogous to automotive architectures, the APU volume could be restricted to 187.5 l. Based on the previous experience with similar stack technology, a power output of 7.5 kW_e is expected. These figures result in the target power density of 40 W_e/l.



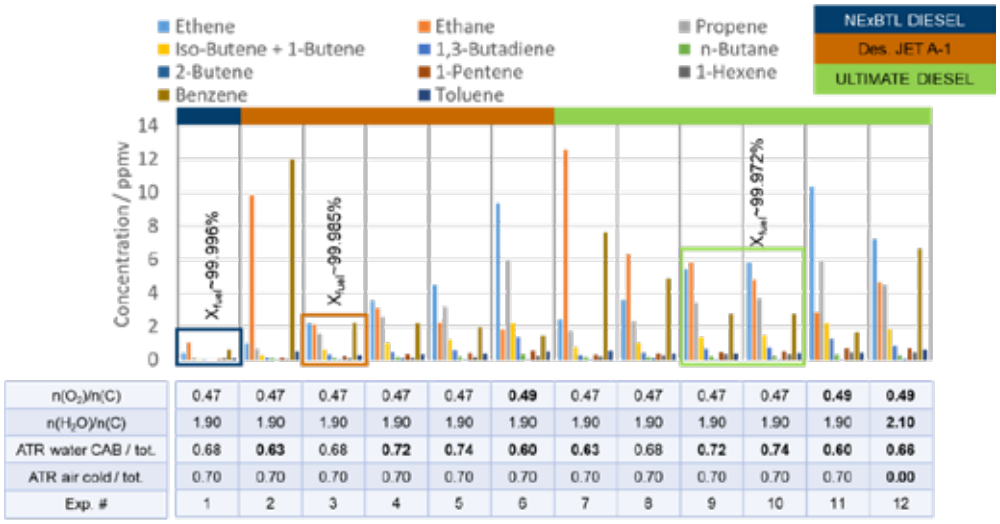


Fig. 1. System layout and CAD design of the HT-PEFC system in the 7.5 kW_e power class including the diesel fuel processor and the balance of plant components.

RESULTS AND DISCUSSION

In preparatory experiments, several system aspects were tested, validated and optimized. One challenge of the system was to identify the best operation parameters with various fuels to maximize the fuel conversion on one side and to keep the CO content at the target level of < 1% at the anode inlet on the other side. For this purpose, various fossil-based and non-fossil based diesel and kerosene fuels including desulphurized Jet A-1, NExBTL diesel and Aral Ultimate diesel were utilized. Fig. 2 shows the results from 12 experiments focusing on the undesired by-products at the reformer outlet using different fuels and operation parameters. In all of the experiments, the reformer was operated at 100% load with 2.7 kg h^{-1} fuel and the CO content could be kept below the target. Due to the high level of system integration, all reactors are thermally coupled with each other. The reformer can however be considered as the key component of the system since it defines the main control parameters, which are the molar O_2/C ratio and the H_2O/C ratio. In addition, two additional ratios must be tuned, which influence the reformer - catalytic burner coupling and the reformer - shift reactor coupling. The first one is the ratio of water superheated in the burner to the total amount of water used for reforming. Higher ratios increase the temperature level in the reformer, which can have a positive effect on the reforming processes, but simultaneously the inlet temperature of the shift reactor increases, which might be negative for achieving the target CO level in the shift steps. The second is the ratio of cold air feed to the reformer to the total amount of reforming air. Since the remaining part of air is pre-heated to the same temperature with steam in the reformer, higher ratios lead to the opposite effect compared to the first case. Using NExBTL diesel, it was possible to achieve a very high conversion level in the reformer with all by-products below 2 ppmv. A switch to desulphurized Jet A-1 showed a very slight increase in the by-products with the same operation parameters, where ethane, ethene and benzene concentrations reached the 2 ppmv level. Still, further experiments were performed to check, if even lower concentrations can be achieved. Operation with lower heat input to the ATR with a reduced share of superheated steam (exp. 2) led to a sharp increase in ethane and benzene concentrations. Higher heat input (exp. 4&5) led to lower concentrations, which were however not better than those with standard parameters (exp. 3). Operation with higher oxygen to carbon ratio (exp. 6) did not lead to a better performance. After switching to Ultimate diesel, the same parameters were applied in experiments 7 – 11 as in experiments 2 – 6. The overall trend being the same, Fig. 2 shows that the measured concentrations are higher than those with desulphurized Jet A-1. The lowest concentrations were observed in experiments 9 and 10. Therefore, it can be concluded that the higher heat input to ATR had a positive effect in this case. A stronger increase in terms of increasing the O_2/C ratio in exp. 11 or even increasing the H_2O/C ratio and pre-heating the complete reforming air in exp. 12 did not improve the conversion further. As a result, experiments 1 (NExBTL), 3 (Jet A-1) and 9 and 10 (Ultimate), resulted in the parameter combinations leading to maximum conversion with each fuel used.

CONCLUSIONS

In this work, the design of a compact fuel processor based on diesel reforming and high-temperature polymer electrolyte fuel cells was presented. Furthermore, results from preparatory experiments with the fuel processing system were shown.

The focus of the system design was given to achieving the power density and start-up time targets defined by U.S. DOE. After a high-level engineering of the complete system components, it was possible to design and manufacture a 7.5 kW_e system including all balance of plant components at a volume of 187.5 l achieving the target power density. Parallel to system design, operation parameters were optimized using various fuels. It was possible to identify proper operating parameters, which led to a very high fuel conversion of > 99.95% at full load, at the same time keeping CO content at the shift outlet < 1% for stable operation of a HT-PEFC with reformate gas. As the next step, the developed fuel cell system was characterized. The results from the operation of the complete system using renewable diesel fuel will be presented in the conference talk, with a focus on achieved power density and start-up time compared with the DOE targets.

ON THE ORIGIN OF FUEL-CELL CATALYST-LAYER LOCAL RESISTANCES

*A. Chowdhury, S. A. Berlinger J. Petrovick, A. Kusoglu, C. J. Radke, and A. Z. Weber**

ABSTRACT

To achieve high mass activity at low platinum loading, the local transport resistance endemic to polymer-electrolyte fuel cells must be ameliorated. This transport resistance is intimately linked to interactions between and within the proton-conducting polymer (ionomer) and the metal electrocatalyst in the porous catalyst layers. In this talk, the origin and impact of this resistance will be discussed. Specifically, both *in-situ* measurements using limiting current and *ex-situ* ones using a novel microelectrode setup and other techniques will discussed. Such studies provide a holistic view of the resistance components including interfacial effects and transport phenomena. Finally, discussion on the origin of these resistances during catalyst-layer formation and ink processing will be detailed. Throughout, theory will compliment the experimental studies, and various mitigation pathways to decrease the local resistance will be suggested.

Keywords: Fuel cell, resistance, transport phenomena, ionomer, microelectrode

INTRODUCTION

To commercialize successfully polymer-electrolyte fuel cells (PEFCs), the cost must be reduced without sacrificing performance and lifetime. Such cost reductions come about through simplification of balance of plant, increasing cell and stack durability and lifetime, improving cell performance. Of particular importance reducing the amount of the relatively expensive platinum-group-metal (PGM) catalysts [1]. As discussed previously, it is thought that current architectures and materials reach a limit, below which unacceptable performance losses are realized as the PGM loading is decreased [2]. This limit is believed to be due to interactions at the local level where the thin-film proton-conducting polymer (i.e., ionomer) interacts and covers the electrocatalyst particles composed of nanoparticles of Pt on larger carbon particles. These interactions including restricted reactant gas permeation through the ionomer thin-film [3] as well as adsorption and poisoning of Pt sites by the sulfonic-acid moieties endemic in the ionomer.

To quantify the local catalyst-layer resistance and its constituents, there are various methods that have been used. These approaches include analyses on both catalyst layers as well as with model systems. For the former, limiting-current analysis using both hydrogen and oxygen have been implemented. For the latter, ionomer thin-film studies in terms of structure/function relationships have been conducted using planar substrates and microelectrodes. Microelectrodes are sub-milometer electrodes that allow well-defined electrochemical measurements to be performed in a non-liquid (that is, a humidified solid ionomer) electrolyte environment.

In this work, multiple techniques will be used to explore the impact and origin of the local transport resistances in standard fuel-cell electrodes. In addition, a novel microelectrode setup will be described that overcomes several existing limitations in the literature.

EXPERIMENTAL

For this study, Nafion or 3M ionomers were used at different equivalent weights (EWs) to investigate the effect of sidechain density and sidechain length. Vulcan XC72 Pt/C was used as the catalyst.

All electrochemical cell measurements (ECSA, CO displacement, polarization, etc.) were performed with an SP-150 potentiostat with a low current card (Bio-Logic, France). Gases were fed and humidified using a fuel-cell test stand, which also controlled temperature. CL transport resistance was estimated from limiting current measurements using the H_2-pump setup and test protocol as described in [4] using 2% or 1000 ppm H_2 or D_2 in Ar.

Model studies were conducted using analogs of the catalyst-layer interfaces including casting ionomer solutions onto planar platinum and silicon substrates to perform QCM-D, GISAXS, ellipsometry, and conductivity. In addition, solutions were analyzed for properties using isothermal titration calorimetry (ITC), DLS, and zeta potential. Finally, a microelectrode cell was designed and used for permeation experiments through the thin films using a 50-µm platinum microelectrode and small cell heated compartment.

RESULTS AND DISCUSSION

Figure 1 shows the catalyst-layer gas-transport resistance as a function of ionomer:carbon ratio measured from H_2 pump for different ionomer EWs. At low Pt loadings, as was maintained for the examined samples, CL gas transport resistance is mainly due to local transport resistance caused by the ionomer thin film. Thus, the linear increase in gas-transport resistance with ionomer content for the measured samples can be attributed to increased transport resistance through thicker ionomer thin-films that form due to the presence of more ionomer.

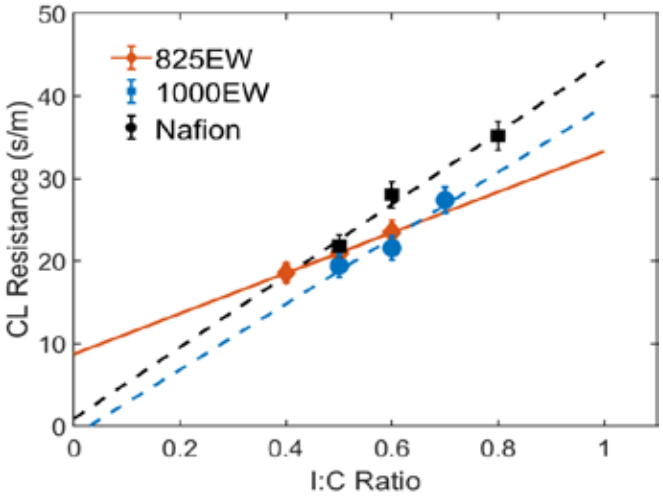

Figure 1. Catalyst layer resistance from limiting current experiments for three different equivalent weight ionomers as a function of ionomer:carbon ratio.

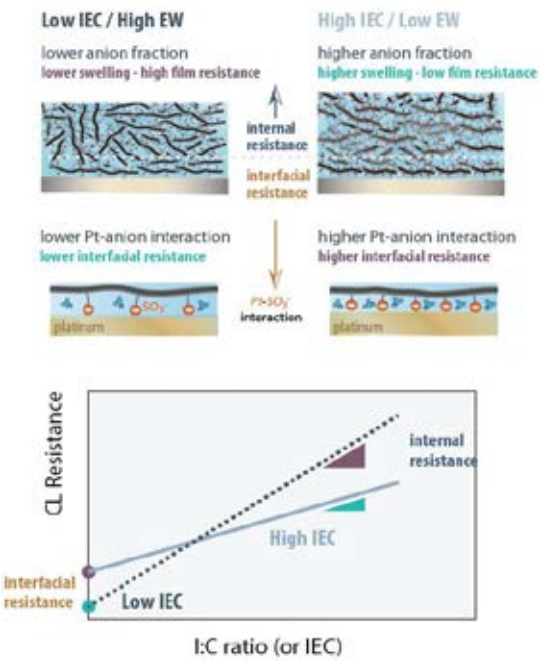

Figure 2. Schematic of resistance interpretation for different ionomer equivalent weights in terms of interfacial and bulk transport components.

Utilizing the analytical model developed by Schuler et al. [4], we divide the overall CL gas-transport resistance into transport and interfacial components. The transport component is due to gas transport through the ionomer thin-film, while the interfacial component is due to catalyst poisoning from sulfonate/Pt interactions. The interfacial resistance is proportional to the intercept and the slope is proportional to transport resistance (i.e, inversely proportional to permeability). Low EW ionomer samples demonstrate higher interfacial resistance and lower

transport resistance indicating more surface interactions and higher gas permeability, respectively. These results agree with model compound trends in that thinner films demonstrate a more structured morphology and lower permeabilities and lower water uptake as measured by the *ex-situ* studies. Similarly, the lower EW samples exhibited sharper morphology in GISAXS, again indicating more ordering and interactions that track with the higher interfacial resistance. Figure 2 shows schematically these trends and explains the experimental observation.

CONCLUSIONS

In this work, both ex-situ model studies of ionomer thin films and in-situ cell studies demonstrate that the local mass-transport resistances at low loadings depend on the ionomer chemistry and are comprised of both a transport dominated by gas permeation and an interfacial components dominated by interactions between the sulfonic-acid moieties and the platinum surface. It is shown that lower equivalent weights cause higher interfacial and lower transport constituents of the local resistance. Furthermore, these interactions are due to ionomer morphology that is a function of the original solvent environment during catalyst-layer formation.

ABSTRACT

In order to study thermal management influence on the performance od 1kW edge-cooled proton exchange membrane fuel cell stack without external humidification comprehensive numerical analyses are conducted. Two numerical approaches are considered and compared for a prescribed load profile: (i) lumped model and novel (ii) real-time transient computational fluid dynamics model incorporating realistic modeling of forced air convection on the edge-cooling of the stack. The developed computational fluid dynamics model is used to study the influence of (i) bipolar plate materials (ii) operating delta pressure along the flow field and (iii) different cooling fin configurations on the water and heat balance inside the stack. The results indicate that (i) maximal and average temperatures of the stack are almost linearly correlated to the thermal conductivity of bipolar plate materials and maximal temperatures can be significantly higher (ii) the operating delta pressure can be manipulated to increase the performance of the stack and (iii) the cooling fin redesign has major influence on the overall temperature uniformity across the stack. Additionally, the heat transfer between the stack and metal hydride tank is studied.

Keywords: PEM fuel cell, Portable stack, Water and heat management

INTRODUCTION

Air-cooled proton exchange membrane (PEM) fuel cell stacks are gaining momentum as power sources for portable applications such as electric bikes, unmanned aerial vehicles (UAVs), forklifts, etc. Usually the power of portable stacks (PS) is up to several kW [1,2]. Most of the heat generated during PS operation is dissipated into the surrounding atmosphere via forced air convection along the cooling channels or edge-cooling fins, while the higher power stacks require liquid cooling. The emphasis during the design phase of PS is primarily directed towards determining the most suitable material for bipolar plates and the accompanying thermal management. Some of the thermal management objectives are: (i) ensuring the appropriate heat transfer from the stack during startup, i.e. accurately determining the required convection flow rate, to achieve sufficiently high operating temperature from startup at ambient temperature, thus preventing flooding (occurring if the flow rate is high and temperature of the stack is low) or membrane dehydration (occurring if the flow rate is low and temperature inside the stack is high); (ii) ensuring sufficiently high heat removal rates via forced air convection during the operation characterized by stable temperature of the stack, i.e. loosely termed steady-state operation; (iii) ensuring as low as possible temperature difference between the inside and outside portions of the stack by choosing the materials with favorable thermal properties; (iv) properly design the stack and edge-cooling fins to ensure sufficiently high heat removal rates; (v) design the frame for the stack which will ensure that the cooling air is directed to uniformly flow along the edge-cooling fins. In previous studies [3,4] it was shown that the operating temperature inside PEM fuel cell is highly non-uniform and it is not accurate to represent the operating temperature with just one parameter, while at the same time if the temperature profile is controlled it can be exploited to result in high performance of the cell by manipulating the water vapor saturation profile, i.e. relative humidity profile inside the cell. The main contributions of this work to the research field are evident in outlining that the commonly used lumped models can be misleading for dynamic analysis of PEM fuel cell performance due to inability to accurately calculate the maximal temperature inside the stack and this work also outlines under which circumstances the lumped models can be used. This work also presents a novel transient CFD model for analysis of thermal management of PS which gives insight in mass and heat transfer both inside and outside of the cell (internal heat and mass transfer and forced air convection edge-cooling), while other works focus on only one aspect and simplify the other to a significant extent.

MATERIALS AND METHODS

The stack used in this study, Figure 1, was developed by Proton Energy Systems. The stack displays many innovative features including in-flow configuration, cooling and stack clamping. It consists of 60 cells, each with an active area of 65 cm^2. The design is rectangular with 10:1 aspect ratio to allow for efficient heat conduction of the edge of the cells, where fins are extended for cooling.

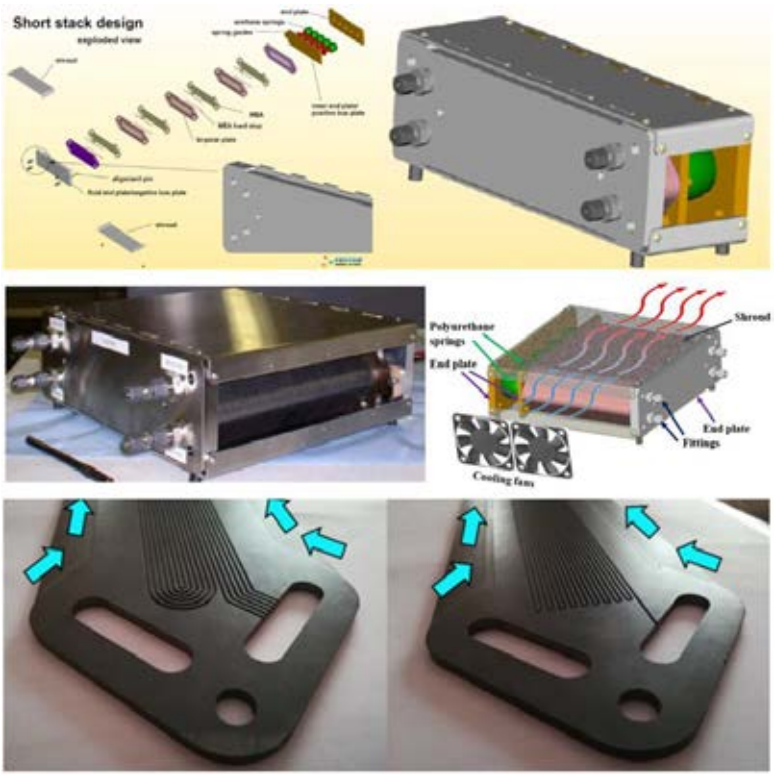

Figure 1. Above: Proton Energy System's short stack exploded view (left) with annotated parts and assembly (right); Middle: Proton Energy System's 1-kW fuel-cell stack (left) and transparent shroud assembly (right); Below: Cathode (left) and anode (right) flow fields with annotated air-coolant flow direction along the edge-cooling fins.

The bipolar plates including the fins are fabricated from a molded polymer/graphite mixture (made by SGL Carbon) with effective thermal conductivity of 20 W m^{-1} K^{-1}. The stack is cooled by air flow along the longer edge of the cells where the fins are located.

RESULTS AND DISCUSSION

The results of the lumped model and CFD analysis are shown in Figure [5]. The cell temperature increases from ambient to steady-state shows similar trends, although the lumped model predicts slightly lower steady-state temperature. The CFD data also indicates that the temperature fluctuations are always present due to the unsteady nature of the flow and modeling of the air as ideal gas, resulting in convective flow and vortex genesis in the wake region behind the stack. The temperature decrease after 5500 s reaches higher minimal value in the CFD model vs. lumped model, and after increasing the current the temperature oscillations of the CFD model are more severe and it can be noted that the steady-state predicted by the lumped model near ca. 10000 s is not yet steady-state when CFD model is observed. The highest difference between the lumped model vs. CFD model is evident after 10000 seconds by comparing the 3 cases. For case (i) the steady-state temperature of the cell in the CFD model is decreased at a slower rate when compared to the lumped model and converges to a significantly higher steady-state value (by ca. 10 °C), and similarly also in case (ii). In case (iii) the fan must be turned on and off approx. 6 times more frequent to keep the stack temperature between the 55 and 60 °C range. The differences are a result of directly calculating the heat transfer coefficient in the CFD analysis vs. fixing the value in the lumped model and a result of modeling the complex flow involving air as ideal gas in the CFD model. Regardless of the differences, it can be noted that the average temperatures predicted by the lumped model and time to reach steady-state are reasonably well predicted by the lumped model but the CFD model is more physically valid therefore it will be used in the following chapters for more detailed analysis.

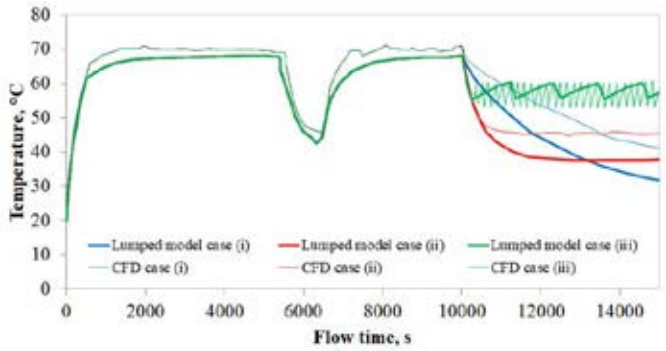

Figure 2. History of cell temperature: lumped model vs. CFD for cases (i), (ii) and (iii).

CONCLUSIONS

The following conclusions are drawn from this work:
(i) although commonly used, the lumped model is not accurate for predicting the temperature of the edge-cooled stacks due to the capability for only predicting the average temperature of the stack, while the maximal temperature can be several tens of degrees higher inside the stack when materials with low thermal conductivity are used, thus leading to severe dehydration of the membrane; (ii) by comparing the average and maximal temperature of the stack for different bipolar plate materials, it can be seen that the outside temperature of the stack is quite similar for graphite (thermal conductivity 20 W m^{-1} K^{-1}) and nickel (thermal conductivity 91.74 W m^{-1} K^{-1}), i.e. 57.53 °C vs 52.41 °C, respectively, during steady-state operation, while the internal maximal temperature of the stack is significantly different (77.36 °C vs. 58.29 °C, respectively), indicating the requirement for carefully determining the appropriate material to be used for production of bipolar plates for edge-cooled stacks; (iii) higher pressure drop along the flow field can be used as a supplementary method for achieving higher performance of the stack since the water vapor saturation profile is pressure-dependent, or the whole stack can be operated at elevated pressure to increase the performance;
(iv) the edge-cooling fin geometry has significant influence on the overall temperature distribution, by redesigning the edge-cooling fins the maximal temperature and average temperature of the stack was reduced from 77.60 °C and 57.53 °C to 63.55 °C and 46.57 °C, respectively, indicating the necessity for careful design of the flow distributors for edge-cooling portable stacks; (v) the developed CFD model can also be used to study the heat transfer between the stack and MH tank. Although the heat generated by the stack was not sufficient to release the required mass flow rate of hydrogen for stack operation at 1 kW power, which was also experimentally demonstrated using similar power air-cooled stack (Nexa 1.2 kW) where 3 MH tanks were used and in that case it was possible to release the required amount of hydrogen from the tanks.

ABSTRACT

In the present study, sulfonated silica (S-SiO_2) nanoparticles (NPs) which are cheap and stable at low humidity are synthesized and employed in electrode structure of PEM fuel cell. Here, electrospinning is utilized to prepare hybrid fiber PEM fuel cell electrodes containing commercial Pt/C catalyst and S-SiO_2 NPs with poly(vinylidene fluoride) (PVDF) and poly(vinylidene fluoride-*co*-trifluoroethylene) (PVDF-TrFE) binders (carrier polymers). The morphology of electrospun electrodes have been investigated by scanning electron microscopy (SEM) to determine optimum electrospinning conditions to achieve a uniform Pt/C and S-SiO_2 NPs distribution on carrier polymer and fiber thickness. Consequently, catalyst distribution along the nanofibers have also been investigated by transmission electron microscopy (TEM). Moreover, sprayed electrodes are prepared and morphology of electrospun and sprayed electrodes are compared. After obtaining fiber-based hybrid and sprayed electrodes, membrane electrode assemblies (MEA) are prepared and fuel cell tests are performed with using H_2/air at different humidity. In-situ cyclic voltammetry (CV) and impedance analysis have also been performed. These novel electrospun hybrid electrodes possess not only superior PEM fuel cell performance compared to sprayed electrodes but also better performance at low humidity.

Keywords: Electrospinning, Catalyst layer, Electrode, Sulfonated silica, PEM fuel cells

INTRODUCTION

Polymer electrolyte membrane (PEM) fuel cells draw great attention due to their clean operation, high power density and efficiency, compactness and fast start-up and response times [1]. Membrane electrode assembly (MEA) is the heart of the PEM fuel cells. Therefore, development of MEA design and materials is one of the most important research areas. The two main problems of MEA are: i) commonly used perfluorosulfonic acid based membrane/ionomer (commercial Nafion® membrane/ionomer)is very expensive, its ionic conductivity is strongly based on humidity of environment, degrades easily under low humidity conditions; ii) platinum (Pt) which is used as a catalyst in electrode structure is very expensive and its reserves are limited. For that reasons, there are barriers to commercialization of PEM fuel cells. Therefore, development of electrodes with low-Pt loading, non-Pt group metal (non-PGM) catalysts, and alternative hydrocarbon-based/inorganic ionomers has gained growing attention in the past few decades [2, 3]. Compared to other inorganic ionomers, sulfonated silica provides higher surface area, water retention and proton conductivity, even if used very little in the electrode structure [4].

In recent years, electrospinning is frequently used technique to produce nanomaterials especially in the field of energy (for examples; solar cells, fuel cells, lithium ion batteries, lithium sulfur batteries, supercapacitors) [5]. Electrospinning is also a promising technique for creating nanostructured fuel cell electrodes with superior catalyst utilization and long-term durability [6,7]. This technique provides enhancement of the triple phase interface where electrochemical reactions occurred at active catalyst site.

Herein, we report novel hybrid PEM fuel cell electrodes fabricated to provide better Pt utilization and improved water management via electrospinning and sulfonated silica ionomer. Our experiments focused on determining the effects of electrospinning ink composition, carrier polymer, and nanofiber diameter on catalytic activity and fuel cell power output.

MATERIALS AND METHODS

Materials

Johnson Matthey HiSpec 4000 (40% Pt on Vulcan carbon) catalyst was used for all electrodes. High molecular weight (Solef®, Mw = 380,000) polyvinylidene fluoride (PVDF) powder was purchased from Solvay. PVDF-TrFE with 70/30

mol composition powder purchased from PolyK Technologies, LLC. All solvents (Dimethylformamide, acetone, tetrahydrofuran, dimethylacetamide) were supplied from Sigma-Aldrich. Nafion® NR212 membrane and Sigracet 39BC GDL were obtained from FuelCellStore.

Methods

The electrospinning ink was prepared via a facile method in which the DMAc is first added to Pt/C catalyst followed by bath sonication. Afterwards, acetone and sulfonated silica were added to the ink followed by another bath sonication while stirring it intermittently to obtain a homogeneous ink. Finally, the previously prepared carrier polymer solution was added to the ink and the final ink solution was stirred overnight. Tab. 1 shows summary of ink and electrode composition. After preparation of ink, it was loaded into a 5 mL syringe and was electrospun onto the collecting drum collector. Fig.1 shows schematic of electrospinning setup used in experiments. The obtained fiber material was then pealed for further morphological and electrochemical analysis.

MEAs were fabricated using 5 cm^2 electrospun electrodes as a cathode, and sprayed electrodes as an anode (0.1 and 0.2 mg_{pt}/cm^2 loading). Commercial Nafion®212 membrane was located these two electrodes and hot pressed 5 min. hot pressed at 133 °C.

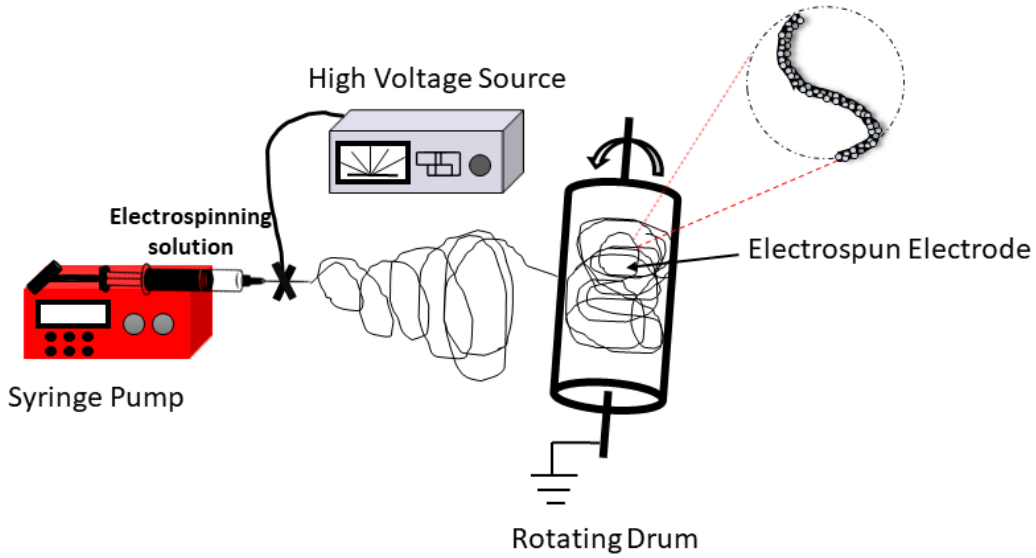

Fig. 1. Schematic diagram of electrospinning set-up and electrospun electrode preparation

Table 1. Summary of ink and electrospun electrode composition

INK	BINDER	Total Solid Ratio Wt. %	ELECTRODE COMPOSITION Wt. %

RESULTS AND DISCUSSION

Morphology of electrospun electrodes are investigated by SEM. Fig. 2.a shows the SEM image of 65Pt/C/20PVDF/15S-SiO_2 (Ink 2) electropun electrode and Fig. 2.b. 65Pt/C/20PVDF-TrFE/15S-SiO_2 (Ink 6). It can be depicted that Pt/C and S-SiO_2 NPs well distributed along the PVDF and PVDF-TrFE carrier. The average fiber diameter is 510 nm for PVDF and 520 nm for PVDF-TrFE carrier.

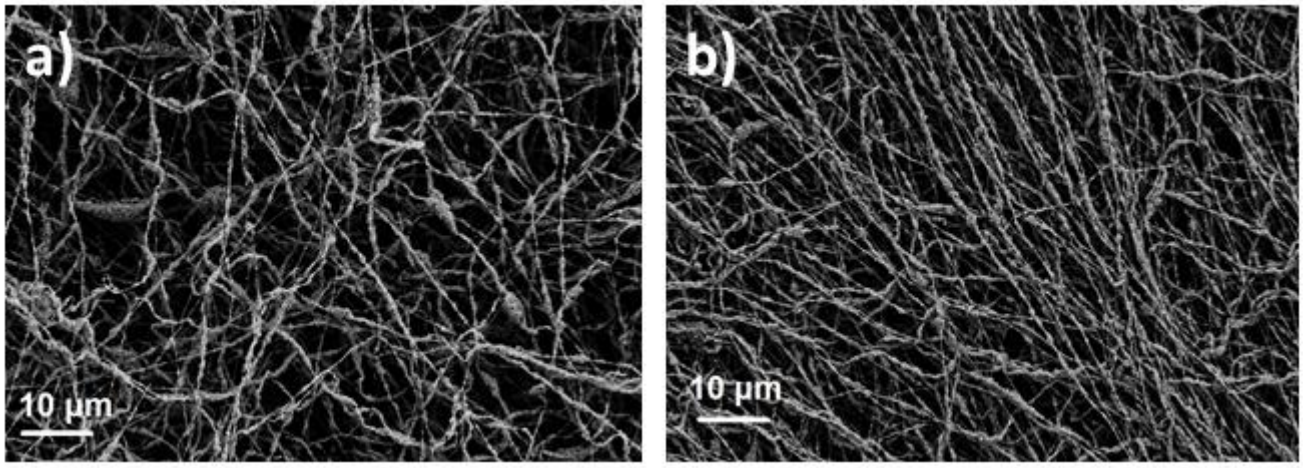

Fig. 2. SEM images of electrospun a) Pt/C/S-SiO_2/PVDF, and b) Pt/C/S-SiO_2/PVDF-TrFE electrodes

CONCLUSIONS

In conclusion, electrospun Pt/C/S-SiO_2/PVDF, and Pt/C/S-SiO_2/PVDF-TrFE electrodes were fabricated, characterized and tested in PEM fuel cell for the first time in literature. Electrospinning is a powerful, robust, and effective technique for fabricating high-performance PEM fuel cell electrode with Pt/C catalyst and S-SiO_2 particles. Optimization of electrospinning solution (solvent, polymer, ionomer (S-SiO_2) amount), and setup parameters (flow rate, voltage, humidity) are crucial to obtain porous and uniform catalyst layers. Carrier polymer type and amount in electrospinning solution are also very important to obtain uniform fiber network, and relatedly high-power output during PEM fuel cell operation. According to obtained result, electrospun Pt/C/S-SiO_2/PVDF and Pt/C/S-SiO_2/PVDF-TrFE show superior electrochemical activity and fuel cell performance compared to sprayed electrode. Moreover, utilization of S-SiO_2 as an ionomer, provides better performance at lower humidity during fuel cell testing. The outstanding performance of electrospun electrodes arise from uniform distribution of Pt/C catalyst, high catalytic activity, and better proton and reactant gas transport to the catalysts during fuel cell operation.

ABSTRACT

The catalysts for fuel cells, based on the platinum-decorated polypyrrolle nanotubes were synthesized. The structure, element contents, electrochemical surface areas of the catalysts' nanoparticles were investigated using TEM, EDX, XPS, RDE analysis. Using obtained catalysts, the catalyst-coated membranes were prepared by ultrasonic spraying techniques. The performance, electrochemical surface areas, high frequency resistance and durability of the CCMs were tested in proton exchange fuel cells.

Keywords: fuel cells, polypyrrolle nanotubes, platinum nanoparticles, performance, durability.

INTRODUCTION

The renewable and clean energy, including fuel cell (FCs) technologies, is very important and promising direction for nowadays [1]. One of the most crucial parts of the fuel cells is catalysts. In this field there are two main tendencies. One of them is decreasing of amount of platinum group metal catalysts [2]. Nevertheless, platinum or platinum-contained catalysts still are the most effective in electrochemical reaction in fuel cells. Other direction is finding durable and stable catalysts' supports. Now, the most popular support for catalysts is carbon, which is lightweight and cheap, but unstable under electrochemical potential. It is lead to low durability and limited working period of the catalysts [2, 3].

In our work we propose to use polypyrrole nanotubes (PPy NTs) as a supports for catalysts for proton exchange membrane FCs. The ordered structure, as well as the presence of nitrogen atoms in the PPy NTs could increase the durability of such type of the catalysts during the *in situ* test in real fuel cells. Moreover, it is also possible to increase the utilization of the platinum, which will lead to the decreasing of metal loading.

EXPERIMENTAL

PPy NTs were synthesized as described in [4]. Pt nanoparticles were deposited on PPy NTs by solvothermal method using ethylene glycol (EG) as the reducing agent. PPy NTs with calculated amount of H_2PtCl_6 precursor and polyvinylpyrrolidone (PVP) as capping agent were ultrasonicated in EG by ultrasound probe (Sonopuls HD 3100, Germany) for 10 min at 20 kHz to obtain the homogeneous dispersion. Than the mixture was added to the reactor and heated at 160 °C under continuous stirring during 1 h. After cooling to the room temperature the dispersion was centrifugated, cleaned with a plenty of water and dried at 60 °C.

RESULTS AND DISCUSSION

The structure of the platinum-decorated PPy NTs was investigated using TEM measurements. As you can see from fig. 1, the PPy NTs are decorated with Pt NPs homogeneously. The size of the precipitated Pt NPs is equal 3-6 nm.

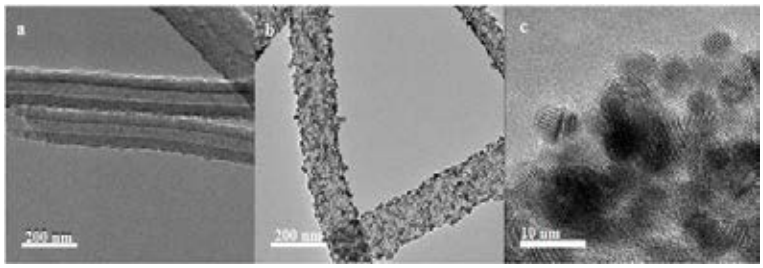

Fig. 1. TEM images of the PPy NTs (a) and Pt-decorated PPy NTs (b, c).

The amount of Pt on the PPy NTs-Pt NPs according EDX analysis is equal 24.4 $\%_{wt.}$

The porous structure and the specific surface areas of the NPs were measured using N_2 adsorption/desorption analysis (Table 1).

Table 1. Microporous and mesoporous structure of the PPy NTs and Pt-decorated PPy NTs according to the N_2 adsorption/desorption analysis.

Samples	BJH from desorption		Gurvich	BET		DR	
	S_{cumul}	D	V_{tot}	V_m	S_{BET}	V_m	V_{micro}
	m^2/g	nm	cm^3/g	cm^3/g	m^2/g	cm^3/g	cm^3/g
PPy NTs	43.91	4.03	0.1608	7.9391	34.6	8.7475	0.0135
PPy NTs-Pt	22.16	3.81	0.0598	1.4907	6.5	1.3625	0.0021

As you can see (Table 1), both PPy NTs and PPy NTs-Pt have both macro and mesopores. However, after decoration of PPy NTs with Pt nanoparticles all parameters, which characterized porous structure and surface of the materials significantly decrease. It is connected with possible precipitation of the Pt NPs on the surface's roughness, such as pores.

The electrochemical activity of the synthesized catalyst NPs was measured using rotating disk electrode (RDE) method. The current-voltage (C-V) curve of the Pt catalyst (fig. 2) demonstrates the intensive peak of H_2 desorption with the shape, characterised for polycrystalline Pt [5]. The electrochemical surface area is equal 284 cm^2/mg.

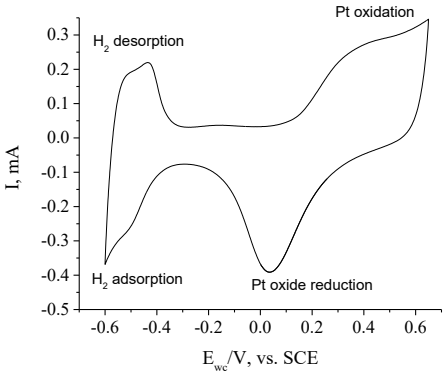

Fig. 2. C-V curve (RDE) of PPy NTs – Pt (speed 50 mV/s, 30 cycles, in N_2-purged 0.5 M H_2SO_4, 25 ^{0}C, range from -0.6 to 0.6 V).

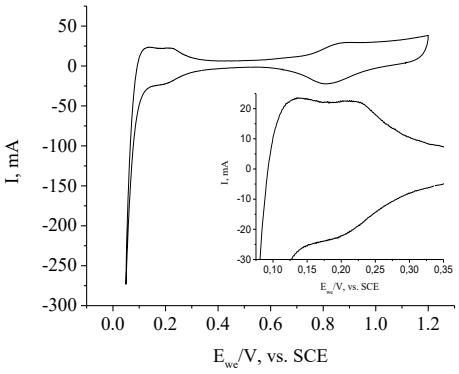

Fig. 3. C-V curve (*in situ* in fuel cell station) of PPy NTs – Pt (speed 50 mV/s, 30 cycles, 70 ^{0}C, 100% RH, N_2/H_2, no backpressure, range from 0 to 1.1 V).

Then the catalytic ink, based on synthesized catalyst, Nafion ionomer and solvents, was prepared. Catalyst-coated membrane (CCM) was prepared by ultrasonic spraying techniques using SonoTek ExactaCoat machine. Nafion® PFSA NR-212 (Chemours, USA) was used as polymer electrolyte membranes. The Pt loading of the cathode was 0.3 $mgPt/cm^2$. The sprayed catalytic layer was covered by GDL (Sigracet 25 BC). 0.3 mg/cm^2 Pt/C 40% on Sigracet 29 BC carbon paper was used as anode. The active area was 4 cm^2.

Prepared CCMs were tested in fuel cell using 3 kW FC testing station (MTM (LC), Czech Republic). Testing in fuel cells were carried out at 70 °c, 100 % relative humidity, 8 bar pressure cell, 0.5/0.5 bar O_2/H_2 or air/H_2 atmosphere, 2/1 or 3/2 stoichiometric value of O_2/H_2 or air/H_2, respectively.

C-V curve *in situ* was measured in fuel cell (fig. 3). The ECSA of the CCMs is 133 cm^2/mg. The power densities are 0.9 and 0.4 W/cm^2 in O_2/H_2 and air/H_2, respectively. It is also possible to improve the CCM performance by

optimization of Nafion ionomer content. Also due to the investigation of the PPy NTs influences on the catalyst's stability, the durability test of the CCM is continuing.

CONCLUSIONS

The Pt-decorated polypyrrole nanotubes were obtained. The catalyst powder demonstrates the high electrochemical activity in half-cell. Using synthesized catalyst, the catalyst-coated membrane was prepared using ultrasonic spraying techniques. The power density and electrochemical surface area of the CCM were measured in the fuel cell station. The performance of the prepared catalysts is equal 0.9 and 0.4 W/cm^2 in O_2/H_2 and air/H_2, respectively. The durability test of the catalysts support is continued.

ABSTRACT

The thermally expanded graphites (TEGs) as fillers for PEM bipolar plates were obtained. The influence of the air and nitrogen atmosphere, as well as the different temperatures on the structure and properties of TEGs were investigated. The morphology, porous structure, chemical composition of the TEGs were analysed using SEM, XRD, BET, EDX, and XPS. It was shown that the obtained TEGs have three times higher electrical conductivity, comparable with commercial graphites. The obtained TEG is used as filler in the preparation of the polymer composites bipolar plates with electrical conductivity reaching DOE targets.

Keywords: Thermally expanded graphite, Carbon fillers, Polymer composites, Bipolar plates, PEM fuel cells

INTRODUCTION

The EU climate challenges for 2030 are to reduce greenhouse gas emissions (basically CO_2) by 40% versus 1990 emissions, raise the share of renewable energy and energy efficiency by 27% [1]. Achieving the Paris Agreement's targets may be accomplished through application of renewable energies using innovative technologies such as fuel cells (FCs). Fuel cells have been developed as a candidate for zero emission and alternative power sources for both mobile and stationary applications. These devices convert chemical energy into electrical energy, water and heat, without any pollutant emission. Moreover, FCs, especially proton exchange membrane FCs (PEM FCs), have been proposed as a power source due to high energy efficiency, high power density, low operating temperature and other advantages [2].

The bipolar plates (BPs) are one of the most important components of fuel cells' technology. The BPs conduct heat and electricity between cells, provide a gas flow field, remove heat and are a physical barrier avoiding the mixing of the oxidant, fuel and coolant fluids [3]. According to *Tsuchiya et al* [4], the BPs account for about 80% of total weight and 45% of the cost of PEM FCs. Developing effective nonporous materials for BPs with high electrical and thermal conductivity, high mechanical and chemical resistivity, etc., is an actual challenge nowadays. In spite of the variants of BPs from different materials such as metal, graphite or composite [3]–[5], it still has many problems with achieving desired properties and reliable production.

The electrically conductive carbon-based polymer composites are promising materials for the creation of BPs for PEM FCs because of such advantages as high stability in acidic solution, high mechanical strength, lightweight, low cost and the chance to mold into different shapes and sizes. Nevertheless, high electrical and thermal conductivity and flexural strength are the main problem which are not completely solved yet. Owing to improve these parameters of BPs it is necessary to prepare high electrically conductive fillers, which will form the conductive channels in the bulk of the polymer matrix. In recent studies, electrically conductive polymer composite BPs have been obtained with such carbon fillers as natural graphite flakes [6], carbon black [7] or from the combination of various fillers such as graphene, carbon fibers and natural graphite [8], etc. But the filling factor for these composites is high and the electrical conductivity does not always reach the DOE targets [9].

In this study, the preparation of the thermally expanded graphites (TEGs) as the high electrically conductive fillers for PEM BPs is investigated. The TEGs' microstructure and the chemical structure are studied by different techniques. Additionally, the polymer composites bipolar plates are prepared using commercial graphite mixed with the obtained TEG.

MATERIALS AND METHODS

Production of the thermally expanded graphites

For TEGs preparation, the expandable graphite flakes (ES 350 F5) were put into the muffle oven either air or N_2 atmosphere for 1 minute. The temperature was varied from 400 to 800ºC (for air atmosphere, because of the oxygen degradation of the materials) or from 600 to 1200ºC (for N_2 atmosphere).

The morphology of the TEG was analyzed using Scanning Electron Microscopy (SEM). The crystalline structure was investigated by Transmission Electron Microscopy (TEM) and X-ray Diffraction (XRD). The chemical content of the elements was determined by energy dispersion X-ray Spectroscopy (EDX), X-ray photoelectron Spectroscopy (XPS) and Fourier-Transform Infrared Spectroscopy (FTIR). For the analysis of specific surface area and porous structure of the TEGs, the nitrogen adsorption was measured using the Brunauer-Emmett-Teller analysis (BET). The resistance (R) of the fillers was measured by impedance spectroscopy (four-point probe measurement arrangement).

Preparation of the polymer composite bipolar plates

The polymer composites are based on epoxy resin and carbon-based powders, as matrix and fillers, respectively. In order to obtain good interaction between the matrix and the fillers, increase the amount of latter, and, as a result, increase the electrical conductivity of the bipolar plates, a solvent is used. After the solvent's evaporation, the hot compression molding is used in order to obtain the polymer composites samples. The electrical conductivity of the polymer composites is analysed using the impedance spectroscopy.

RESULTS AND DISCUSSION

In this section, the influence of different preparation conditions (temperature, atmosphere) of the TEGs on the morphology, the chemical and physical structure and the electrically conductive properties of the fillers will be discussed. SEM images (Fig. 1a-d) show significant differences in the morphology of graphite before (Fig. 1a, b) and after (Fig.1c, d) the thermal treatment. It is possible to see flakes did not change the xy dimensions (0.5 -1 mm) but drastically increased the thickness (from 30-50 µm to more than 3mm).

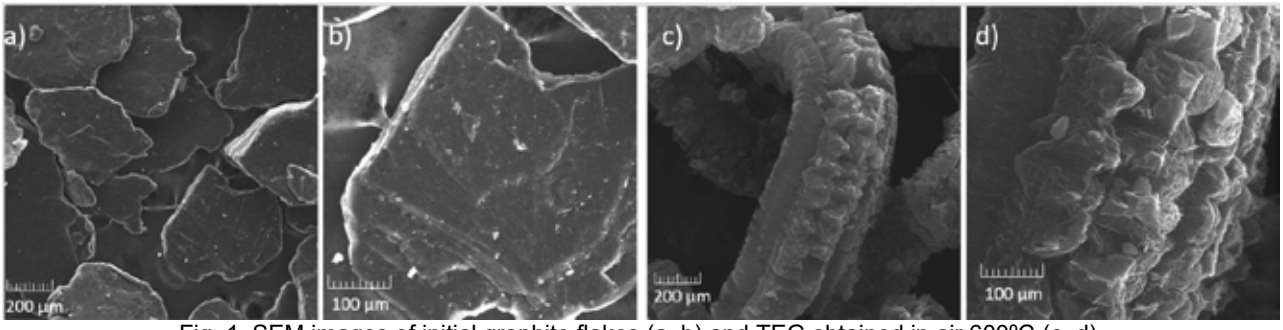

Fig. 1. SEM images of initial graphite flakes (a, b) and TEG obtained in air 600ºC (c, d).

Worth to notice, that the temperature and atmosphere of the TEGs' preparation do not influence on the sizes and shapes of the particles, but it can change their chemical composition.

EDX analyse demonstrate the elemental content in the TEGs, prepared in different conditions (Table 1). Table 1 shows that the amount of Carbon slightly increases but, Oxygen and Sulfur contents decrease for TEGs, comparable with initial graphite flakes. Also, the difference between the samples obtained at the same temperature but different atmosphere is negligible.

Table 1. Chemical composition of graphites before and after thermal treatment in both air and nitrogen atmosphere at different temperatures according EDX.

Samples	C [wt%]	O [wt%]	Na [wt%]	S [wt%]
Expandable graphite	92.29	6.23	0.06	1.43
TEG at 600ºC in air	97.42	1.73	0.34	0.51
TEG at 600ºC in N_2	97.66	1.25	0	0.33

The porosity and average surface area of TEGs were analysed. It was found that the conditions of preparation of TEGs do not influence critically on these parameters. The average surface area of TEGs is equal to 27 m^2/g and a mesopore diameter is around 4 nm.

In the same way as the different conditions of the TEGs' preparation have insignificant changes in the morphology, the electrical conductivity behave similar. The TEGs obtained in air and 600 ºC has 1670 S/cm, meanwhile for the TEG obtained in nitrogen but same temperature, the electrical conductivity is equal 1730 S/cm. For comparison, the electrical conductivity of the commercial graphites is 3 times lower (~500 S/cm) than the conductivity of TEGs.

The polymer composites bipolar plates with own design of flow fields are prepared using epoxy resin and the obtained TEG as filler. The electrical conductivity of prepared BPs reaches the DOE target. The performance of membrane electrode assemblies in prepared BPs is tested in-situ in the fuel cell station.

CONCLUSIONS

Thermally expanded graphites for BPs' preparation were obtained at different temperatures and atmospheres. It was shown that the conditions of TEGs' obtaining have not significant influences on the morphology, the chemical composition nor electrical conductivities of the fillers. The electrical conductivity of the obtained TEGs (1670S/cm) is three times higher than for the commercial graphites. Moreover, due to the high electrical conductivity of TEGs, the polymer composites bipolar plates reach the DOE target in terms of electrical conductivity.

ABSTRACT

Liquid water accumulated in the catalyst layer and gas diffusion layer (GDL) of a polymer electrolyte fuel cell (PEFC, PEMFC) results in performance deterioration due to inhibition of transport of the reactant oxygen in the cathode (Flooding). To enhance the drainage in the GDL, the application of a microporous layer (MPL) is effective to the catalyst layer side of the GDL substrate. To elucidate the effects of two-phase flow on the oxygen transport in an MPL for its optimized designs, we model three-dimensional porous structures of in-house MPLs with pore network model (PNM) for convective air permeation and oxygen diffusion. Pore diameter distribution derived by a focused ion beam scanning electron microscope is employed in the PNM. Air permeation measurements combined with oxygen diffusion measurements with changing liquid saturation by using gas chromatography validate the model.

Keywords: Polymer electrolyte fuel cell, Gas diffusion layer, Microporous layer, Pore network model, Pore diameter distribution

INTRODUCTION

Polymer electrolyte fuel cells (PEFCs, PEMFCs) are promising as zero-emission power sources for future automobiles and houses. However, proper water management among the catalyst layer, gas diffusion layer (GDL), and flow channels of a PEFC is necessary to improve its performance. In particular, excess liquid water is generated in a high current density region. The liquid water may cause clogging in the catalyst layer and GDL, resulting in performance deterioration due to inhibition of transport of the reactant oxygen in the cathode (Flooding). To enhance the drainage in the GDL, the application of a microporous layer (MPL) composed of carbon black (acetylene black) and water repellent polytetrafluoroethylene (PTFE) is effective to the catalyst layer side of the GDL substrate[1][2]. In this research, we focus on mass transfer in the three-dimensional porous structure of MPLs. Pore diameter distributions of our in-house MPLs derived by a focused ion beam scanning electron microscope (FIB-SEM) have been employed in pore network models (PNMs)[3][4][5] with convective air permeation and oxygen diffusion. Gas permeation measurement for air permeabilities as well as gas chromatography for oxygen diffusivities was also carried out to validate the models. Oxygen diffusivities were evaluated for dry MPLs and those with a wetting liquid of different liquid saturations. The aim of this research is thereby to develop reliable and practical numerical models validated with experiments taking into account liquid saturation for the optimized design of the MPLs, elucidating the effects of two-phase flow and water clogging on oxygen transport in an MPL.

MATERIALS AND METHODS

MPL slurries (20wt% PTFE) were applied to GDL substrates (Toray TGP-H-030: 5wt% PTFE) with changing added water amount so that the MPLs have maximum pore diameters, d_{max}, of ca.2 μm, 5 μm, and 15 μm (referred to as Samples A, B, and C, respectively). The porosity of the MPLs was estimated with the Archimedes method by immersing the MPL-coated GDL substrates in a non-volatile wetting liquid (GALWICK, Porous Materials Inc., USA) having a sufficiently small surface tension. Three-dimensional structural analysis of these MPLs was performed using an FIB-SEM to determine pore diameter distribution. PNM models (Open PNM 1.2) constructed based on the porosities and pore diameter distributions gave air permeabilities and oxygen diffusion resistances. In addition, air permeability was measured with the equipment shown in Fig. 1. The air permeability (permeance) was obtained by dividing the air flow rate through a GDL by the air permeation area and the pressure difference (ΔP = 1.2 kPa). Fig. 2 shows an experimental set-up for ex-situ measuring oxygen diffusion resistance in a GDL. Differential pressure in a GDL was minimized by the flow rate of air and nitrogen with a mass flow controller and a pressure gauge during the measurement of oxygen diffusion resistance. Oxygen concentration in outlet gas of the lower channel in Fig. 2 was determined by gas chromatography (GC). Oxygen diffusion resistance in a GDL was obtained by dividing oxygen diffusion flux in a GDL

by the logarithmic mean concentration difference of oxygen between GDL surfaces, given the dimensions of the fixture. On the other hand, for measurement under wet conditions, a GDL fully impregnated with GALWICK was discharged by increasing differential air pressure in a GDL every 20 kPa to reduce liquid saturation from unity because ex-situ control of liquid saturation with GALWICK in hydrophobic pores is more reliable than that with water in terms of equilibrium of forces. Oxygen diffusion resistance was then similarly determined.

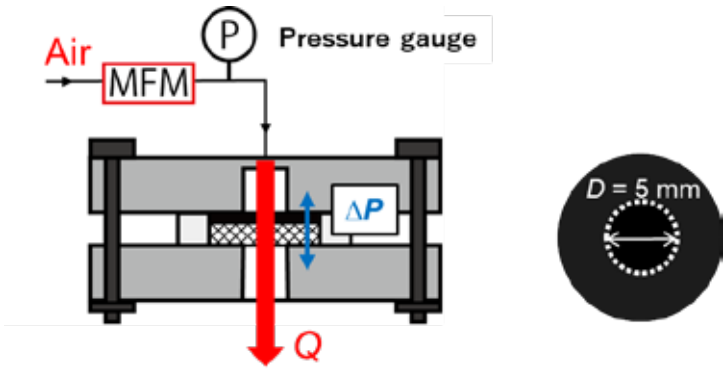

Fig. 1 Schematic of air permeability measurement

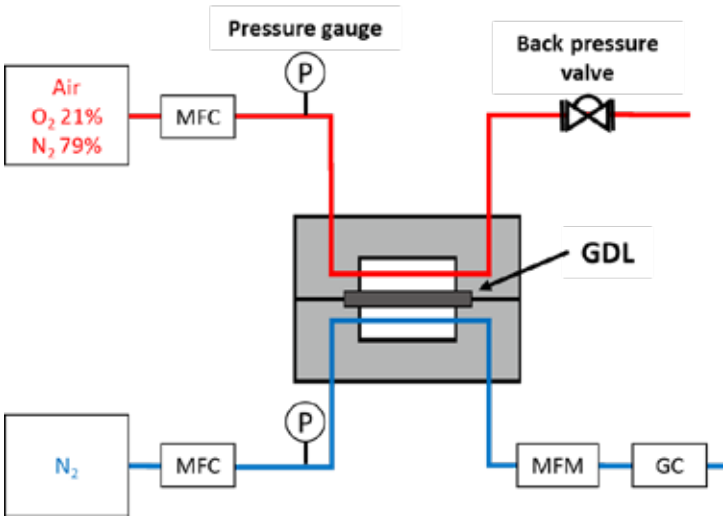

Fig. 2 Schematic of the oxygen diffusivity measurement

RESULTS AND DISCUSSION

Air permeability (permeance) (Fig. 3) and oxygen diffusion resistance of the GDLs under dry conditions derived with the PNM calculation were compared with measured values. PNM of the MPL with the larger maximum pore diameter showed higher air permeability and lower oxygen diffusion resistance, which were consistent with the experiment. On the other hand, in the MPLs impregnated with GALWICK, the oxygen diffusion resistance decreased when the liquid saturation decreased with the discharge of GALWICK. In addition, the pressure at which GALWICK begins to discharge and it is fully discharged (saturation ≈ 0) were both higher for the MPL with the smaller maximum pore diameter. Because these trends were consistent with the experiment, the change in oxygen diffusion resistance with the change in liquid saturation with GALWICK was successfully reproduced by PNM.

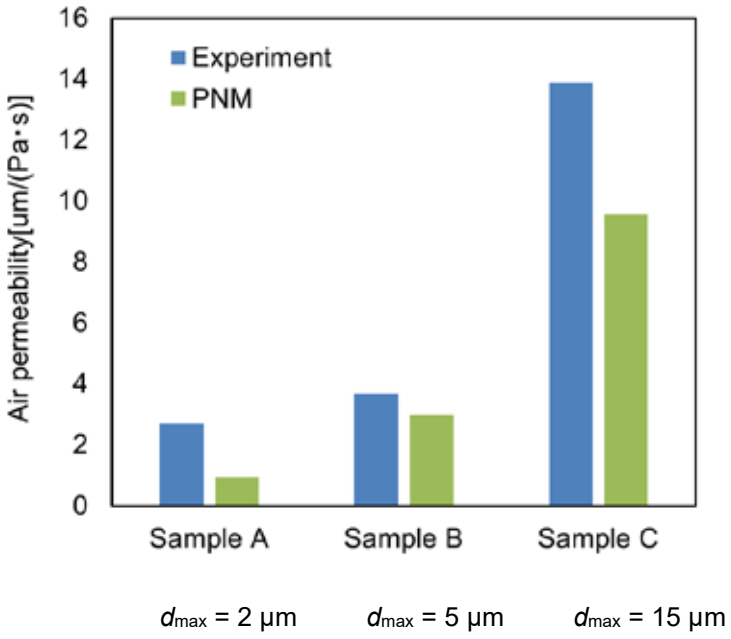

Fig. 3 Air permeability by the PNM calculations and experiments

CONCLUSIONS

Air permeabilities and oxygen diffusion resistances for dry and wet conditions of the MPLs having different pore diameter distributions agree in their trends between PNM and experiment. Thus PNM is validated and useful to model oxygen and water transports in MPLs with employing wettability (contact angle) of the pores. Numerical models with PNM for optimized designs of MPLs are feasible.

ABSTRACT

Cogeneration is the parallel high-efficiency generation of thermal and electrical energy from a single main energy source. It allows the recuperation of lost heat during the generation of power, resulting in 20 to 30% more efficient than independent generation. Recently, among many candidates in micro-cogeneration systems, the PEMFC (proton-exchange membrane fuel cell) represents a promising technology, allowing the use of hydrogen (H2) as a fuel source in the building and outperforming by its higher flexibility and low investment cost. In this article, the behavior of a micro-cogeneration system based on a PEFMC for a 120 m2 inhabited house is studied. This system is used to meet the thermal (DHW and heating) and electrical needs of a family of 3 people which its annual electrical and thermal energy demands are 2607 kWh and 12705 kWh respectively. The system component are a PEMFC cell, a hydrogen boiler, a hydrogen supply circuit, an air supply circuit, water management system and a heat management and recovery system. The findings indicate that this technology is very promising. The total efficiency of the system exceeds 75% in most of the time and the effective coverage rate of annual thermal and electrical needs is achieved.

KEYWORDS: Micro-cogeneration, Fuel cells, Hydrogen

INTRODUCTION

In this period, mostly of researcher head to developing cogeneration system based on fuel cell (FC) for small-scale to its various advantages comparing with other listed systems. Jaouhar et al [1], investigated the performance of a micro-cogeneration system based on PEMFC by studying the effect of the different key parameters and system response to the simulated demands. Two system design (1-KW, 5-KW) and two operational strategies were used. The results show that the system has a primary energy consumption 30% less than the conventional system. After the rapid growing of research in this domain, the researcher head to find the optimal operation of PEMFC based micro-cogeneration system. As OH et al [2], where they determined the optimal operation of a micro-combined heat and power (CHP) system with a 1-KW PEMFC as prime mover. In this article, we seek to investigate the performance of a developed micro-CHP system composed of 750-W PEMFC, backup boiler, gas management unit, water and heat recovery control unit. The system goal is to respond to the electrical and thermal needs of a single-family house. Thus, an hourly dynamic simulation was applied in Caen, France (49.1811 N, -0.3712 E) for a 120m2 single-family house, where the FC performance was detail studied.

SYSTEM DESCRIPTION

The proposed micro-CHP system is composed of 750-W PEMFC (70°C) cooled with water circuit in order to absorb the waste heat. The PEMFC power is constant throughout operation. Therefore, a 1080-W of thermal power is extracted of the fuel cell to cover the domestic hot water (DHW) and space heating demands(SHD). The mathematical modeling of the fuel cell is described by the equations bellows [3,4]:

$$P_e = N_{cell}\, i\, A\, V_{cell} \quad (1)$$

where P_e is the electrical power produced by the fuel cell, N_{cell} is number of cells, i the current density, A the cell area and V_{cell} the cell voltage.

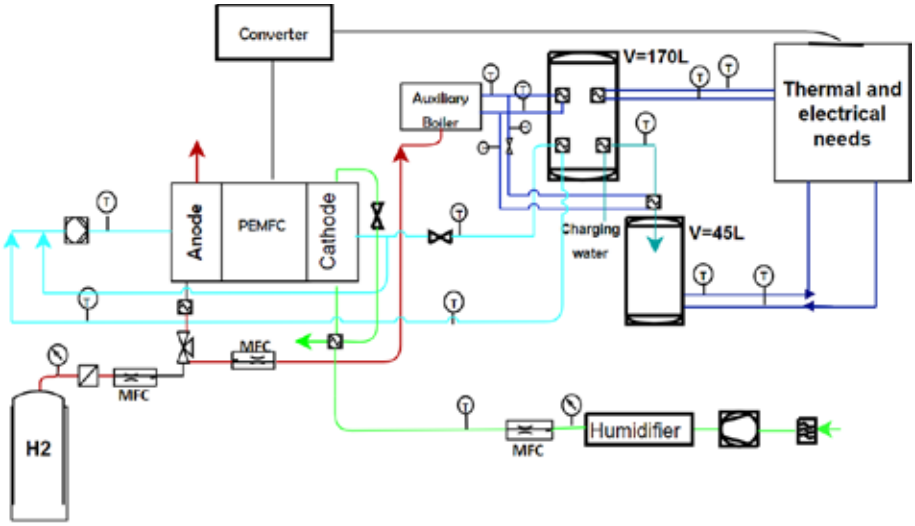
$$Q_{stack} = N_{cell}\, i\, A(1.48 - V_{cell}) \quad (2)$$

A backup condensing boiler with maximum thermal capacity of 12-kW, which use the hot fume to heat the boiler water return. This type of boiler has a high efficiency. The boiler interferes when a highly demand exist in order to meet the needs. The power given by the boiler is calculated by:

$$Q_b = n_{H2,b}\, \Delta H_{H2} \quad (3)$$

where Q_b is the boiler thermal power, $n_{H2,b}$ is the molar hydrogen fraction consumed by the boiler and ΔH_{H2} is enthalpy of combustion of H2.

Fig.1 represent the system scheme. Two tanks of 170L and 45L respectively were adopted in order to respond to the thermal demands. The large tank was responsible of the space heating demand where it was heated principally by the fuel cell in operation time and secondly by the boiler. The domestic hot water was delivered by the 45-L tank which is heated by the first tank and the boiler in case of large demand. The hydrogen and air supply circuits are equipped by the different management apparatus (filter, compressor, humidifier), measuring and controlling equipment (mass flow controller, pressure gauge, thermocouple…) in order to deliver the inlet gases to fuel cell as required. As well, a heat recovery unit composed of heat exchangers, pumps, valves..., was integrated to perform a good use of the extracted heat.



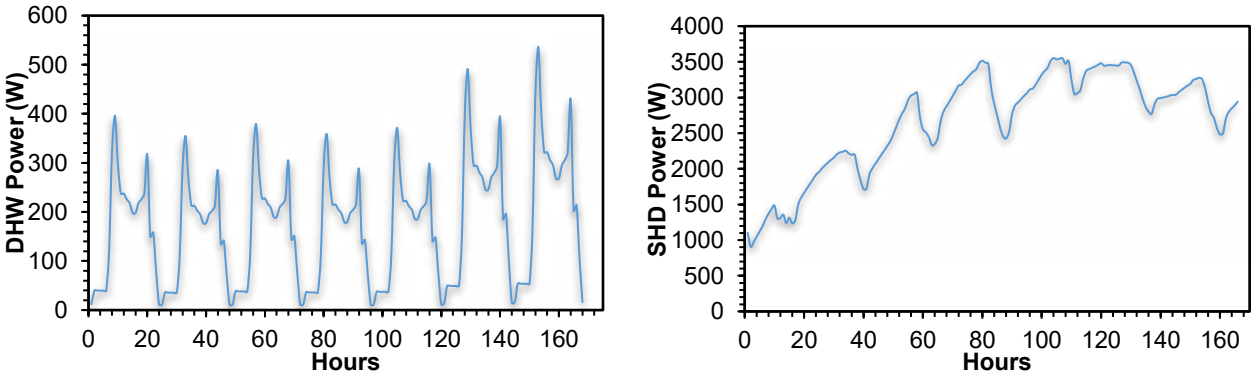


Fig. 1-System scheme

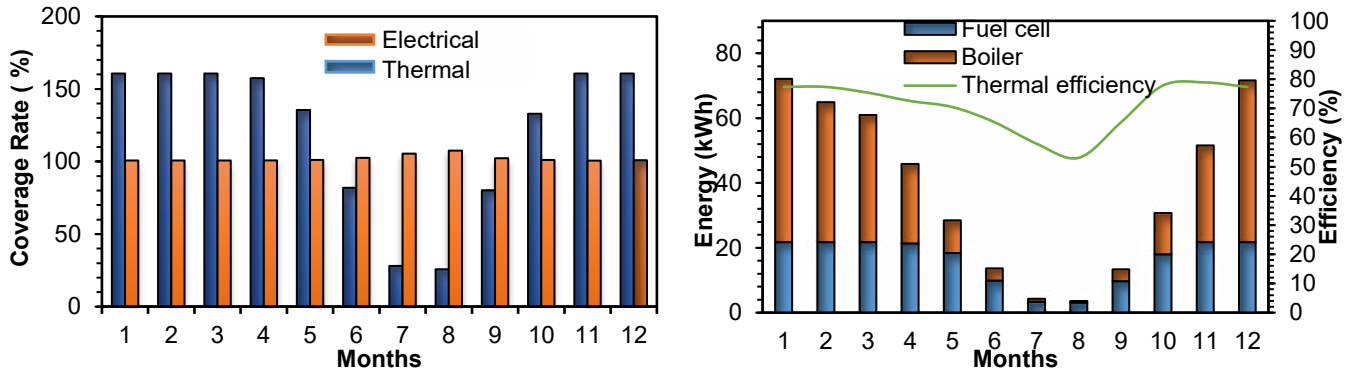
THERMAL AND ELECTRICAL DEMANDS

In order to evaluate the system feasibility, it's necessary that the system be examined with a thermal and electrical demands that represents the real case. Thus, the hourly electrical and thermal demands for the proposed scenario were simulated over a year based on statistical approach [5][6]. The SHD and DHW profile for one week is represented by Fig.2.



(a) (b)

Fig. 2- Weekly profile of : (a) space heat demand , (b) domestic hot water demand

RESULTS

In order to evaluate the system, a simulation was performed for one year, where the daily, monthly and yearly performance of the system was examined. Fig.3-a shows the system electrical and thermal response to the needs represented by the coverage rate (CR) which is the ratio between the produced and demanded energy. As it can be seen, the system response to the thermal needs was satisfying, which according to the strategy adopted, the system must cover all the thermal needs by priority. Thus, the effective thermal coverage rate of the system was 100% throughout the year. This results reflect the system stability in responding to the needs despite the varied weather from winter to summer. Even though the system priority was to feed the thermal demands, the system was capable to

feed the house electrical needs in most of the time with an effective electrical coverage rate of 120%. The low system production in summer months refer to the low space heating and domestic hot water demands in this period, where the fuel cell power produced (1080-W) can be enough to cover the needs. As declared before, in low heat demands the fuel cell stop working to prevent any damage.

(a) (b)

Figure 3- (a) Monthly system electrical and thermal coverage rate, (b) Monthly average system components thermal energy produced

As discussed earlier, the boiler role is to provide the needed power to feed the excess needs that fuel cell can't provide it alone. The condensing boiler with its high efficiency help the system to be stabilized all the operation time. Fig.3-b shows the monthly average energy produced by each of the heat source unit. It's remarkable that the boiler has produced much more than the fuel cell did in the winter period where the demand were really huge. The fuel cell must produce in normal operation 21-KWh of thermal energy per day (20 hours/day). The effective thermal energy produced by the fuel cell throughout the year was 16-KWh due to the low operation time of fuel cell in summer, while the boiler effective energy produced was 22-KWh with a maximum of 80-Kwh in December and minimum of 0.5-KWh in August. The thermal efficiency represented in Fig.3-b shows the effect of the fluctuated demands in summer on the system. While the system was standing with a thermal efficiency of 70-80%, it decreased to nearly 50% in July-August where the consumed energy was high with respect to the operation time.

CONCLUSION

In this study, we discussed the feasibility of an improved micro-CHP system based on low temperature PEMFC. The system was equipped by a condensing boiler, heat tank, and control and management units. All component were mathematically modeled and validated using experimental data. The system shows a good performance in responding to the estimated needs where the effective electrical and thermal coverage rate were 120% and 100% respectively

DESIGN AND INVESTIGATION OF A VARIABLE-NOZZLE EJECTOR FOR A 120 kW PEMFC STACK

[1] Yikang Lu, [2] Xuhui Wang, [3*] Sichuan Xu
School of Automotive Studies, Tongji University, 201804, Shanghai, China

ABSTRACT

Ejector is an ideal recirculation device which entrains anode exhaust from PEMFC stack via the entraining effect of supersonic low-pressure jet. Ejectors have advantages of tiny size, light weight, simple structure and no parasitic power consumption but achieves bad performance in off-design conditions, especially when stack load is relatively low. A variable-nozzle ejector applied for 120kW stack is designed based on a 1-D ejector model. The results show that through shrinking throat ejector's entraining performance can be improved effectively. When stack load is higher than 60kW, the performance with maximum throat can meet the requirements. With load decreasing to 8.9kW, the throat diameter should be gradually reduced to 0.4mm and the demand of primary pressure is raised to 1181kPa accordingly.

Keywords: PEMFC ejector, Variable-nozzle, Entrainment ratio

INTRODUCTION

In vehicle PEMFC (proton exchange membrane fuel cell) system, hydrogen recirculation is mostly adopted to achieve a high fuel utilization as well as a good water balance inside the stack. Ejectors are ideal recirculation devices. Under the entraining effect of supersonic jet, the anode exhaust is drawn into the ejector thus to perform recirculation. Due to the demand of recirculation rate in PEMFC water management, ejector's entraining effect is much more important than its compressing effect. Ejectors have advantages of tiny size, light weight, simple structure and no power consumption but achieve bad entraining performance in off-design conditions. When PEMFC stack output is low, ejectors couldn't produce sufficient hydrogen recirculation.

Through changing the internal structure, the working range of ejectors can be enlarged. Xue et al.[1] placed 4 nozzles in suction chamber and through the cooperation of different nozzles the ejector operates well within stack loads of 20-25kW and 35-100kW. Brunner et al.[2] proposed a variable-nozzle design and adjusts throat's opening dynamically through controlling the axial position of a taper needle in the nozzle. Their results show that shrinking throat is beneficial to entraining performance when hydrogen supply rate is low. Hosseinzadeh et al.[3] designed 2 ejectors according to current levels of 85A and 180A, by the parallel work of which the hydrogen recirculation system can achieve an entrainment ratio of over 2 within current range of 60A-180A. Brunner's variable-nozzle design was later compared in their work, the results show that a variable-nozzle ejector has nearly the same working range as 2 parallel ejectors.

In this work, a 1-D ejector model is built based on Soklov's theory[4] and validated with ejector's bench test applied for a 60kW PEMFC stack. Ejector's performance curves with different throat diameter were studied and a variable-nozzle ejector applied for a 120kW PEMFC stack was designed.

MODEL DEVELOPMENT

Model assumption

1. Primary and secondary fluid are regarded as single-phase ideal gas. Because in bench test there isn't a real stack, primary and secondary fluid are pure hydrogen with equal temperature.

2. The mixing of primary and secondary fluid starts at the entrance of mixing chamber and ends before the exit.

3. The velocity distribution at the cross section of mixing chamber's inlet can be divided into primary region and secondary region and in each region the velocity distributes uniformly.

4. Flow in ejectors is isentropic and no shock wave or vortex take place.

5. Gas at the inlet of primary and secondary fluid is in stagnation condition.

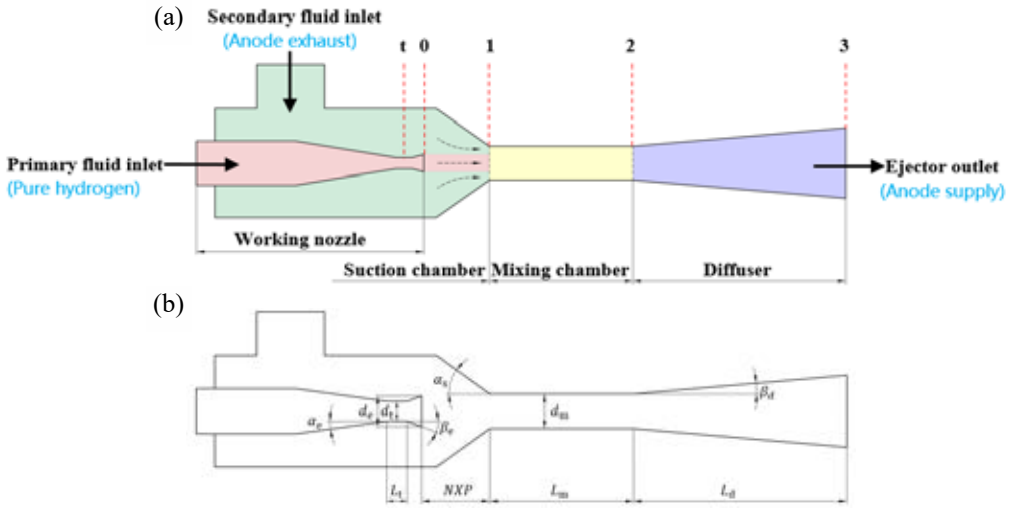

Fig.1 Structure of a PEMFC ejector: (a) internal flow field, (b) dimensions

Model functions

$$\dot{m}_p = \begin{cases} P_p A_e q_{p0} \sqrt{\frac{k}{R_g T_0}\left(\frac{2}{k+1}\right)^{\frac{k+1}{k-1}}} & \left(\frac{P(\lambda_1)}{P_p} < \varphi_{epr} < 1\right) \\ P_p A_t \sqrt{\frac{k}{R_g T_0}\left(\frac{2}{k+1}\right)^{\frac{k+1}{k-1}}} & \left(0 < \varphi_{epr} < \frac{P(\lambda_1)}{P_p}\right) \end{cases} \quad (1)$$

$$P_b = \frac{P_s}{\pi_{m2}}\left[\varphi_{epr}\pi_{p0}\frac{A_e}{A_m} + \pi_{s1}\left(1 - \frac{A_e}{A_m}\right) + C\frac{k\varphi_{epr}}{\varphi_3}\pi_*\frac{A_t}{A_m}\right] \quad (2)$$

$$C = \varphi_1\varphi_2\varphi_3\lambda_{p0} + \varphi_2\varphi_3\varphi_4\mu\lambda_{s1} - (1+\mu)\lambda_{m2} \quad (3)$$

Eq. (1) calculates primary mass flow under both critical and subcritical state of working nozzle. Eq. (2)-(3) are equations of ejector's performance curve based on the conservation of mass and momentum in mixing chamber.

RESULTS AND DISCUSSION

Seen in Fig.2(a), when ejector's backpressure is higher than the back-flow pressure P_{bf}, ejector works in back-flow state and has no recirculation effect. When the backpressure gradually decreases, ejector becomes sub-critical and the entrainment ratio increases sharply. When the backpressure furtherly decreased to be lower than the critical pressure P_{cr}, ejector enters a stable critical state and the entrainment ratio is constant at maximum value μ_{hp}. Fig.2(b) demonstrates a good agreement between the model results and the experimental data of a 60kW fixed-nozzle ejector, based on which a pre-study of variable-nozzle scheme was carried out. Eq. (1) explains that shrinking nozzle's throat raises primary pressure. Therefore as shown in Fig.2(c), under the double effect of shrinking nozzle and raising primary pressure, a smaller throat results in bigger maximum entrainment ratio and higher critical backpressure. Whether ejector works in critical or subcritical state as marked by red lines, shrinking nozzle improves entraining performance.

A 120kW fixed-nozzle ejector was designed according to the operating conditions under 120kW stack load, and the variable-nozzle scheme was later proposed to reach the target entrainment ratio. λ_t and λ_{m2} are superficial isentropic velocity at the throat and the exit of mixing chamber respectively. When λ equals 1, the working nozzle or the ejector itself become critical. Seen in Fig.3(a) and (b), with initial structure (D_t=2mm) ejector can't achieve required entrainment ratio when stack load is lower than 60kW and nozzle becomes subcritical (λ_t<1) when load is lower than 40kW. Shrinking throat improves ejector's performance, especially with low stack load. At a load of 8.9kW, if the throat diameter is less than 1.2mm, ejector starts to recirculate and nozzle enters critical state. When throat diameter furtherly decreases to 0.4mm, ejector reaches target performance. Because the primary pressure becomes too high under relatively high stack load with small throat, which is unacceptable considering the selection of pressure regulator, the final control methods of variable-nozzle and primary pressure is stated in Fig.3(c). When stack load is lower than 60kW, the throat diameter needs to shrink gradually to 0.4mm and the primary pressure needs to be raised accordingly to 1181kPa.

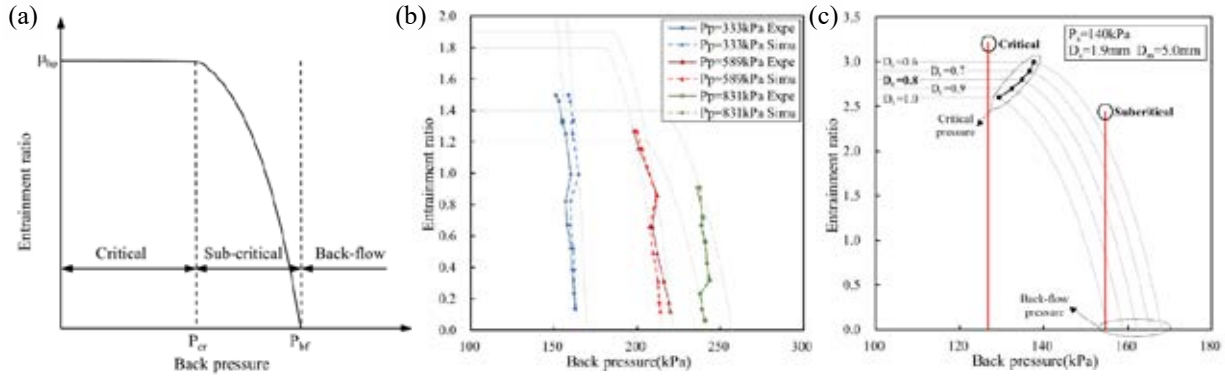

Fig.2 Characteristics of 60kW fixed-nozzle ejector: (a) typical performance curve, (b) model validation,

(c) performance with different throat diameter

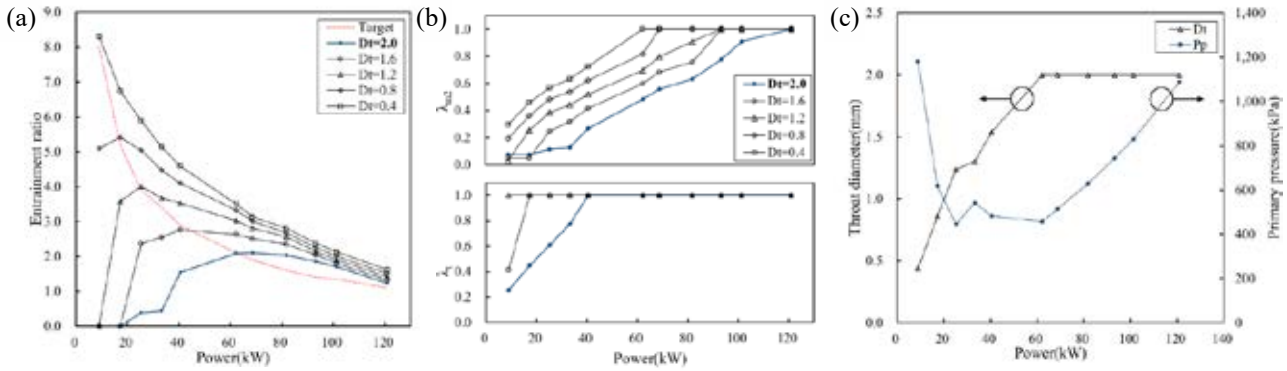

Fig.3 Characteristics of 120kW variable-nozzle ejector: (a) change of entrainment ratio, (b) change of superficial isentropic velocity,

(c) control method of throat and primary pressure

CONCLUSIONS

- A 1-D ejector model is built based on Soklov's theory with good accuracy. By shrinking nozzle's throat, the maximum entrainment ratio and critical backpressure can be raised, which is beneficial to entraining performance whether ejector works in critical or subcritical state
- A 120kW variable-nozzle ejector is designed. When stack load is within 60kW-120kW, ejector with maximum throat can provide required recirculation flow rate. When the load is smaller, throat needs to shrink gradually to a diameter of 0.4mm and the primary pressure needs to be raised accordingly to 1181kPa at the load of 8.9kW.

ABSTRACT

Project Giantleap developed a fuel cell range extender for a battery electric bus. Several enhanced control functionalities were implemented to observe the state of health and to reduce the fuel cell stack degradation. The operation of the stack was remarkable. It showed very low degradation level in different operating conditions including some transient operations failures in coolant circuit. The range extender system was built in a trailer attached to a battery electric bus and successfully tested and demonstrated.

Keywords: Fuel cell, Range extender, Diagnostics and Prognostics, Control Unit

INTRODUCTION

City buses have long been considered an early market for the introduction of fuel cells, since a large deployment of fuel-cell buses is able to economically sustain its own hydrogen refuelling infrastructure. Several demonstration projects have demonstrated the feasibility of fuel-cell buses, in particular the long-running CHIC project, followed by the JIVE and JIVE2 projects. However, experience has also shown that availability and reliability of fuel cell buses is not mature yet: The project Giantleap addresses this challenge by improving the lifetime and reliability and reducing the total cost of ownership (TCO) of fuel cell systems in city buses. This is achieved through an advanced control system that includes novel diagnosis and prognosis approach. The system is, therefore, able to avoid or reduce faults and mitigate or slow down degradation.

THE GIANTLEAP PROJECT

The Giantleap project is a European project funded by the European Commission's public-private partnership Fuel Cell and Hydrogen 2 Joint Undertaking (FCH2JU). The Giantleap team consists of three research institutions SINTEF from Norway, Universite de Franche-Comte (UFC) from France, Faculty of Electrical Engineering, Mechanical Engineering and Naval Architecture (FESB) University of Split from Croatia, and 2 OEMs Bosch Engineering (BEG) and ElringKlinegr (EK) from Germany, and one end user – bus manufacturer, VDL Enabling Transport Solutions (VDL-ETS) from Netherlands. The team and interactions between the partners are shown in Fig. 1.

At the very beginning of the project the team has decided to develop and construct a prototype fuel cell range extender with built-in diagnostic and prognostic features into a control unit and demonstrate it by connecting it to a battery electric bus.

FESB in collaboration with SINTEF, has developed a method of quick and simple measurement of low-frequency intercept in the impedance spectrum (ELFIS) as an indicator of stack degradation. UFC has developed a PEMFC stack model using the Energetic Macroscopic Representation EMR formalism, that was used to predict both the fuel cell stack ageing and its interactions with the balance of plant (BoP), namely hydrogen line, air supply and the cooling subsystem. A voltage decay is observed with the stack ageing, and its trend is analyzed and confronted to the observed long-term testing results. The model integrates the stack ageing laws and is adapted for on-board prognostic and health management purposes. SINTEF in collaboration with BEG has developed the control logic which was used in the Fuel Cell Control Unit (FCCU) provided by BEG that ensures that the fuel cell and other BoP-components always are kept within safe operating conditions from startup to shut-down and during normal operation modes when the fuel cell delivers charging power to the bus. Several enhanced control functionalities were implemented to observe the state of health and to reduce the degradation.

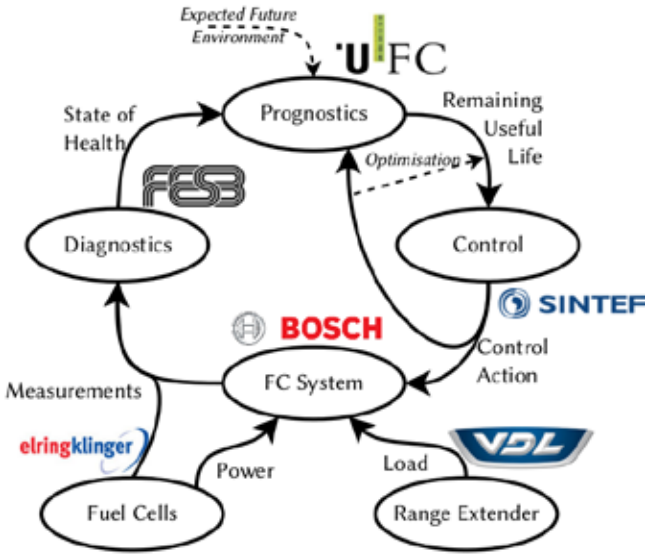

Fig. 1 The team and interactions between the partners

ElringKlinger has developed and provided full-size stack modules for laboratory experiments and for the integration into the fuel cell range-extender bus system. The NM5 stack platform suitable for mass production which is used in this project offers the possibility of realizing highly efficient systems due to a very low pressure drop on the cathode side. Patented structures within the metallic bipolar plate ensure a very homogeneous gas distribution and therefore operational stability especially in partial load at lower gas flow rates. Besides sensors, valves, droplet separators and bypass structures also the passive hydrogen recirculation unit as a major part of the anode sub-system is already integrated into the stack module. Hydrogen gas recirculation in general is important to maintain optimal gas distribution as well as humidification of the dry hydrogen supplied by the tank system of the trailer.

A robust fuel cell system including a reliable control system was designed by Bosch Engineering (BEG) and it is shown in Fig. 2. This system was assembled, tested on the test bench at BEG facilities before it was delivered for integration into the range extender, and brought into operation in a first demonstration prototype trailer at VDL-ETS facilities and on road.

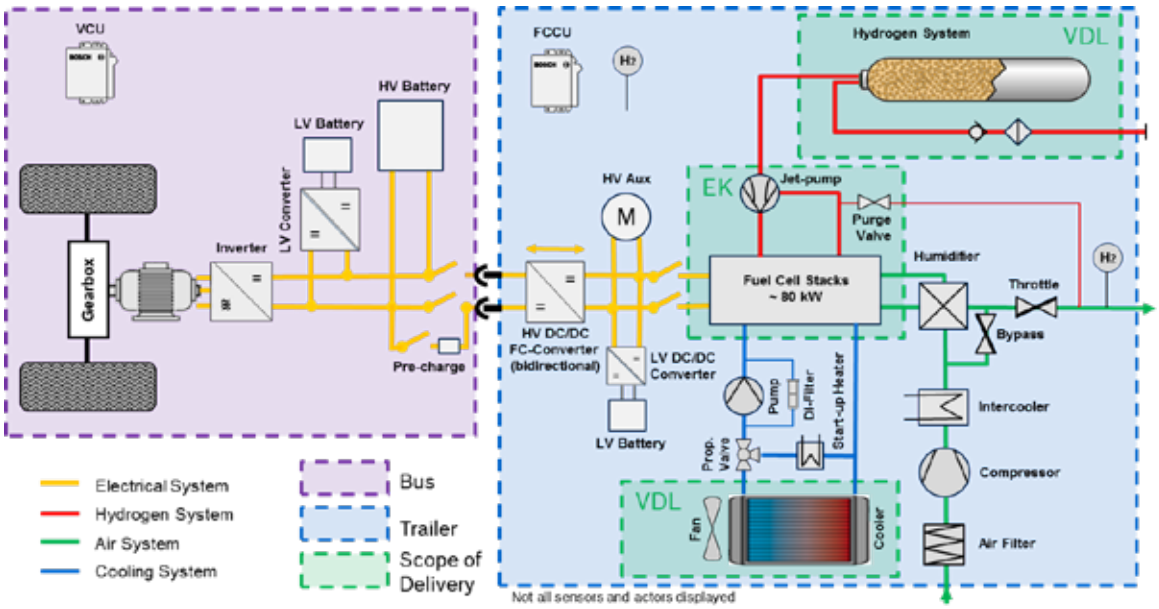

Fig. 2 Fuel cell system design

As part of the fuel cell system development, the BoP components were selected considering their robustness and expected lifetime. This applies to all BoP components, but in particular on the three main components that cause most system failures or have a large impact on system cost, i.e. air supply unit, pressure reducer and the cathode inlet humidifier. These components were evaluated separately on a test bench before being integrated in the system. In

general, the system was equipped with noninvasive sensors to perform prognostics and data evaluation to support the validation of the Prognostics and Health Management PHM control system during demonstrations and experiments.

VDL-ETS has facilitated and developed the mobile test platform as a trailer connected to an electrically driven VDL E-powered bus, shown in Fig. 3. The trailer includes the fuel cell system developed and tested by BEG and the hydrogen storage system holding 30 kg of hydrogen at 350 bar. The trailer is also equipped with vehicle lighting and brake subsystems for safe operation during testing. All electrical connections for high voltage power supply and communication have been provided. For software interfacing VDL-ETS assisted BEG and EK in communication for the safe start-up and shut-down of the system and linking signals to the vehicle.

Fig. 3. The trailer design (left) and the trailer built (right)

CONCLUSIONS

After three and a half years, the Giantleap project successfully concluded with a prototype demonstration in operational environment (i.e. on road, TRL 7) as opposed to the originally planned relevant environment (i.e. in a laboratory test bench, TRL 6). The bus and its range extender were tested while driving around VDL-ETS's premises in Valkenswaard, Netherland (Fig. 4).

Fig. 4. The trailer attached to the bus during test drive

Bosch Engineering has strengthened their activities in fuel-cell systems, and now offers balance-of-plant components specifically for such systems. While the project has been running, VDL-ETS has become the world's largest zero-emission bus manufacturer (outside of China), though most of these are battery buses., and over 90% of VDL-ETS's bus sales today are zero-emission. As the project concludes, the prototype developed in Giantleap has already evolved in a new generation ready to be demonstrated in passenger long-haul service between Rotterdam and Zeeland within the project 3-Emotion. Similar fuel cell range extender modules are being used in trucks.

ACKNOWLEDGEMENT

This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking under grant agreement No 700101. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and Hydrogen Europe and Hydrogen Europe Research.

ABSTRACT

Turbines can effectively recover 25-40% of the power consumed by centrifugal compressors, which significantly improve the efficiency of the proton exchange membrane fuel cell system. In this paper, a turbine impeller for an 80kW fuel cell stack is optimal designed. A multi-objective optimization method for turbine impellers is presented via integrating uniform design, back-propagation neural network and multi-island genetic algorithm. The numerical results indicate a considerable improvement to total-static expansion ratio and isentropic efficiency of the turbine impeller by 4.2% and 6.8% at the design point, respectively. It is shown that reducing impeller outlet diameter ratio can improve the efficiency. A lower impeller inlet width and a higher outlet diameter ratio are beneficial to increase the expansion ratio.

Keywords: Turbine, Fuel cell vehicle, Uniform design, Back-propagation neural network, Multi-island genetic algorithm

INTRODUCTION

Fuel cell vehicles (FCVs) are characterized by zero emissions during driving, short fuel filling time and long driving distance, which are considered to be one of the ultimate clean energy vehicles. Among the various auxiliary parts of the FCS, air compressor is the most consuming component, accounting for about 10~20% of the output power of the fuel cell stack [1]. However, turbines can effectively recover 25-40% of the power consumed by compressors, which significantly improve FCS efficiency.

With the development of effective computational tools, there has been an increase in the use of coupling numerical simulations and optimization methods to release the impeller design process from depending on the designers' experience. However, the design process is a formidable optimization task involving computationally intensive models and multiple objectives. Thus, surrogate models have gained more and more attentions in the optimization of turbomachinery [2].

In this paper, a multi-objective optimal design method for turbine impeller is proposed via integrating uniform design (UD), back-propagation (BP) neural network and multi-island genetic algorithm (MIGA). The subsequent sections are organized as follows: First, detailed aerodynamic evaluation of turbines is carried out based on numerical model and validation by comparison with experimental results. Then, the flowchart of a multi-objective design optimization method is introduced. Impeller inlet width (b_1), impeller inlet lean angle (λ_1), impeller outlet width (b_2), impeller outlet angle (β_2) and impeller outlet diameter ratio (δ) and impeller axial length (L) are selected as optimal variables. Finally, the effect of geometric parameters of turbine impeller on the aerodynamic performance is evaluated.

MODELS AND METHODS

Numerical Model and Validation

To evaluate the aerodynamic performance of turbines, RANS equations coupled with the two-equation k-ω based shear stress transport (SST) turbulence model are applied. After the verification of grid independence, the number of grid nodes for impeller is 1,500,000. The aerodynamic performance curve is shown in Fig.1, which can be seen that the isentropic efficiency of the turbine based on the present model agree reasonably well with the experimental data.

Multi-objective Optimization Method

A turbine impeller for an 80kW fuel cell stack was designed via a multi-objective optimization method as shown in Fig. 2. It consists of three parts: UD, BP neural network and MIGA.

The UD method is one of DOE method developed by Fang and Wang, which is suitable for multi-objective and multi-level problems [3]. The entire experimental domain can be adequately explored with less arrangements. For DOE of five factors and ten levels, the UD method only needs 10 times, compared with 105 times by the general method and 102 times by the orthogonal method.

The BP algorithm is one of the most widely used in neural network training, which is improved by Rumelhart on the basis of neural network algorithm in 1989 [4]. It is a multilayer neural network model, including input layer, output layer and several hidden layers. Fig. 3 shows a three-layer model. It can realize the mapping from any M-dimension input to N-dimension output. BP neural network has a good nonlinear fast mapping ability. By studying the mapping relationship between the complex geometric parameters and the aerodynamic parameters, the time of 3D numerical simulation can be greatly reduced.

MIGA was proposed by Kaneko et al. based on improvements in parallel distributed genetic algorithms (PAGAs) . The main characteristic of MIGA is that each individual population is divided into several islands. Selection, crossover and mutation are carried out on each island separately. By using the roulette method, some individuals are selected from each island and moved to different islands on a regular basis.

Seven structural parameters are selected as optimal variables. b_1 influences inlet velocity and impeller flow capacity. λ_1 affects the distribution of inlet aerodynamic parameters in the circumferential and the span wise direction. b_2 determines the outlet flow area. It is closely related to the distribution of outlet aerodynamic parameters in the span wise direction. β_2 and δ affect the flow area and flow angle of the impeller outlet, thus they affect the outlet relative speed. The outlet relative speed determines the impeller internal flow loss. L determines the length and shape of the impeller passage, which affects the flow field distribution and the internal flow loss.

The turbine impeller is optimized for maximizing its total-static expansion ratio and isentropic efficiency with constraints on the averaged mass flow rate of impeller inlet and outlet. The corresponding mathematical expression for aerodynamic optimization of the impeller is as follows:

$$\begin{cases} \max\left(\pi_{ts}(x), \eta_{is}(x)\right), \\ x = (b_1, \lambda_1, b_2, \delta, \beta_{2s}, \beta_{2h}, L)^T \\ \text{s.t. } 0.99\dot{m}_{ave}(ref) \le \dot{m}_{ave}(x) \le 1.01\dot{m}_{ave}(ref) \end{cases} \quad (1)$$

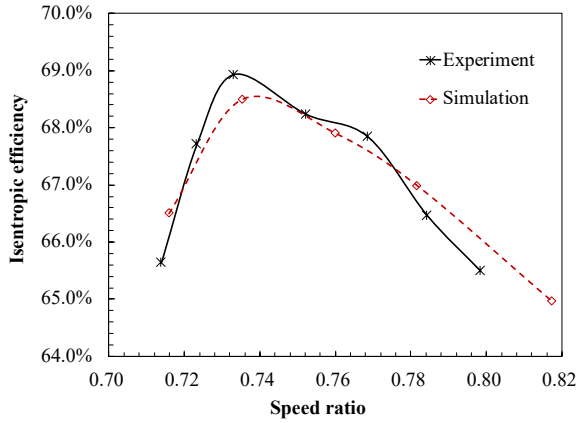

Fig. 1. Aerodynamic performance at 100,000 rpm speed for validation of the numerical model

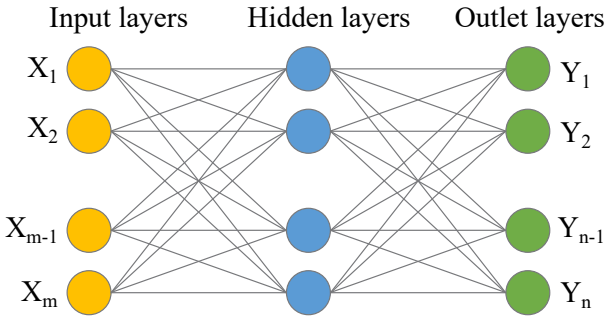

Fig. 3. BP neural network with one hidden layer and n outputs

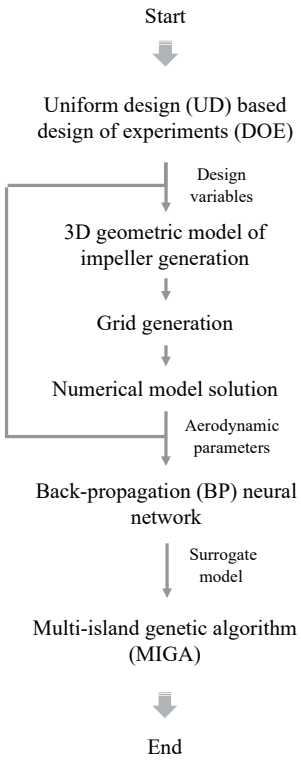

Fig. 2. Flow chart of the multi-objective optimization method

RESULTS AND DISCUSSION

The numerical results indicate a considerable improvement to total-static expansion ratio and isentropic efficiency of the turbine impeller by 4.2% and 6.8% at the design point, respectively. Fig. 4 shows the weight factors of geometric parameters in the aerodynamic performance of impellers. It can be seen that the impeller inlet width (X1)

and the outlet diameter ratio (X4) have a major impact on the aerodynamic performance. The weight factors of X1 and X4 in isentropic efficiency are 15.4% and 66.7%, respectively. The weight factors of X1 and X4 in expansion ratio is 44.5% and 38.2%, respectively. However, as the value of X4 increase, the value of expansion ratio increases, and the value of isentropic efficiency decreases at the same time. Similar phenomenon can be found for impeller inlet lean angle (X2). Therefore, there are trade-off relations between expansion ratio and isentropic efficiency, for larger expansion ratio is achieved by lowering its isentropic efficiency.

As the inlet width decreases, the inlet absolute velocity increases, which facilitates the conversion of pressure energy into kinetic energy. The increase of the inlet absolute velocity decreases the relative flow angle. As shown in Fig. 5, when the absolute angle of the entrance is constant, the inlet relative flow angle (incidence) is decreased (change from green flow condition to blue). According to the aerodynamic theory of turbomachinery, the decrease of the incidence is beneficial to improving the internal flow stability.

Although impeller outlet width and outlet angle have little influence on expansion ratio and isentropic efficiency, choosing a reasonable value can reduce the exit velocity loss and internal flow loss. Fig. 6 shows that the optimized impeller absolute flow angle is closer to zero, which indicates that the exit velocity loss is reduced. However, the absolute flow angle at 90% - 100% span wise increases. This is due to the mixing of the leakage flow and the transverse flow at the top of the suction section.

CONCLUSIONS

A systematic method is established to analyze the influence of geometric parameters on the aerodynamic performance of turbine, and an appropriate geometry of small-scale turbine for fuel cell vehicle is obtained. The method can optimize the main parameters of the turbine, which considerably saves time and reduces cost, and can effectively improve the aerodynamic performance.

- The weight analysis of geometric parameters shows that impeller inlet width and outlet diameter ratio have a major impact on the turbine aerodynamic performance.
- Reducing outlet diameter ratio can improve the efficiency. A smaller impeller inlet width and a larger outlet diameter ratio are beneficial to increase the expansion ratio.

ABSTRACT

Polybenzimidazole (PBI) membranes are highly sought after for HT-PEMFCs due to their thermal stability, mechanical strength and protonic conductivity. In this study, PBI polymer and the membranes were synthesized for HT-PEMFC applications. Then, the polymer was characterized by using NMR and TG analyses. All the characteristic peaks were observed in the NMR results and PBI polymer decompose around 550 °C. After the synthesis, pristine and multi-walled carbon nanotube (MWCNT) supported membranes were prepared, doped with phosphoric acid and characterized by using TGA, FT-IR, XRD, SEM and EIS tests. The characteristic bonds of the polymer for both undoped and doped membranes were seen in FT-IR results. XRD results showed the semi-crystalline structure of the polymer. SEM results enabled to observe the homogeneous dispersion of the MWCNTs within the membrane. Finally, EIS tests were carried out in anhydrous conditions. The conductivities were obtained for pristine PBI membrane as 0.0518 S/cm, 0.0667 S/cm and 0.0895 S/cm, respectively. For the 0.5wt% PBI/MWCNT membrane, they were calculated as 0.0401 S/cm, 0.0586 S/cm and 0.0613 S/cm for 120 °C, 140 °C and 160 °C, respectively. For the 1wt% PBI/MWCNT membrane, slightly higher conductivities were obtained as 0.0429 S/cm, 0.0621 S/cm and 0.0655 S/cm for the temperatures 120 °C, 140 °C and 160 °C, respectively.

Keywords: PBI, MWCNT, PEM, fuel cell, membrane.

INTRODUCTION

PEMFCs use most commonly Nafion membranes and their working temperature is usually under 90 °C. However, the low working temperature is not enough for an efficient working condition due to low oxygen reduction kinetics and low tolerance towards gas impurity, as well as heat and water management problems. Thus, a new type of membrane, polybenzimidazole, was introduced [1]. Due to high working temperatures, the possibility of liquid water forming in the porous media is eliminated and a required low relative humidity does not need water management [2]. Since then, good mechanical strength, high conductivity and outstanding thermal stability up to 200 °C for this type of membrane have been presented [3]. Carbon-based fillers such as carbon nanotubes, carbon black, graphene oxide, etc., are observed to be used in PBI membranes to improve not only the physical but the conductive properties also [4]. Moreno et al. [5], showed that the MWCNT-supported PBI membranes produced by the spin coating method have higher tensile strengths, as well as higher protonic conductivity and open-circuit voltage (OCV). Similarly, other studies reported an increase in both tensile strength and ionic conductivity for the composite membranes prepared with functionalized MWCNTs [6-8]. Wu et al. [9], concluded that the functionalized MWCNTs decrease the gas permeability while increasing the ionic conductivity for direct methanol fuel cells. Shao et al. [10], introduced a new “one-pot” method to synthesize sulfonated MWCNT-supported PBI and demonstrated an increased tensile strength in the membranes.

In this study, both pristine and CNT doped PBI membranes were prepared by casting method and their properties were observed through characterization methods, such as NMR, SEM, FT-IR, TGA, XRD, EIS.

MATERIALS AND METHODS

3,3′-Diaminobenzidine tetrahydrochloride hydrate (DAB.4HCl.xH_2O, ≥96%, Sigma-Aldrich) and isophthalic acid (IPA, 99%, Sigma-Aldrich) were used as the monomers and polyphosphoric acid (PPA, reagent grade 115%, Sigma-Aldrich) was used as the solvent for the polymerization reaction. Calcium chloride (technical grade) was used as the drying agent and pure nitrogen gas was used to make the reactor inert. N,N-Dimethylacetamide (DMAc, ReagentPlus®, ≥99%, Sigma-Aldrich) is used for membrane preparation. The acid doping process was carried out

with o-phosphoric acid (PA, 85%, Sigma-Aldrich). Multi-walled carbon nanotubes (MWCNTs) were synthesized in Istanbul Technical University, Energy Institute, Material Production and Preparation Laboratory, by using the chemical vapor deposition method at 500 °C, using acetylene.

PBI Synthesis

A three-necked flask was chosen as the reactor. $CaCl_2$ was used as a drying agent and nitrogen gas was used to make the reactor inert. PPA was added to the reactor and heated to 140 °C. Then, DAB.4HCl (1/26.5 in weight of PPA) was added and stirred mechanically. After that IPA (equimolar amount of DAB) was added to the bubble and heated to 170 °C. Finally, the temperature was increased to 200 °C and the reaction carried on for 24 hours. The viscous polymer solution was filtered, washed and isolated.

Membrane Preparation

5wt% PBI/DMAc solution was prepared with ground polymer. The solution was stirred magnetically at 80 °C for 2 hours. The clean solution was cast on the petri dish and dried overnight. Thus, the pristine PBI membrane was obtained.

The MWCNT supported membrane preparation is not different from the pristine membrane preparation. The only difference is that PBI solution was mixed with 0.5wt% and 1%wt MWCNTs and homogenized ultrasonically for 6 hours. Then the solutions were cast into petri dishes and dried in the oven.

RESULTS AND DISCUSSION

The 1H-NMR results showed that the synthesized polymer had all the characteristic peaks of PBI, with imidazole protons at 13.421 ppm and aromatic protons between 9.2 ppm and 7.5 ppm.

The acid doping was carried out at room temperature for 5 days. At the end of 5 days, the membranes were dried thoroughly with a paper towel first, then in the vacuum oven at 90 °C for 5 hours. The doping levels were calculated as 14.3 mol PA/PBI for the pristine PBI, 5.9 mol PA/PBI for the 0.5wt% MWCNT/PBI membrane and 7.3 mol PA/PBI for the 1wt% MWCNT/PBI membrane

TGA analyses yielded excellent thermal stability for PBI polymer and the pristine membrane, with a decomposition temperature around 550 °C. A weight loss between 220-420 °C was observed for the composite membranes and it is attributed to the PBI coated MWCNT decomposition. All the membranes were thermally stable up to 220 °C, thus suitable for HT-PEMFC applications.

XRD analyses gave the semi-crystalline structure of the polymer with a broad peak around $2\theta = 25°$. The intensity of the peak increases with the increasing MWCNT amount.

FT-IR results of both doped and undoped membranes showed the peaks of the corresponding bonds of a PBI polymer. N-H stretching between 4000-2000 cm^{-1} and benzene/imidazole rings between 1700-1000 cm^{-1}. The peaks at 1620, 1530, 1440, 1280 and 790 cm^{-1} mean strong C=C/C=N stretch, the characteristic of 2-substitution, the characteristic of benzimidazole in-plane vibration, C-N stretch and C-H bending, respectively. The 2920 cm^{-1} peak signifies the N-H group, where the narrow peaks below 2000 cm^{-1} belong to phenyl groups. Acid doping gives a dramatically changed result. C-N, H-N and cycle deformations occur between 2000-1000 cm^{-1}. The phosphoric acid doping causes a shadowing over the visibility of the peaks due to hydrogen bonding and the vibrations of hydrogen phosphate groups. Doping also introduces a new peak at 1495 cm^{-1}, related to the C=N vibrations of the $C=NH^+$ group. The absorption bands of the MWCNTs are almost invisible for the composite membranes, due to the non-covalent π-π interactions.

SEM results yielded the morphological structure of the membranes. The tips of the MWCNTs were clearly visible as white dots. The lack of lumps indicates a good dispersion of the MWCNTs, along with the uniform distribution of the white dots.

EIS tests were carried out to measure the impedances and to calculate the ionic conductivities at different temperatures, 120 °C, 140 °C and 160 °C. While the conductivities of the pristine membrane were found as 0.0518 S/cm, 0.0667 S/cm and 0.0895 S/cm, the conductivities of the 0.5wt% PBI/MWCNT membrane were determined as 0.0401 S/cm, 0.0586 S/cm and 0.0613 S/cm for 120 °C, 140 °C and 160 °C, respectively. As expected from 1wt% PBI/MWCNT membrane, slightly higher conductivities were obtained. The temperatures 120 °C, 140 °C and 160 °C yielded 0.0429 S/cm, 0.0621 S/cm and 0.0655 S/cm, respectively.

CONCLUSIONS

PBI membranes with different amounts of MWCNTs were prepared and characterized in order to investigate the effect of MWCNTs. The polymer was synthesized via solution polymerization method and was characterized first by NMR, which ensured the characteristic peaks of PBI. Then FT-IR showed peaks that were clearly belong to PBI. Combined with the result of the TGA, it was concluded that the synthesized material was indeed PBI.

The polymer was dissolved in DMAc, to obtain mechanically strong and thermally stable membranes for HT-PEMFC applications. Then, the membranes were further tested with XRD and TGA. While XRD analyses showed the semi-crystalline structure of the polymer, TGA analysis yielded thermal stability up to 550 °C.

The surface morphology was investigated along with the MWCNT distribution within the membranes by using SEM analyses. It was concluded that the ultrasonic homogenization resulted in well-dispersed MWCNTs. It was also seen that the MWCNT-support increased the acid doping level for the composite membranes, due to acid retention.

The EIS results exhibited an increase in the ionic conductivity for all the membranes with the increasing temperature. Increasing MWCNT-support also showed an increase among the composite membranes.

ABSTRACT

In this work, a 20 W 3-cell proton exchange membrane (PEM) fuel cell stack is developed and studied. This is an initial prototype for the future development of a 200 W stack to be used in an unmanned aerial vehicle (UAV). For this specific application, several considerations need to be made, such as size, weight and operation mode of the stack. The influence of several operating parameters on the stack performance is evaluated. The fans speed (air supply and temperature regulation) and the short-circuit (water production) are the most influential parameters due to their effect on the humidification state of the stack. H_2 purge and pressure do not significantly impact the performance. The purge, however, could be a more important factor in a larger stack.

Keywords: Proton exchange membrane, fuel cell stack, unmanned aerial vehicles

INTRODUCTION

The usage of unmanned aerial vehicles (UAVs) in both civil and military applications has increased in the last years [1]. Small UAVs are generally powered by electric batteries. However, they present some disadvantages, such as low energy density, resulting in short flight times, and long recharging periods. Fuel cells systems generally allow longer flight times [2] and faster refueling. Fuel cells directly convert the chemical energy in a fuel (generally H_2) in electric energy. Proton exchange membrane (PEM) fuel cells are the most common for small UAVs due to their high power density, high efficiency, fast dynamic response and fast start up time [3]. PEM fuel cells use solid polymer electrolyte membranes and a catalyst (generally platinum) to allow the generation of electricity at low temperatures. In this work, a small 3-cell PEM fuel cell stack was developed. This 20 W stack is an initial stage for the development of a 200 W PEM fuel cell stack, which will be tested as the power supply of a UAV commercialized by a partner company. The performance of the stack was evaluated and the influence of several operation parameters was investigated. This study will provide significant information for the future scale-up.

EXPERIMENTAL

Description of the stack

Fig. 1 contains a drawing of the fuel cell stack components. Due to the intended application, the size and weight of the stack are important parameters to consider. The end-plates were made of duralumin, a lightweight material, to give support to the rest to the stack components. The current collectors, made of gold coated copper, connect the stack to the test load/motor. Between these two components, a gasket is used to electrically isolate the end-plates. The bipolar plates, made of graphite, distribute the gas to the membrane electrode assembly (MEA) through their flow field. 25 cm^2 MEAs were used, having Nafion N212 membrane, Pt on carbon catalyst and carbon cloth gas diffusion layers (GDLs). The MEAs are surrounded by gaskets to avoid H_2 leakage. The stack operates with an open cathode with a parallel flow field. The air feed is accomplished by two fans (24 V / 6.9 W, PWM controlled), also responsible for the stack cooling. The stack also operates in a dead-end anode mode with a serpentine flow field. To remove excess water and N_2 that accumulate in the anode, periodical purges are performed. For the intended purpose of the stack, the humidification of the inlet gases is unfeasible, therefore, the stack humidification is facilitated by periodically short-circuiting the stack. The short-circuit momentarily increases the current of the stack, increasing the water production.

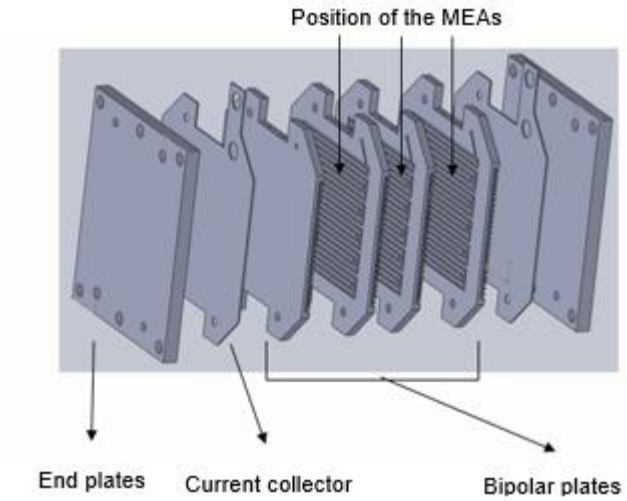

Fig. 1. Fuel cell stack components.

RESULTS AND DISCUSSION

Stack performance

The performance of the stack is shown in Fig. 2. These results were obtained with the fans at 50 % duty cycle, H_2 purge interval and duration of 15 s and 0.5 s, respectively, short-circuit interval and duration of 15 s and 0.1 s, respectively, and H_2 pressure of 50 kPa. As shown in Fig.2, the 3-cell stack reaches a power of 21 W at 15 A.

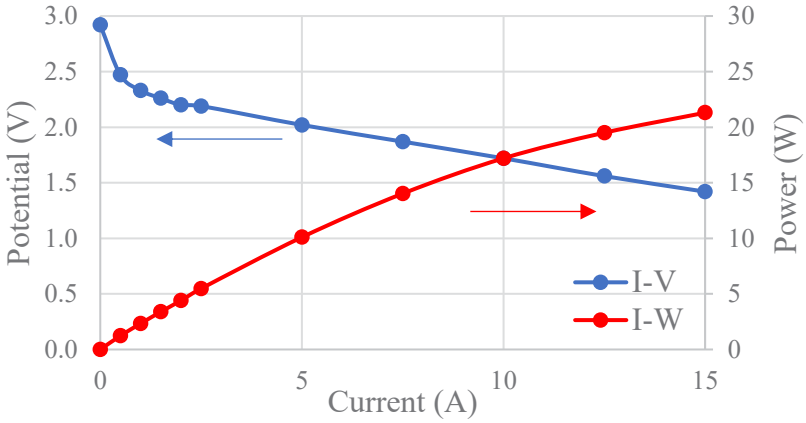

Fig. 2. Performance of the fuel cell stack.

Effect of operating conditions

The influence of operating parameters of the stack was studied. The results are presented in Table.1. For each current, a higher voltage represents a higher performance. The baseline operating conditions are the same as those indicated above when discussing the stack performance.

The fans speed was the most influential operation parameter for the stack performance. It was notorious that, for high currents (12.5 A), low fan speeds (<= 40%) are not capable of maintaining an appropriate temperature, leading to the drying of the membranes decreasing the stack performance.

The short-circuit presented a clear influence on the performance, especially the duration. A higher duration and frequency improve the humidification of the membranes improving the performance. However, the increase in current during the short--circuit may decrease the lifetime of the MEAs and affects the efficiency of the system. Nevertheless, these values may be used for maintenance/reconditioning of the stack in case of a long rest period or operation in dry conditions.

Besides the parameters indicated in Table 1, the effect of purge duration (0.1 to 1 s) and frequency (5 to 60 s) and H_2 pressure (10 to 60 kPa) were also evaluated. Both parameters did not have a relevant impact on the stack performance. In case of the purge, this may be due to the small amount of cells of the stack, allowing the complete removal of the

water (and possibly N_2) from the anode, even in the less favorable conditions (low purge duration and frequency). This parameter needs to be evaluated again in a larger stack as the total amount of water and N_2 to be removed will be considerably higher.
These results will be used to scale-up the stack for a 200 W output and to design the automatic control system so that the stack can be used as power supply for a small UAV.

Table 1. Effect of operating conditions on the stack performance.

		Potential (V) at a given current		
		1 A (0.04 A cm^{-2})	**5 A (0.20 A cm^{-2})**	**12.5 (0.50 A cm^{-2})**
Fans speed (%)	**20**	2.35	2.01	1.22
	40	2.39	2.05	1.44
	60	2.38	2.06	1.55
	80	2.40	2.09	1.56
Short-circuit duration (s)	**0.10**	2.37	2.05	1.55
	0.25	2.40	2.09	1.58
	0.50	2.43	2.15	1.65
Short-circuit frequency (s)	**5**	2.41	2.08	1.56
	30	2.37	2.03	1.52
	60	2.34	2.02	1.49

CONCLUSIONS

In this work, a PEM fuel cell stack was developed and the influence of the operation conditions on the performance was evaluated. A 3-cell stack was developed with specific materials and configuration to allow its application in an unmanned aerial vehicle. Of the operation parameters tested, the fans speed was the most influential. When the speed of the fans is low, at high currents the stack reaches a temperature sufficient to cause the drying of the membranes, decreasing the performance of the system. The short-circuit, related with the water production, also influences the humidification of the membranes, affecting the performance of the stack. A more frequent or long lasting short-circuit improved the performance due to a higher water production. H_2 purge and pressure did not significantly impact the performance of the system.

ABSTRACT

In the present work, the behaviour of a parallel serpentine bipolar plate of a proton exchange membrane fuel cell (PEMFC) working under dynamic load cycling (FC-DLC) was experimentally studied. Current density and temperature distribution along the cell active area was examined at different stages for the dynamic load of the urban cycle representative of fuel cell electric vehicle applications. Experimental results showed uniform temperature distribution in the active area of the fuel cell at both low and high intensities, with temperature differences below 2 ºC. This homogeneity in temperature distribution supported the suitability of the proposed parallel serpentine design concept.

Keywords: Fuel cell, Bipolar plate, Dynamic load cycle, Current density measurement

INTRODUCTION

Currently there is a high demand for propulsion systems supported by renewable energy sources in the transport sector, one of them being PEMFCs. Due to their clean properties, high efficiency and low operating temperature, fuel cells are a good alternative and they have become a potential substitute for conventional combustion engines [1]. The application of PEMFCs to the transport sector requires that the design, testing and operation of PEMFCs should correspond to the specific operating conditions and loads of the dynamic load of the urban cycle. The methodology followed to examine the performance of MEAs under operating and stress conditions for automotive applications has already been described by the European Commission in the JRC Science Policy Report [2].

One of the key components in PEMFCs are the bipolar plates (BPs) as they represent a significant part of the volume, weight and cost. The material and design of the channels in the BPs have to ensure an appropriate water management within the cell and improve the performance of the cell at high current densities. Materials include graphite, coated metallic or composite plates, and different flow field designs such as parallel or serpentine, and alternatively also bioinspired designs have been proposed [3].

Different local conditions may exist in PEMFCs that lead to an inhomogeneous current production. Analysing the measurement of the current density and temperature distribution is important for a better understanding of PEMFC behaviour, efficiency and possible points for future improvements in the design of the BP. Previous works have studied the design of BP channels by measuring the polarisation curve [4], but fewer studies have also analysed the local phenomena from sensors that measure the current density and temperature distribution within the cell [5].

The objective of this research is to analyse the effect of the dynamic load of the urban cycle on the temperature and current density distributions of a PEMFC with a parallel serpentine channel design. Current density and temperature distribution were experimentally measured and PEMFC performance results were analysed.

EXPERIMENTAL SECTION

A fuel cell with an active area of 50 cm^2 was analysed. A parallel serpentine flow field design was proposed. Several previous experimental tests of the polarization curve IV were performed under different flow configurations, taking as a reference the following conditions: operating temperature of 65 ºC, pressure of 0.5 bar(a), anode stoichiometry of 1.3, cathode stoichiometry of 2.5 and anode and cathode relative humidity (RH) of 60%. Additional experiments were carried out modifying the inlet and outlet of the gas hose on the fuel cell test bench and the results in terms of the polarisation curve were compared with the conventional flow configuration.

A Current Density Measurement (CDM) sensor [6] was included in the PEMFC to measure both current density and temperature distribution during the experimental tests of a dynamic load of the urban cycle, representative of the real conditions to which the fuel cell is exposed in a driving cycle [2].

RESULTS AND DISCUSSION

To perform the dynamic load of the urban cycle, the IV hysteresis curve was obtained, including the increasing current part up to a maximum current value and the decreasing current curve part. The reference current value was calculated as the average of the two curves for a given voltage and this result was selected for the reference current value of 100 % in the dynamic load cycling test. In Fig. 1 load cycle and the corresponding cell voltage evolution can be observed, where the minimum voltage was kept above 0.3 V during the test.

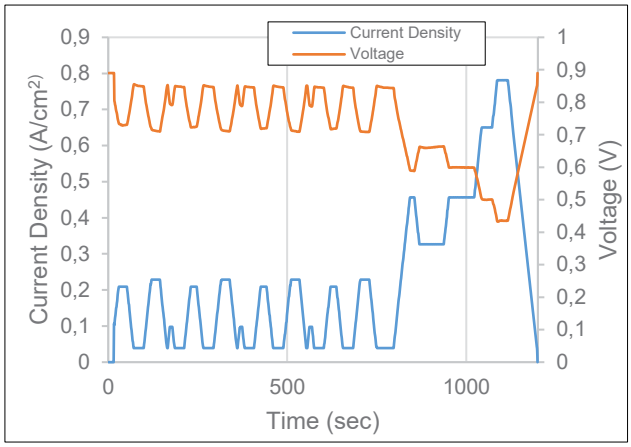

Fig. 1. Dynamic load cycling for operating conditions: P_{cell} = 0.5 bar, T_{cell} = 65 ºC, Relative Humidity at anode and cathode 60%, Stoichiometric factors at anode and cathode 1.3 and 2.5 respectively, and conventional flow configuration.

During the tests, temperature distribution transient data were obtained with the CDM sensor and local temperature distribution and the potential inhomogeneous zones were analysed. In Fig. 2, temperature distribution within the PEMFC active area is shown for both low and high intensities (left and right respectively). For low intensities the difference in temperature across the active area remained between 67 and 68 ºC, while for high intensities measured temperature differences were found to be higher, between 67.5 and 69 ºC.

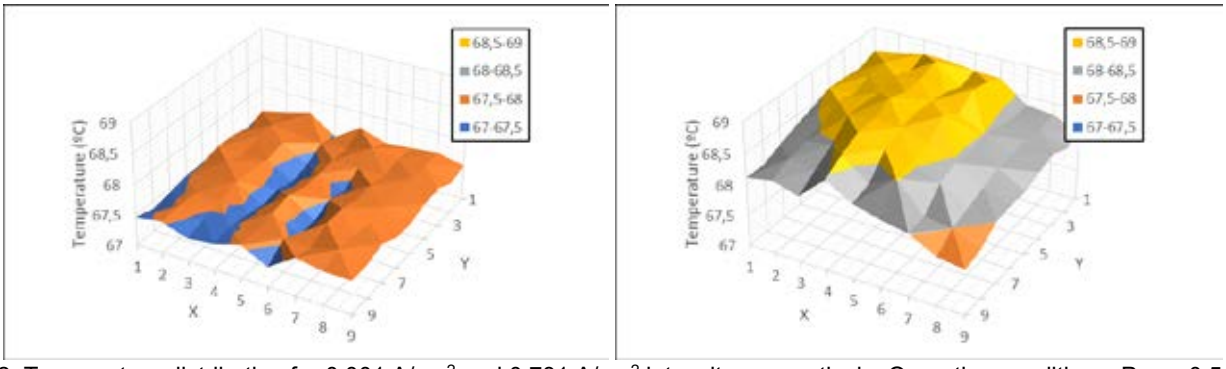

Fig. 2. Temperature distribution for 0.001 A/cm^2 and 0.781 A/cm^2 intensity, respectively. Operating conditions: P_{cell} = 0.5 bar, T_{cell} = 65 ºC, Relative Humidity at anode and cathode 60 %, Stoichiometric factors at anode and cathode 1.3 and 2.5 respectively, and conventional flow configuration.

CONCLUSIONS

The dynamic load of the urban cycle was tested with a parallel serpentine flow field PEMFC BP design. Both current density and temperature distribution were measured using a CDM sensor. Experimental results showed uniform temperature distribution in the active area of the fuel cell at both low and high intensities, with temperature differences below 2ºC. This homogeneity in temperature distribution supported the suitability of the proposed parallel serpentine design concept.

ABSTRACT

Efforts towards improving performance and durability of polymer-electrolyte fuel cells (PEFCs) require an understanding and expansion of the design space for proton-exchange membranes (PEMs) in the presence of additives used to enhance their stability. One such additive utilized in PEMs is Cerium, due to its ability to act as radical scavenger to improve membrane stability. While showing promise in durability improvement, doping a multivalent cation such as Cerium into a proton-form PEM ionomer alters it structure and transport properties, the implications of which for membrane and cell performance remain relatively unexplored. In addition to the doping strategies employed for optimizing durability, membrane thickness is another factor for optimizing cost and performance. Thus, it is of interest to understand and quantify the extent to which membrane properties are dependent on these distinct factors that can be used as design parameters. This talk presents a summary of key aspects of doping and thickness effects in a membrane based on a comprehensive experimental study on PEM properties, including water uptake, conductivity and nanostructure characterization, which are then implemented into multi-physics fuel-cell models to demonstrate the expanded design space for PEMs that account for the materials and environmental parameters affecting both performance and durability.

Keywords: Fuel Cell, Ionomers, Cerium, Thickness, Durability

INTRODUCTION

Polymer electrolyte fuel cells (PEFCs), if optimized for durability, cost, and performance, have offer great prospects to revolutionize transportation in the form of fuel-cell vehicles (FCV) for automotive and heavy-duty applications.[1] In a PEFC, ion-conductive polymers, ionomers, primarily function as a selective proton-exchange membrane (PEM) facilitating ion transport between the catalyst layers (CLs), while also function as a electrolyte binder in CLs wherein they are mixed with the catalyst supports and particles (e.g., Carbon and Platinum) to improve mass transport of reactants to catalytic sites and remove product water. Perfluorosulfonic acid (PFSA) is the most widely used ionomer in PEFCs, due to their remarkable ion transport properties and mechanical stability.[2] However, PFSA-based PEMs still exhibit vulnerability to attacks by hydroxyl radical species during operation, which could possibly reduce their effectiveness as separators. During cell operation, chemical degradation occurs due to formation of hydrogen peroxide, H_2O_2, and its radicals that attack the ionomer and leads to its local decomposition.[3, 4] A popular strategy to combat this problem is to introduce scavengers, like cerium (Ce), into the membrane so that they can neutralize the radical species generated in and near the PFSA and improve chemical durability.[2-4] Such cation-doping, however, creates a complex multi-ion system (Fig. 1),[4, 5] thereby altering the mechanisms of transport understanding of which is extremely important for developing strategies for effective doping levels and utilization in membrane design. Thus, controlled Ce-doped PFSA provides a representative model system for studying the underlying origins of transport in cation-exchanged ionomers in PEM fuel cells (Fig. 1). While doping strategy is a design parameter employed for enhancing PEM durability, membrane thickness is another key factor for optimizing cost and performance.[6, 7] It is of interest to understand and quantify the extent to which membrane properties are dependent on these distinct factors that can be used as design parameters. The focus of this talks is to present an overview of two key factors impacting PEM properties, namely thickness[7] and Ce-doping,[4] based on a systematic experimental and theoretical investigation and demonstrate how they are utilized in cell models. The combinatory roles of operating conditions and doping-levels in membrane performance are also elucidated using multi-physics fuel cell simulations.[8, 9]

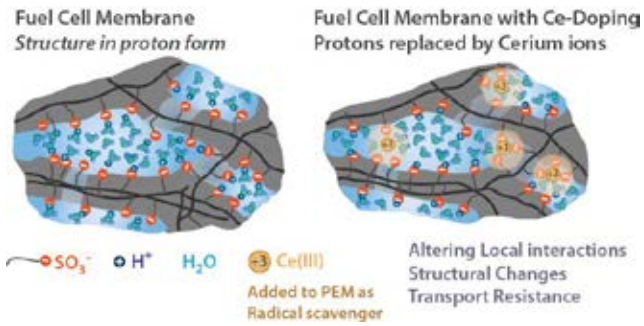

Fig. 1. Cerium added to Fuel-Cell proton-exchange membrane (PEM) as radical scavenger results in a complex structural state with implications for both transport (and performance) and durability.[4]

EXPERIMENTAL

Ce-doped Nafion membranes are prepared with various degrees of Ce(III) and Ce(IV) ion-exchange to obtain a mixed proton-cerium state in ionomer membrane. A systematic experimental investigation is carried out to measure water uptake and conductivity of Nafion-Ce membranes as a function of humidity and temperature, and the impact of Ce on nanostructural features of membranes are investigated using small- and wide-angle x-ray scattering (SAXS/WAXS). Collected data are modeled to examine how Ce-doping influences structure-hydration and conductivity-hydration relationships, which is analyzed using dilute-solution theory as well as concentrated solution theory. Moreover, the effect of thickness on fuel-cell membranes is investigated based on a PFSA membrane. Membrane structure and properties are measured as a function of thickness, in controlled environment. The impact of relative humidity and temperature on the proton transport was also investigated for selected membrane thicknesses, to provide insights towards membrane design for high-temperature fuel-cell operation. The acquired data are analyzed to identify to what extent thickness impacts properties and to provide insights on the extent to which thickness can be considered a design parameter for PEMs.

RESULTS AND DISCUSSION

In this study, hydration and conductivity measurements, along with small- and wide-angle X-ray scattering are employed to elucidate how structural and concentration changes due to cationic additives in controlled environments alter solvation behavior and meso/nano-scale morphology of Ce-doped PFSAs, and ultimately govern their ion transport.[4] Both water uptake and conductivity decrease with increasing Ce-doping, at all humidity levels, even though the magnitude of the reduced transport functionality intensifies at higher humidity values. Using the Nernst-Stokes-Einstein equation, the impact of Ce on the local solvation structure of water in the membrane can de delineated the from mesoscale changes in transport pathways, which were characterized using data from x-ray scattering experiments. SAXS/WAXS experiments reveal that nanostructural features, especially spacing and inter-connectivity of hydrophilic nano-domain decrease with increasing Ce-loading, in a nonlinear fashion. While the effects of Cerium on membrane uptake and nanostructure is relatively minimal below 10% Ce-exchange, this impact on structure-properties is exacerbated with increasing Ce-exchange up to 50%.

Exploration of the relationship between conductivity and hydration reveals universal correlations, which are validated by transport models based on dilute- and concentrated solution theory.[1, 9] The results indicate that conductivity diminished with doping level but different than expected by simple substitution of proton by another cation. Overall, Ce-doping tends to increase transport resistances in the membrane especially in dry-hot conditions, a critical finding for automotive fuel cells. Also, since Ce gradients form within the membrane during operation, which is confirmed by both experiments and simulations, low average Ce loadings can yield very high local Ce concentrations, thereby deteriorating membrane transport even more dramatically. This effect of the latter phenomenon is confirmed using a multi-physics model,[8] which is used to simulate cell performance with and without the acquired data on Ce-dependent properties.

Lastly, the collected dataset on thickness-dependent properties indicate transitions in certain structural features below 10 μm, accompanied by an increased anisotropy in swelling and conductivity. Many properties deviate within 10-20% without monotonic changes with thickness, however, linear correlations are observed between thickness and thermal-mechanical properties and gas permeability, although the latter is less significant.

CONCLUSIONS

The combined experimental and theoretical analysis reveals a decrease in hydration and a nonlinear decrease in conductivity with increasing cerium loading, which is driven by fundamental phenomena such as cation solvation at

molecular level and morphological changes. The implications of these structure-property changes on membrane performance and optimization are analyzed and simulated using membrane transport theories and cell-performance models, respectively. Experimental and theoretical results are used to generate a design map for PEMs with additives that account for various operation conditions (humidity and temperature) and material parameters (doping levels). These conclusions could also translate into other mixed-cation systems relevant to fuel-cells to model and examine not only other radical scavengers but also cations originated from other sources, such as contamination and cobalt leaching. These results have significant implications on the design of experiments and membranes for optimizing not only the ionomers as PEMs but also the ionomers in fuel-cell catalyst-layer design for an expanded investigation of polymer electrolyte fuel cell performance and durability. Additionally, identifying the thickness-dependence of PFSA properties could help expand the parameter window of PEMs, thereby enabling their optimization for automotive fuel cells, heavy-duty applications, and electrolyzers.

ABSTRACT

One challenge for the automotive application of polymer electrolyte fuel cells (PEMFC) is the start-up at sub-zero temper-atures due to the freezing of water inside the cell. The temperature has to rise above 0 °C before the ice completely blocks the cathode pores and inhibits the oxygen reduction and species transportation. A promising solution to quickly increase the temperature of the fuel cell in a sub-zero environment is a metal hydride reactor. This thermochemical heater can exothermally absorb hydrogen and heat up the heat transfer fluid of a PEMFC stack.

This work presents a transient 2D numerical model of a single fuel cell thermally coupled to a metal hydride reactor via the heat transfer fluid. Both components are validated with experimental data. The simulation of the coupled system yields the necessary preheating time up to 0 °C to avoid any ice formation and potential damages due to ice in the cathode. Another cold start strategy is the potentiostatic start-up after a shorter preheating time, i.e. ice may be formed but a quicker cold start is possible. The criterion for a successful start in this work is an average temperature of 20 °C in the cathode catalyst layer, because the cold start can fail due to the blockage of the pores in the catalyst layer with ice but also with liquid water. For temperatures from - 5 °C to - 30 °C and cell voltages from 0.9 V to 0.1 V the preheating duration is varied to determine the optimum cold start procedure.

Keywords: PEMFC, Simulation, Cold start, Metal hydride, Preheating

INTRODUCTION

One challenge for the widespread application of polymer electrolyte fuel cells (PEMFC) is the start-up with temperatures below 0 °C. The water stored in the polymer electrolyte membrane and catalyst layer and produced during oxygen reduction reaction may freeze and block the electrode pores. This reduces the reaction sites and species transport which decreases the electrical power of the cell. If the frozen or liquid water blocks the pores completely the cold start fails.

A solution for this problem is the assisted cold start instead of a self start, i.e. external heating of the fuel cell. This can be achieved by heating up the coolant with an electrical heater [1, 2] or with a metal hydride reactor (thermochemical preheater). Such a device utilizes the pressure of the hydrogen tank and produces heat upon hydrogen absorption. After a successful cold start, the waste heat of the fuel cell during normal operation recharges the metal hydride reactor (desorption of hydrogen) [3, 4, 5].

MODELING

The simulation of the assisted cold start is performed with a 2D transient modeling framework called NEOPARD-X [6, 7] which is based on DuMux [8]. The governing model equations are described in references [6, 7,9, 10]. It includes following features:

- A 2D along-the-channel geometry (Fig. 1) with nine spatially resolved layers in the fuel cell (anode and cathode channels, GDLs, MPLs, CLs and the membrane) and three layers in the metal hydride reactor (heat transfer fluid, reactor shell and metal hydride bed)
- A multiphase Darcy model for the two-phase, multicomponent transport within the porous electrodes
- Phase change of water in the pores, membrane and ionomer (Fig. 1)
- A hydrogen absorption (and desorption) model in the metal hydride
- A membrane model including coupled water and proton transport as well as transport of dissolved gas species

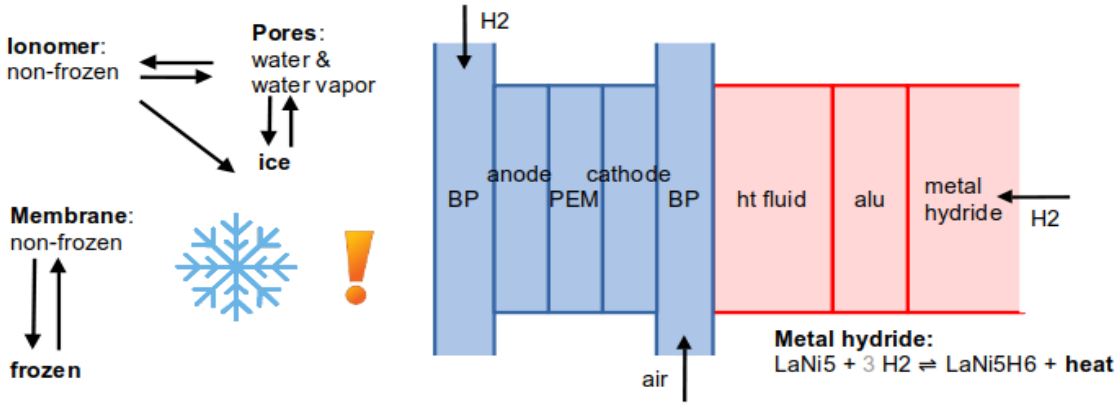

Fig. 1. Simulation domain of the fuel cell coupled to the metal hydride reactor.

- Proton transport through the ionomer within the CLs and electron transport through the support phase of the porous electrodes
- Butler-Volmer kinetics for the ORR and HOR reactions
- An ionomer film model describing the oxygen transport from the gas phase through the ionomer film to the cathode catalyst
- Energy transport through all layers of the cell

The fuel cell has a channel length of 10 cm and an active area of 73.8 cm². In the experimental setup, a fuel cell stack with 15 cells (end plates are neglected) is heated by one metal hydride reactor. One cell is then effectively heated by 20.7 g metal hydride (LaNi5) and thermally coupled by 31.1 g coolant (50 % Glysantin) and 19.7 g reactor shell (AlSi10Mg).

RESULTS AND DISCUSSION

One possible cold start strategy is the preheating until the mean temperature reaches 0 °C in the cathode catalyst layer (CCL) before starting the fuel cell to completely avoid ice formation and potential degradations in the CCL. According to the simulations, cold start without ice formation is possible from - 5 °C in 14.8 s, - 10 °C in 24.2 s, - 15 °C in 37.0 s and from - 20 °C in 61.1 s. However, the maximal temperature increase with external heating only is 24.3 K and takes longer time.

Another cold start strategy is the potentiostatic start-up when the CCL temperature is still below 0 °C. While ice formation is possible, this strategy allows for faster start-ups in colder environments. For example, the time for a successful cold start with - 20 °C is 142 s for 0.7 V cell voltage, 74.7 s for 0.5 V, 50.4 s for 0.3 V and 45.0 s for 0.1 V. The corresponding preheating times for - 20 °C are 15 s, 35 s, 30 s and 30 s for 0.7 V, 0.5 V, 0.3 V and 0.1 V, respectively. The criterion for a successful cold start is here defined as the CCL temperature reaching + 20 °C, since next to freezing also flooding of the CCL is a common cause for a failed cold start.

Lower cell voltages enable faster cold starts, because the overpotential, especially the concentration overpotential, is larger and, hence, the heat production higher. The cold starts at - 20 °C with 30 s preheating time with two different cell voltages are compared in Fig. 2. On the left, the start-up with 0.5 V fails due to the high saturation of frozen and liquid water in the CCL. While the mean temperature reaches + 3 °C, the temperature distribution is inhomogeneous and the areas closer to the gas inlet and outlet are still below 0 °C due to the thermal mass of the bipolar plate gas manifold. However, this failure is close and a 5 s longer preheating time yields a successful cold start.
By lowering the cell voltages, the waste heat is significantly increased [11, 12] (Fig. 2 right). Upon starting, the CCL temperature quickly increases from - 8.7 °C to 0 °C within 1.7 s. The cold start would then finish much quicker if the thermal mass of the coolant would be smaller. Hence, it is recommended to turn off the coolant circulation upon the potentiostatic start with a low cell voltage, because the CCL temperature is then higher than the coolant temperature.

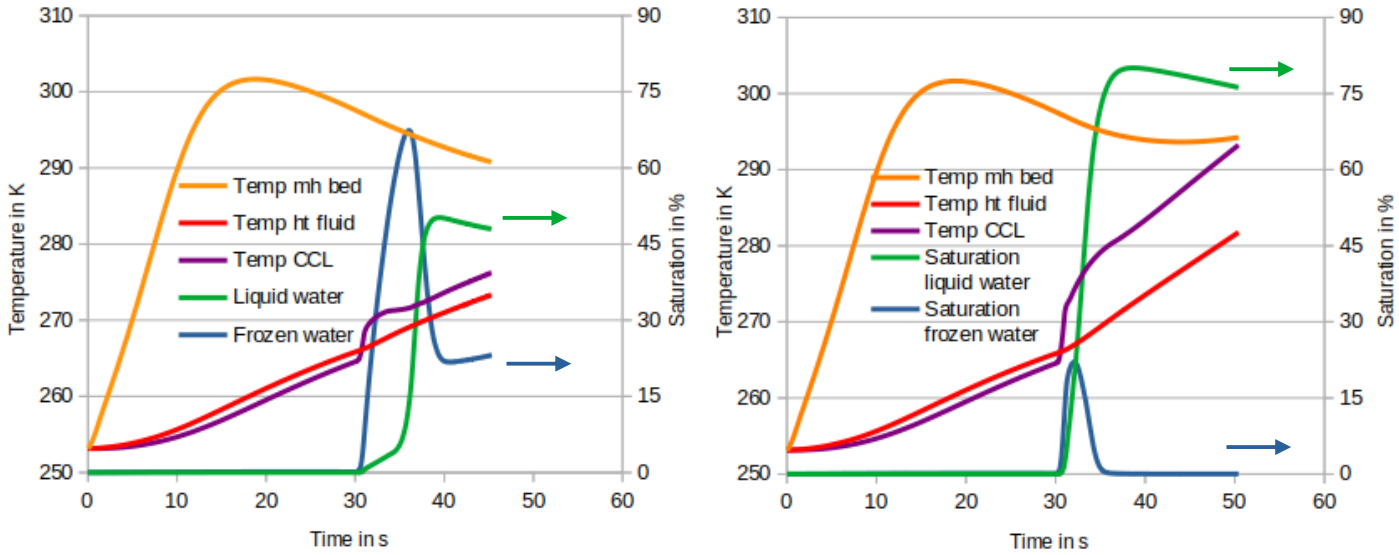

Fig. 2. Cold start from - 20 °C and 30 s preheating time. Left: cell voltage of 0.5 V results in a failed start due to high saturation of liquid and frozen water. Right: 0.3 V yields higher heat production and a successful start-up.

CONCLUSIONS

This work models the assisted cold start of a PEMFC with a thermochemical preheater (metal hydride reactor) and investigates effective start strategies for temperatures from - 5 °C to - 30 °C. The first strategy is the preheating of the cell up to 0 °C and then starting the cell. This procedure avoids ice formation and potential damages in the cathode, but is slow (e.g. 61 s from - 20 °C). A faster cold start strategy is heating the fuel cell up to about - 8 °C, switching off the coolant circulation and starting the cell with a low voltage (~ 0.1 V). Such a low voltage yields a high concentration overpotential and thus a high heat production.

ABSTRACT

The main objectives for the design of modern PEM fuel cells are to ensure minimize costs and size and ensure operation at elevated power densities with minimized accumulation of water inside the flow fields. Currently, number of authors are dedicated to increasing the flow field complexity, resulting in higher performance but also elevated manufacturing costs. By minimizing the complexity of the flow field and avoiding complex 3D structures, the main candidate still remains the serpentine flow field due to favorable characteristics of low pressure drop and good water removal. Due to discrepancies found in literature, in this work, the focus is on investigation of the liquid water accumulation inside the flow field of PEM fuel cell using up-to-date numerical model and full-scale single cell geometry with active area of 25 cm^2, experimentally and numerically using computational fluid dynamics modeling. The initial simulation model is calibrated using experimental data and later modified according to literature recommendations, outlining the influence of designs on water accumulation, resulting in significant performance improvement using simple geometry. The future goal of the research is upscaling the developed geometry for 50 cm^2 active area and comparing the numerical results with experimentally obtained locally resolved current density distribution.

Keywords: PEM Fuel Cells, Computational Fluid Dynamics, Experimental, Flow Fields

INTRODUCTION

PEMFCs are considered as the primary candidate for replacing internal combustion engines for transport applications in the near future due to high efficiency, clean and silent operation, compact size, capability of fast recharging, etc. Besides the MEA, the main influence on the performance of the cell is attributed to the flow field channels. The main objective of the flow field channels is to achieve uniform reactant distribution along the entire flow field of the cell with low pressure drop to avoid the requirement for pumping power for air. However, since PEMFC generates water and heat during operation, there are also two additional requirements – to ensure proper heat removal and avoid hot-spots which are detrimental to the health of MEA and to efficiently remove the generated water. Due to the reasons specified, it is not simple to design one-for-all flow field type. Due to complex relation between water and heat management inside PEMFC flow fields and MEAs, there are large number of different directions of flow field design, lately mostly oriented towards the development of flow fields which are highly complex and costly to produce, such as seen in first Toyota Mirai [1], resulting in designs which give high performance but at a very high financial cost and only for some narrow range of operating conditions. Also, evident by new Toyota Mirai, they have radically changed the flow field in the new Mirai and significantly decreased the complexity of the flow field and changed to simple zig-zag flow field, due to reasons specified. For this reason, we have decided to pursue the direction of simplifying the flow field design and reducing the cost while orienting towards achieving good dynamic performance, heavily dependent on the ability to remove the water from the cell. Highly accurate numerical model with advanced multiphase model is developed, shown in detail in Penga et al. [2], giving insight into the water distribution for different flow fields which can be produced using only a small CNC machine and tested in laboratory under different ambient conditions, with final goal in aim – to design a scalable flow field which may not give the highest performance under all circumstances, but will ensure good water removal even if we scale the cell to much larger size, but use the same number of serpentines, channel width, depth and land width, etc.

MODELING AND EXPERIMENTAL

The equations making up the numerical model are developed and shown in detail in a previous study by Penga et al. [2], while the experimental procedure regarding the polarization curve recording are described in another work by Penga et al. [3]. Numerical modeling is carried out using commercial software ANSYS Fluent v17.2 with PEM fuel cell add-on module. The geometry of the original flow field configuration is shown in Fig. 1., Model 1. The other geometries are adapted as a result of literature recommendations. Model 1 and 2 use triple serpentine, while Model 3 and 4 use quadruple serpentines. Model 2 is based on recommendations from Kerkoub [4]. The active area of the flow field is 25

cm^2, i.e. 50 mm x 50 mm. Mesh is fully structured with minimal orthogonal quality exceeding 0.99 and 4 subdivisions across the height of each MEA component and channel depth and width. Operating conditions are specified below in Table 1.

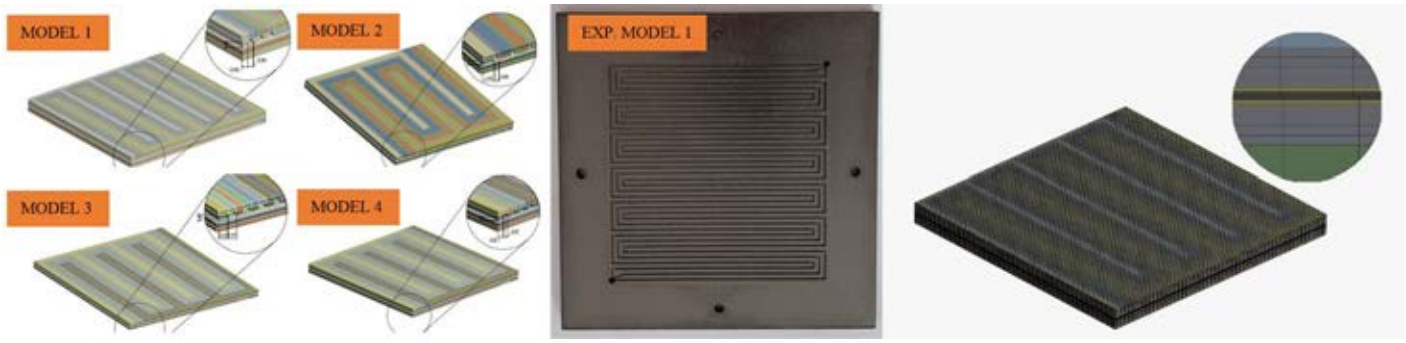

Fig. 1. Computational domains for different models (left), experimental flow field for Model 0 (middle) and mesh (right)

Table 1. Operating conditions, MEA and model geometrical parameters

Operating conditions				MEA geometrical parameters			Model geometrical parameters					
				Component	Units	Value		Units	Model 1	Model 2	Model 3	Model 4
	Units	Anode	Cathode	Current collector	mm	2 x Ch. depth	Active area	cm^2	25	25	25	25
Pressure inlet	kPa	100	100	Substrate	mm	0.155	Ch. width	mm	0.9	0.8	0.87	0.87
Relative humidity	%	50	50	Micro-porous layer	mm	0.02	Rib width	mm	0.9	2.4	0.87	0.87
Temperature cell	°C	80	80	Catalyst layer	mm	0.01	Ch. depth	mm	0.9	0.45	0.45	0.7
Flow	NLPM	0.4	80	Membrane	mm	0.015	No. serp.	/	3	3	4	4

RESULTS AND DISCUSSION

The resulting polarization curves are shown in Fig. 2. Model 1 was calibrated using the experimental polarization curve. The experimental polarization curve was recorded using 1 hour hold times at 4 different currents and low relative humidity operation to avoid accumulation of liquid water at higher currents. Such long hold times are necessary because the CFD analysis results in steady-state solution, and it is not possible to achieve steady-state with short hold times, as evident in a previous study [2]. The cathode and anode reference exchange current densities and concentration exponents are fine-tuned to result in good mutual agreement between the experimental and model polarization curve, evident from Fig. 2 (left). The fine-tuned values for Model 1 electrochemical parameters are used for all of the remaining models. Model 2 geometry was based on study of Kerkoub et al. [4], using channel to rib ratio of 0.33, which should result in increased performance. However, from Fig. 2. (left), it can be noted that the performance is almost identical to Model 0 regarding the operational efficiency, but it can also be noted in Fig. 2. (right) that the water removal is significantly improved vs. Model 1. Models 3 and 4 show higher performance along the entire range of operational current densities and significantly lower quantities of liquid water inside the flow fields, they both use 4 serpentines.

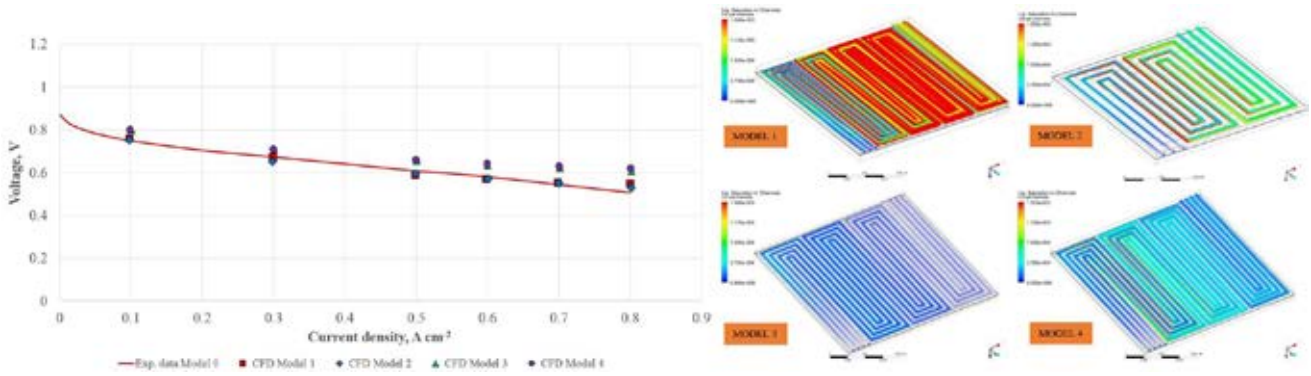

Fig. 2. Polarization curves (left) and liquid saturation inside channels (right)

Table 2 shows parameters of interest. It can be seen that performance related, Model 3 and 4 are the best. Model 3 shows lower quantities of liquid water inside the channels and CL, higher oxygen mass fraction in CL and lower overall temperature inside the cathode CL. For this reason Model 3 is chosen as the best and will be used for upscaling.

Table 1. Operating conditions, MEA and model geometrical parameters

CONCLUSIONS

The objective of this work was to thoroughly analyze four different serpentine configurations of simple serpentine flow fields on a 25 cm^2 PEMFC using up-to-date numerical model and to outline which flow field is the most promising candidate for upscaling on 50 cm^2 size in a future study where the results of numerical model will also be compared with locally resolved current density distribution using current scan shunt. The most influencing parameters on the performance are namely number of serpentines and channel depth. Channel depth of 0.45 mm vs. 0.9 mm and 0.7 mm, was found as optimal as well as four serpentines vs. three. Although literature suggests that channel to rib ratio of ca. 0.33 would be beneficial, this was not the case as out study found out.

ABSTRACT

This research applies the topology optimization method to propose an optimum radial flow field in polymer electrolyte membrane fuel cells with circular endplates. The cathode flow field is investigated in two dimensions, with the reactant gas modelled as a single-phase isothermal flow at steady-state. The gradient-based topology optimization approach is used, where the objective function is set to maximize the amount of power generated. The flow field evolves freely within the circular domain, and the resulting geometry is compared to a square endplate fuel cell with a single serpentine flow field. The results show that the optimized radial flow field significantly outperforms the serpentine flow field in power generation. Furthermore, the optimized radial flow field presents a lower pressure loss than the traditional serpentine flow field.

Keywords: PEM fuel cell, Topology optimization, Radial flow field, Circular endplate

INTRODUCTION

In Proton Exchange Membrane Fuel Cells (PEMFC), the performance can be further enhanced by modifying the geometry of the bipolar plates where the flow field channel structure plays a significant role. Several studies have been conducted on square endplates with different channel configurations such as parallel, serpentine, and interdigitated. In contrast, few studies have been undertaken on circular endplates with radial flow fields. In our research, the Topology Optimization Method (TOM) is employed to find an optimal radial flow field, and its performance is compared with a conventional serpentine flow field.

The flow field of PEMFC with square endplates has seen many improvements in the literature. For the time being, flow field topology optimization is the most robust design technique, primarily marked by Secanell et al. [1] in 2010 and recently applied on the flow field of PEMFCs with square endplates by Behrou et al. [2] in 2019. This research implemented a density-based topology optimization method, and the results demonstrate better power output, improved reactant distribution, and reduced pressure drop compared to classical flow fields. In contrast, fuel cells with circular flow fields have not been sufficiently developed over time. Perez-Raya [3] published a paper in 2010 on a radial design for circular endplates of PEMFCs. They placed the flow inlet in the center with four outlets on the perimeter and also added small rectangular ribs in the domain to better disperse the reactants. As a result, a serpentine configuration still had a better performance power than the suggested radial flow field; however, it required more pumping power. Their study demonstrated that channel design is a significant factor in designing radial flow fields to compete with conventional types. Later in 2012, Friess et al. [4] developed a novel radial flow field design for the cathode side of a PEMFC, which had a series of rings machined to various radii. They stated that the performance was increased compared to the parallel and serpentine flow fields and the pressure drop was at about half of the serpentine flow field. The performance of a radial flow field can be further improved by focusing on the ideal size of channels and ribs. In this way, the study by Wanchao et al. [5] in 2019 was carried out with a radial flow field in three cases. The flow field was modeled with eight independent sectors, each having ribs in the radial and angular directions. The results reveal that channel depth has a negligible effect while channel and rib widths directly impact radial flow field performance. Their comparison confirmed that the design with optimal dimensions yields a higher power density, improved water discharge, and lower pressure drop. This highlighted the significance of the channel structure in radial flow fields.

Studies in the literature lead us to conclude that significant improvements have been made in the channel configuration of fuel cells with square endplates. In contrast, circular endplates are limited to a few studies. Accordingly, radial flow fields can outperform flow fields in the square domain. Thus, our study aims at optimizing radial flow fields using a topology optimization approach to improve circular PEM fuel cells' performance.

NUMERICAL MODELING

The Finite Element Analysis is used to study the model numerically, and the Topology Optimization Method is applied to the design domain using COMSOL Multiphysics. The cathodic side of a PEM fuel cell consists of the bipolar plate (BPP), gas diffusion layer (GDL), catalyst layer, and membrane. Since the topology optimization method is computationally expensive, we reduced the simulation space from 3D to 2D using the depth-averaging procedure [2]. The 2D model is created by averaging the material properties of BPP and GDL to define equivalent porosity, permeability, and species diffusivity.

Governing Equations

A single-phase, steady-state, isothermal model is assumed, and the conservation equations can be summarized as follows.

$$\nabla \cdot \boldsymbol{u} = 0 \qquad \text{Conservation of mass} \tag{1}$$

$$\frac{1}{\epsilon^2}\rho \nabla \boldsymbol{u} \cdot \boldsymbol{u} = -\nabla p + \frac{1}{\epsilon}\mu \nabla^2 \boldsymbol{u} - \frac{12\,\mu}{H_{tot}^2}\boldsymbol{u} + \frac{\mu}{\kappa}\boldsymbol{u} \qquad \text{Conservation of momentum} \tag{2}$$

$$H_{tot}\,\rho\,\nabla \omega_k \cdot \boldsymbol{u} = H_{tot}\nabla j_k + R_k \qquad \text{Conservation of species} \tag{3}$$

In Eqs. (1,2), u is the velocity vector, ρ is the gas density, p is the relative pressure, μ is the dynamic viscosity, and H_{tot} is the sum of the heights of BPP and GDL. The third term on the right-hand side of Eq. (2) takes into account velocity gradients normal to the 2D plane. In Eq. (3), ω is the mass fraction of the species, k={O_2, N_2, H_2O}, and R_k is the reaction source term. The diffusion flux, j_k, is calculated from a mixture-averaged formula that includes the diffusivity factor f. Also, the porosity ϵ, permeability κ, and diffusivity f, are the design-dependent properties of the averaged materials. The local current density, i_{loc}, lies within the reaction source term and is calculated with the Butler-Volmer formulation.

Topology Optimization Method

An optimal radial flow field is derived using a density-based topology optimization method. The topology optimization formulation is defined as follows:

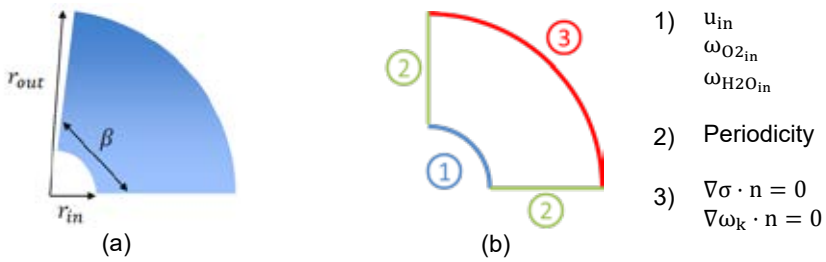
$$\underset{x}{Minimize} \quad -\int_{\Omega} V_{cell} \cdot i_{loc}\, d\Omega \tag{4}$$

$$Subject\ to \quad \frac{V(\boldsymbol{x})}{V_0} \le \overline{V}, \quad 0 \le x_i \le 1, \quad i=1,\ldots,N \tag{5}$$

Here, the objective function is defined as maximizing power generation and, in other words, minimizing the negative of the calculated power. V_{cell} is the cell voltage, V(x) is the final volume of the design, V_0 is the volume of the entire design domain, and $\overline{V}$ is the maximum volume fraction set at 50% to constrain the amount of material used in the optimization procedure. x_i is the independent design variable bounded continuously between zero and one, and N is the number of design variables. The design-dependent properties, $\epsilon(x_i)$, $\kappa(x_i)$, and $f(x_i)$ are interpolated with linear, modified RAMP, and SIMP material models respectively [2]. To eliminate checkerboard and mesh dependency issues, Helmholtz Filtering is used. Hyperbolic Tangent Projection is then applied to refine the unwanted grayscale areas. The discrete adjoint method is applied to analyze the sensitivities of the objective function and constraint with respect to design variables. Finally, the Globally Convergent Method of Moving Asymptotes (GCMMA) optimizer is used to solve the gradient-based optimization problem.

RESULTS AND DISCUSSION

In this work, the radial flow field in a circular fuel cell is optimized, aiming to maximize the power output. Different topologies are obtained with different constant values, and the results are compared to the serpentine flow field fuel cell with a single channel. To achieve comparable results, the two cells have the same active area and function under identical conditions. The circular cell domain and boundary conditions are shown in Fig. 1.



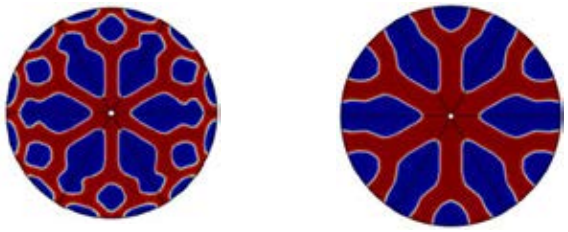


Fig. 1. (a) Domain and (b) boundary conditions for the circular fuel cell

Fig. 2 depicts the optimized topologies of the radial flow field. The ribs are shown in blue, and the flow fields are shown in red. The flow fields are mainly composed of radial channels with bifurcations which increase the reaction area. By comparing the final electrical power obtained by the cell with a traditional serpentine flow field, an improvement of around 20% is achieved. The results also reveal that the new optimized radial flow field has less pressure drop, which improves over a serpentine flow field.

Case 1 Case 2

Fig. 2. Optimized topologies of circular flow fields

CONCLUSIONS

A 2D numerical model has been investigated to simulate the cathodic side of PEMFCs with circular endplates. The 2D simulation appropriately represents the 3D model with the same transport conditions using the averaging procedure. The study is focused on designing circular fuel cells with an optimized radial flow field using the topology optimization method. The optimized topology is compared to a conventional fuel cell with a single serpentine flow field in the square domain. According to the results, the output power of the optimized cell is increased significantly compared to the serpentine flow field. Moreover, the optimized radial flow field has less pressure drop than a serpentine flow field, which is also advantageous.

ABSTRACT

Fuel-cell systems have been considered as an alternative power source to replace internal combustion engines in future vehicles to reach zero emission transportation target. A trustworthy and straightforward fuel cell system is needed to adopt a fuel cell-based power unit successfully. Open cathode fuel cell offers a simple configuration where the ambient air is used directly to provide cooling and serve as an oxidant. Therefore, an open cathode fuel cell system eliminates the requirement for a complex air supply subsystem, minimizing accessory load and reducing the overall cost of the system. The main challenge with the open cathode design is the strong dependence of the stack performance on the ambient conditions. Numerous studies considering the performance of open cathode fuel-cell and various factors affecting them have been reported. This paper presents the investigation of the effects of the environmental parameters on open cathode fuel-cell.

Keywords: Open cathode PEM fuel cell, airflow management, forced convection.

INTRODUCTION

Fuel-cell systems have been considered as an alternative power source to replace internal combustion engines in future vehicles to reach zero emission transportation target. Fuel cells can operate at higher efficiencies than combustion engines and can convert the hydrogen to electrical energy with efficiencies capable of exceeding 60%. Among various types of fuel cells currently available [1], the proton exchange membrane/polymer electrolyte membrane fuel cell (PEMFC) is considered to be the leading candidate for mobile and portable applications, especially for the vehicle power unit. It offers unique features not available in other fuel cells, such as low operating temperature, high power density, quick start-up, fast response to load changes, easy scale-up and high efficiency [2].

In a typical PEM fuel cell, fuel (hydrogen) and oxygen (air) are supplied to the active area inside the cell a series of channels where electricity is generated by an electrochemical reaction, water and heat come out as by product.

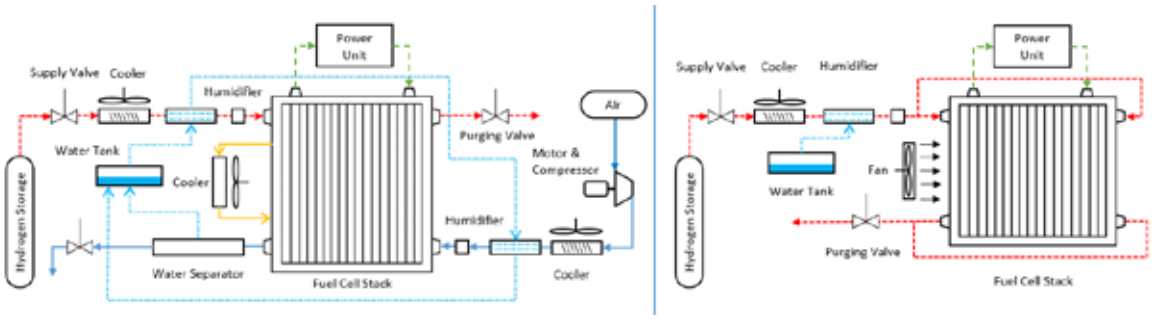

Fig. 1. Schematics representation of a) typical PEMFC and b) open cathode PEMFC system

Two configurations are commonly used for a fuel cell operating with air as an oxidant, i.e. closed cathode and open cathode. It is shown the general schematics of both configurations in Fig.1. The closed cathode PEMFC consists of an air supply, fuel delivery and circulation subsystem, cooling subsystem and fuel cell controller, as shown in Figure 1a. In contrast, an open cathode PEMFC is significantly less complex and less bulky, it is fed with ambient air directly (shown in Figure 1b).

This study evaluates the performance of the open cathode PEMFC system, including all the system components from those of fuel and air supply systems. Parameters such as; the cooling conditions, coolant flow rate, fan power rating in the natural and forced convection cooling at fuel cell stack are optimized to obtain efficient operating conditions. The performance of two different cooling strategies is then compared about the stack performance, complexity and polarisation.

System configuration of an open-cathode PEM fuel cell

The open-cathode PEM fuel cell has the unique merits of simple auxiliary subsystem and low cost; consequently, it can be an alternative power generation device for automobiles and other portable compact electric equipment [6].

As shown in Fig. 2, a 500 W open-cathode PEM fuel cell stack consists of 30 cells. There are many channels on the cells and electrically conductive separator plates between each pair of cells that function as the passageway of airflow and the conductor of electrons flow. The cells are all placed on top of each other and held together by intermediate plates with four blowers attached to the peripheral wallboard. The blowers feed in air consumed by the fuel cell and act as a forced coolant and take out the heat. The open-cathode fuel cell (selecting an H-500 fuel cell [7]) is fueled by hydrogen and oxygen-containing ambient air. The operating parameters of the 500 W open-cathode fuel cell are displayed in Table 1.

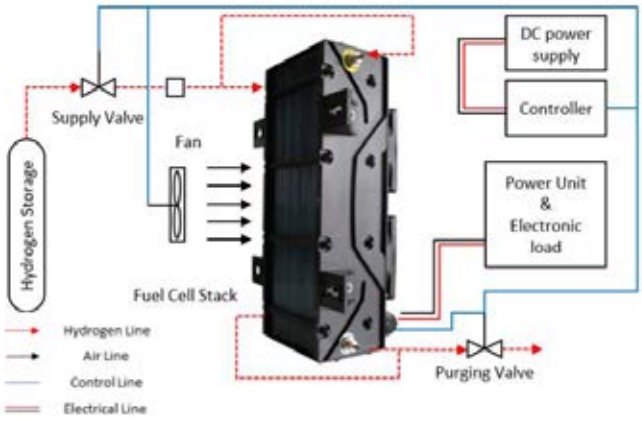

Fig. 2. Schematic diagram of a 500 W open-cathode fuel cell system

Table. 1: Operating parameters of the 500 W open-cathode fuel cell.

Descriptions	Values	Units
Over current shut down	*48*	*A*
Low voltage shut down	*12*	*V*
External power supply	*13/8*	*V/A*
Over temperature shut down	*63*	*°C*
Stack weight	*2500*	*g*
Voltage of blowers	*13*	*V*

Oxygen delivery mode in open cathode PEMFC

Oxygen delivery is an essential aspect in PEMFC operation. It directly affects the thermal performance and power of the fuel-cell stack. A uniform airflow distribution is crucial for the efficient operation of a PEMFC.

Cathode channels in the open cathode PEMFC system are exposed to the atmosphere, and hence the PEMFC operates at ambient pressure. As shown in Figure 1, this configuration simplifies the system, removing the need for a compressor, heater, and external humidifier. In general, there are two types of open-cathode fuel cells regarding the oxygen delivery method: natural convection and forced convection. In this study system, natural convection due to temperature and concentration difference drives air into the cathode channels. In forced convection system uses a fan to direct the ambient air to the cathode channel. Regarding the number of auxiliary devices used, free-breathing fuel cells offer superior simplicity relative to the forced convection counterparts. However, the airflow rate to the cathode might not be sufficient for the optimum reaction without the external fan.

MATERIALS AND METHODS

In this study, a fuel cell model (H-500XP Horizon) was utilized to measure the performances of the open cathode PEMFC stacks. Firstly, dry hydrogen was supplied to the anode side, at room temperature, and four fans supplied the forced ambient air to the open cathode channels. The ambient air is had a marked influence on the performance of an OC-PEMFC. Therefore, all experiment steps were carried out under the following conditions: a room temperature of 25.0 °C (±3.0 °C) and relative humidity of 40% (±15%). An additional voltage monitoring setup was attached to the fuel cell test station to measure the stack voltages of the 30-cell.

RESULTS AND DISCUSSION

A recorded current, voltage and temperature (temperature I-Forced convection, temperature II-Natural convection). values are shown in Tabel.2. As the increase of current, the output voltage of the stack continues to decline. Due to the increase of current, more and more heat is generated, and the average temperature of the fuel cell stack gradually increases. The stack temperature change can be seen for each fuel cell system.

The operating temperature of the PEMFC stack with forced convection is significantly lower than that of natural convection. When the current is equal to 28 A, the output voltage of the two is about 15 V, and the heat production is similar, but the average temperature difference between them is 7.8 °C. The control unit stops the system when the temperature is reached to 63 °C or more to protect the membrane from overheating. The output voltage of the stack with natural convection can be slightly lower than that of the stack with forced due to higher operating temperature [8].

Table. 2: Average voltage and temperature values for each current steps

Time (s)	Current (A)	Voltage (V)	Power (W)	Temp.-I (°C)	Temp.-II (°C)
0	0	27,90	0,00	24,2	24,2

CONCLUSIONS

The fundamental working principle, performance, technical challenges and potential applications of open cathode PEM fuel cells have been studied for both natural and forced air convection modes. Conclusions drawn from this study:

1. The forced convection open-cathode PEM fuel cell has a much better thermal, water and gas management as compared to the natural convection.
2. The fan selection and stack design need to be optimized to ensure high stack power.
3. Performance breakdown over time due to air quality is a significant issue in practical applications.
4. Seasonal temperature variations can affect the performance and durability of the stack. The environmental conditions, system design and material selection need to be carefully researched to ensure the stack can operate efficiently in all seasons.

ACKNOWLEDGEMENT

The authors wish to express their sincere gratitude to Professor Ali Sürmen for his valuable and constructive comments, which remarkably improved the paper.

EFFECT OF PLATINUM PARTICLE GRADIENT DISTRIBUTION IN LOW PLATINUM LOADING CATHODE CATALYST LAYER ON MEA PERFORMANCE

* *Rui Lin, Shengchu Liu*

ABSTRACT
The durability and performance of membrane electrode assembly (MEA) compose the bottleneck of fuel cells industrialization. In this paper, the effects of gradient distribution of Pt particles in the catalyst layer of MEA are studied. Polarization curves are carried out to evaluate the performance of MEAs with different Pt gradient dispersion under different relative humidity. It is found that when the Pt content of the catalyst layer remains unchanged, and the Pt particles are distributed near the membrane, the MEA has better performance because of the smaller oxygen transport resistance.

Keywords: Proton exchange membrane fuel cells, Pt dispersion, MEA, Catalyst layer

INTRODUCTION
The proton exchange membrane fuel cell (PEMFC) is regarded as one of the most potential clean energy technologies due to its high energy conversion rate, environmental friendliness, and high reliability[1]. At present, although the high cost of fuel cell stacks stems from the lack of large-scale applications, the cost of its core material-platinum-based precious metal catalysts also needs to be resolved urgently. Therefore, the development of high-performance, long-life, and low-platinum-loaded membrane electrode assemblies has attracted increasing attention[2, 3].

There will be oxygen transport resistance in each part of MEA during the operation of PEMFC. The oxygen transport resistance can be measured and analyzed by the limiting current method commonly.[4] At present, there are two ways to control the distribution of Pt particles in the cathode catalyst layer. Nonoyama et al.[5] did two types of experiments. In one experiment, the weight ratio of Pt/C remains the same, and the thickness of the catalyst layer (CL) is decreased, and in another experiment, the weight of Pt/C is reduced while the thickness of the CL remains constant. He concluded that the increase in oxygen transport resistance of low Pt loading was related to the reduction in the ionomers on the surface of the Pt particles. Owejan et al.[6] studied the oxygen transport resistance under different platinum loading. He kept the thickness of the catalyst layer constant by changing the weight ratio of Pt/C and adding carbon dilution. The above studies discussed the influence of the thickness of the catalyst layer on the oxygen transport resistance. The first way is to change the thickness of the catalyst layer by changing the Pt/C ratio while keeping the catalyst layer loading unchanged. The second is to keep the Pt/C ratio unchanged and adjust the thickness of catalyst layer doping carbon particles. In the catalyst layer prepared by these two methods, the distribution of Pt particles in different positions in the catalyst layer is the same.[7, 8]

Moreover, in the low Pt loading catalyst layer, the gradient distribution of Pt particles in catalyst layer has not been studied by researchers. Therefore, it is necessary to further explore the influence of the catalyst distribution in the cathode catalyst layer on the performance of the fuel cell under low platinum loading.

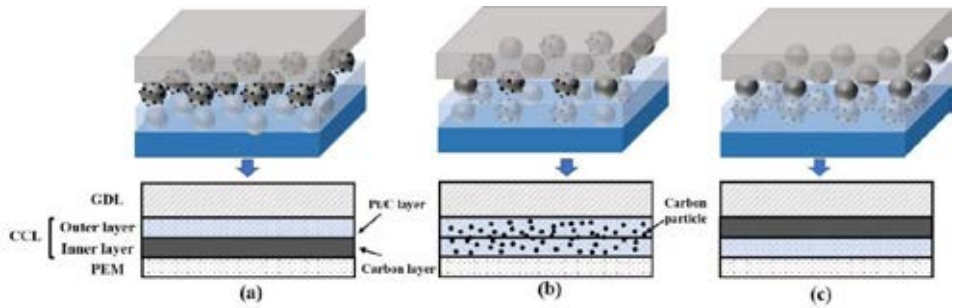

Fig. 1. Different structures of the cathode catalyst layer. (a) Add a carbon layer between CCL and GDL; (b) Add a carbon layer between CCL and PEM; (c) Mixing carbon powder into CCL.

EXPERIMENTAL
All MEA samples were manufactured by the decal transfer method. The catalyst ink was prepared by uniformly mixing 40 % Pt/C (Johnson Matthey), deionized water (DI Water), isopropanol (IPA), and 5 % Nafion solution. The cathode

catalyst layer (CCL) structure with different Pt dispersion positions is shown in Fig. 1. The structure was realized by mixing carbon powder into the CCL. The active area of the CCL and anode catalyst layer (ACL) was 25 cm^2, and the Pt loading was both 0.1 mg/cm^2.

Table 1. The composition of six types of CCL.

MEA-No	Total mass ratio Pt:C in CCL	Mass ratio Pt: C of CCL	
		Inner layer	Out layer
MEA-1	3:7	0	4:6
MEA-2	3:7	4:6	0
MEA-3	3:7	3:7	3:7

RESULTS AND DISCUSSION

The effect of relative humidity on the cell performance

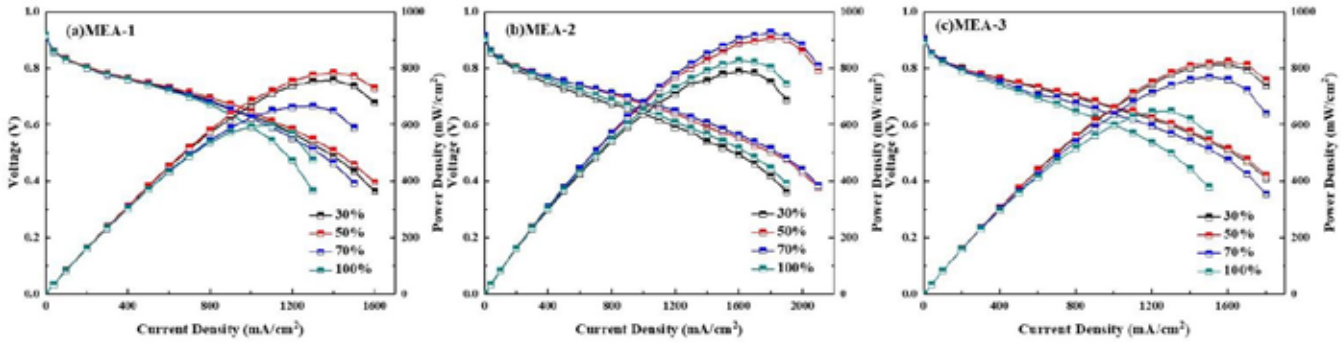

Fig. 2. Polarization curves under different relative humidity. Conditions: cell temperature of 80 °C, anode/cathode backpressure of 150/150 kPa, anode/cathode stoichiometry of 1.5/2.0.

Fig. 2 compared the polarization curves and power density curves under different relative humidity (RH) conditions. By comparing the performance of MEAs with different CL structures, it could be found that the MEA with structure (c) in Fig. 1 showed the best performance. Moreover, as shown in Fig. 2(b), when the RH was 50 %, the performance was almost the same as when the RH was 70 %. The maximum power density of MEA-2 was 905 mW/cm^2, and when the humidity was 30 % and 100 %, the performance of MEA was significantly reduced. This indicated that for the structure of Fig. 1(c), high RH would cause water flooding, and low RH would cause the membrane to dry and cause excessive internal resistance. The MEA-3 showed the second performance on the whole. It could infer from the performance curve that the structure (b) in Fig. 1 had better water retention capacity under low RH and inadequate drainage capacity under high RH. Therefore, the design was suitable for operation under low RH. And the MEA performance corresponding to structure (a) in Fig. 1 was the worst. As shown in Fig. 2(a), when the RH was 50 %, the maximum power density of MEA-1 was 785 mW/cm^2. When the RH was 100 %, the maximum power density was 599 mW/cm^2.

Oxygen transport resistance

The oxygen transport resistance can be measured by the limiting current method. When the absolute pressure was 0 kPa, the value of R_{total} was equal to the pressure-independent OTR (R_{PI}). And the pressure-independent OTR was mainly in the catalyst layer and micropores layer. As shown in Fig. 3, by extending the curve of R_{total}, when the curve intersected the vertical axis, the R_{total} can be obtained when the absolute back pressure was 0 kPa. The R_{PI} of MEAs with the structure in Fig. 1(c) was 10.88 s/m, which was smaller than that of MEAs with other structures. It meant that CCL with Fig. 1(c) was beneficial to oxygen transport.

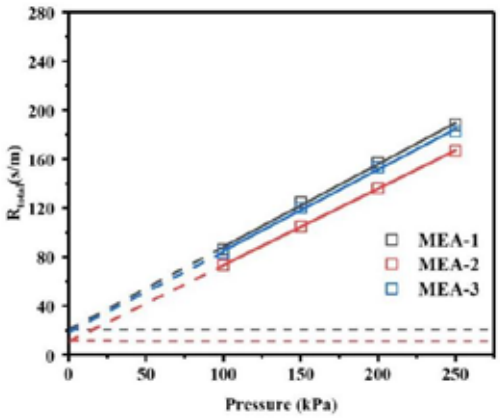

Fig. 3. The relationship between the back pressure and OTR of MEAs.

CONCLUSIONS

In this study, the low loading cathode catalyst layer with gradient dispersion of Pt particles was designed, and the influence of dispersibility on the performance of the MEAs was explored. When the cathode catalyst layer loading was 0.1 mg/cm^2, the maximum power density of MEA-2 can reach 0.927 W/cm^2. The result of the OTR test manifested that MEA-2 had the minimum gas transport resistance. A simple catalyst layer structure was successfully designed and applied to effectively improve the performance of MEAs.

ABSTRACT

Long-run stamping of bipolar plates affects die life, and bipolar plate geometric accuracy, formability and surface quality characteristics. These characteristics, in turn, would affect the corrosion and contact resistance of BPPs, consequently the fuel cell performance. The aim of this study was to investigate the reasons and consequences of the interactions during the mass manufacturing of micro-stamped sheets, and establish correlations between surface interactions vs. corrosion and contact resistance of BPPs. In experimental part of this study, 10,000 SS316L sheet blanks with 51µm in thickness were micro-stamped under 175-225 kN stamping force levels with a constant stamping speed of 1mm/s. Surface inspections, corrosion and contact resistance tests were carried out on the BPPs, periodically. On the other hand, 3-D finite element model of micro-stamping process was established to determine the coefficient of friction at the contact interface of micro-stamping dies and BPPs, von-Mises equivalent stress, plastic strain and final sheet thickness distributions. The results revealed that the roughness values for die pairs and BPPs followed similar trends during 10,000 micro-stampings. The corrosion resistance variation as a consequence of long-run manufacturing was found to be statistically insignificant, and the relation between surface roughness and corrosion resistance was found to be indirect.

Keywords: Bipolar plates, stamping, surface topography, contact resistance, corrosion resistance

INTRODUCTION

PEM Fuel cells are appropriate for the portable power and transportation applications mainly due to their low operating temperature levels and relatively quick-start features. However, cost and durability issues prevent PEM fuel cells from widespread use [1]. If the mass manufacturing of PEM is considered, the cost issue becomes more critical. When the cost of fuel cell power is compared with the internal combustion engines, fuel cell power is 4-10 times more expensive ($30-$50/kW vs. $200-$300/kW) [1-4].

Bipolar plate stands for high volume and high cost component of PEM fuel cells (60-80% of stack weight, 30-45% of stack cost) [5]. Molded graphite material is widespread BPP material for PEM fuel cells due to their excellent electrical conductivity and chemical stability. However, graphite BPP is not competitive in the energy market because of high manufacturing cost and time which is $10.42 and 45 seconds per plate, respectively [6]. Formed thin metallic sheets are promising candidates for a PEM fuel cell stack with high efficiency and low cost [7]. In addition to these advantages, metallic BPPs offer high electrical and thermal conductivity, chemical stability, compatibility for mass production, mechanical strength, cold-start features which are crucial in long-term stability of fuel cell applications. Considering the corrosion resistance requirement of BPPs, stainless steel stands forward as the most appropriate material among the other metallic BPP materials such as Ni, Ti, and Al based alloys [8].

There are several forming methods proposed for different materials such as machining for graphite BPPs, stamping process for metal BPPs and molding for polymer-carbon composites [9-11]. Among these BPP fabrication methods, stamping is the most competitive process since high production rates and cost effectiveness are possible with this technique [9]. Geometric accuracy (thickness and flatness), shape accuracy (channel dimensions, shape and distribution) and surface quality requirements are satisfied by stamping process. Since the surface quality of BPPs is highly affected by tribological conditions and die wear, understanding of material behavior and die/BPP surface interactions in micro-scale is very critical. Previous studies also showed that friction conditions in micro-scale is more aggressive than that for macro-scale because of the higher surface to volume ratio so called “size effect” [12-13]. During the high volume production of BPPs, high contact pressures cause highly localized stresses which result in topographic and tribological changes. These changes, in turn, may influence the corrosion and contact resistance behavior of BPPs, consequently the fuel cell performance. Therefore, surface topography alterations should be monitored and kept in acceptable range throughout the long-run manufacturing conditions.

Previous investigations on the topography and tribological behavior in micro-forming were performed mostly with short-run processes. This study, on the other hand, aimed for monitoring the topographic and tribological changes, contact conditions and their effects on the BPP in long run manufacturing conditions to obtain more realistic results since in real production conditions micro-stamping of BPPs is supposed to take place for ten thousands, if not hundred thousands, of cycles. In the experimental part of the study, investigations of the surface topography and tribological changes on the die and BPP interface during long-run micro stamping process were performed. Furthermore, correlations between surface topography and corrosion/contact resistance characteristics of BPPs were examined. Finite element (FE) based models were also established to observe stress-strain conditions and thickness change distributions on the formed BPPs. The coefficient of friction during the long run micro-stamping process was obtained from finite element analyses and compared with experimental findings.

EXPERIMENTAL AND NUMERICAL ANALYSES

Material and Stamping Dies

SS316L metallic sheet alloy with a thickness of 51 μm was chosen as BPP material. Mechanical and chemical properties of SS316L were presented in Table 1 and Table 2. 10,000 of SS316L sheet blank samples were prepared in 70mm x 70mm dimensions. Figure 1 shows the schematic of the stamping process and micro-stamping dies employed.

Table 1. Mechanical Properties of SS316L (as provided, Brown Metals, Rancho Cucamonga, CA, USA)

Condition/Tempering	Annealed
Modulus of Elasticity (Tension)	193 GPa (28 x 10^6 psi)
Ultimate Tensile Strength	711 MPa (103,100 psi)
Yield Strength at 0.2% offset	341 MPa (49,400 psi)
Percent Elongation in 2 inches	56.00%
ASTM Grain Size	10

Table 2 Chemical composition of SS316L (as provided Brown Metals Company, Rancho Cucamonga, CA, USA)

C	Mn	P	S	Si	Cr	Ni	Mo	Cu	N	Fe
0.021	1.48	0.033	0.001	0.43	16.2	10.03	2.06	0.43	0.04	Bal

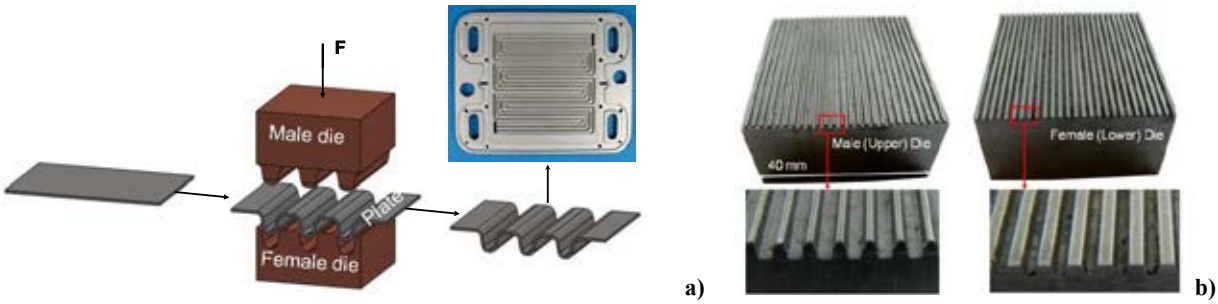

Fig. 1. a) Schematic of stamping process, b) Micro-stamping dies used to form SS 316L sheet blanks

Numerical Analysis

Commercially available explicit/implicit finite element code Ls-Dyna was employed to simulate the micro-stamping process. Due to the symmetry nature of the problem, a quarter 3-D model (Fig. 2) was established to reduce the simulation time. The blanks and blank holder were defined as deformable bodies and modeled with 4-node quadrilateral elements while female and male dies were assumed as rigid parts. The total number of elements used in the models was 52,338. In analysis, at least 11 different FEA were performed with different coefficient of friction values using Coulomb's friction model. In order to determine the range of coefficient of friction experienced in micro-stamping tests, first, a few FEA with the coefficient of frictions of 0, 0.1, 0.2, 0.3, 0.4 and 0.5 were applied and their corresponding channel height results were compared with the experimental results. Then, iterative finite element analyses were performed until the change in coefficient of friction value with respect to previous step is reduced under a level of 0.01. All contacting surfaces were specified as "contact forming one way surface to surface".available in Ls-Dyna. Blank holder force of 3 kN was applied on sandwiched sheet blank between upper

and lower die flat surfaces. Simulations were performed on a personal computer equipped with 2.8 GHz hyper-threading featured processor and 8 GB of RAM. Average computational time of 20 min. was recorded for analyses. This study investigated the effect of long-run manufacturing conditions on the surface topography, corrosion and contact resistance of micro-stamped BPPs. Several FEA analyses were conducted to estimate the coefficient of friction values occurred at contact interface.

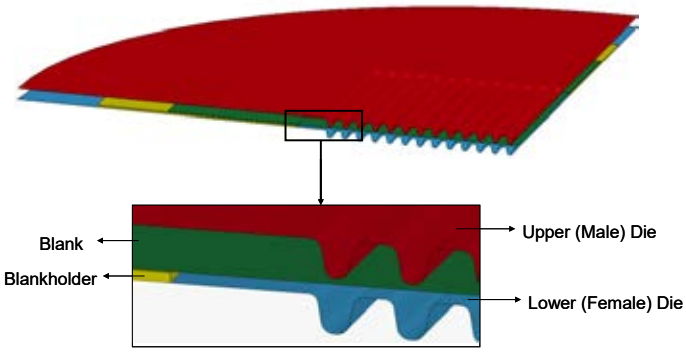

Fig. 2. 3D quarter FE model of stamping process used in fabrication of BPPs

CONCLUSION

Surface roughness analyses for forming die and BPPs demonstrated significant changes during the whole range of experiments. Although without patterned roughness changes was observed, the roughness trend between the microforming die parts (male, female dies) and micro-stamped BPPs was observed to be similar. Corrosion resistance test results showed that surface treatment is required to improve the corrosion resistance of plates to reach the DOE corrosion resistance targets. According to contact resistance tests, SS316L plates exhibited much higher contact resistance than DOE target levels. Contact resistance test results exhibited significant changes over 10,000 micro-stamping process. The correlation between surface roughness and contact resistance of BPPs was deemed to be direct.

The dimensional measurements of channel heights showed insignificant channel height changes at different stages of micro-stamping runs (i.e., 1st, 2000th, 4000th, 6000th, 8000th, 10000th). This implied to dimensional stability of formed products and repeatability of the process. Affected by these findings, coefficient of friction variation was negligibly small and was found to be between 0.18 and 0.19. Finite element analyses provided also useful information on the experienced stress, strain, thickness change magnitudes and valuable data for better die design and longer tool life.

ABSTRACT

In order to increase the utilization of PEM fuel cells, it is very important to develop alternatives that allow wider commercialization. It is well known that one of the most expensive components of the mentioned technology are the electrocatalysts [1] since they are based on scarce metals, such as Platinum. Diverse approaches have been taken to overpass this problem; different research works propose the combination of metals to achieve the required activity. Also, a variety of supporting materials have been studied to increase stability. However, a clear alternative there is still not available. This research work proposes to design and development of PEM fuel cell electrocatalysts with adequate activity and stability, but also optimizing the platinum loading. Multiwalled Carbon Nanotubes were obtained using a modified chemical vapor deposition method and used as support of Platinum particles deposited via a colloidal procedure. Low loadings were achieved. The obtained materials were physical and chemically analyzed with scanning and transmission electron microscopies. Also, an electrochemical evaluation towards the PEM fuel cell reactions was performed using cyclic and linear voltammetry, the proposed system exhibited higher current density per mg of Pt compared to a commercial material.

Keywords: PEM fuel cell, nanostructured electrocatalyst, low Pt loading, carbon nanotubes support

INTRODUCTION

Platinum base electrocatalysts are still monopolizing the PEM fuel cells market since they have the best activity. However, the scarcity of this metal impulses the research field to search for alternatives. The necessity of reducing the utilization of Pt for the PEM fuel cells electrocatalyst has been the motivation of diverse research works such as combining the Pt with other metals, decreasing the metal loading, using co-catalysts, testing different supporting materials, among others. On the other hand, during the last years, it has been established that the Multiwalled Carbon Nanotubes (MWCNT) exhibit great mechanical, chemical, and electrical properties. Hence, its utilization as a supporting material for PEM fuel cells electrocatalysts is currently being explored. The relevant surface characteristics allow the stabilization of metallic nanoparticles as well as promote the electronic transference during electrochemical reactions.

Hence, the main objective of this research work is to generate highly active low Pt loading electrocatalysts, optimizing the utilization of the Pt by creating very well distributed nanoparticles, as well as promoting the interaction with the support, MWCNT. A great advantage of the proposal is that the methodology used to obtain the MWCNT allows a semi-scale production (around 4 grams per batch) [2,3]. Also, the Pt nanoparticles deposition method is simple and accurate, allowing the low metal loading [4,5].

MATERIALS AND METHODS

Multi-Walled Carbon nanotubes (MWCNT) were obtained using a modified chemical vapor deposition methodology (M-CVD) already established and studied by the research group [2, 3]. In addition, a colloidal methodology was used to do the deposition of Platinum nanoparticles over the CNT surface [4,5]. Low Pt loadings were tested, to analyze the behavior of the electrocatalysts.
The structure of the obtained materials was analyzed using electron transmission microscopy (TEM). Also, scanning electron microscopy (SEM) studies were done to obtain the chemical properties and the morphology. On the other hand, the electrochemical evaluation was performed by cyclic and lineal voltammetry in a conventional three-electrode cell. The tests were done in acidic media using Ag/AgCl (KCl sat) as reference electrode, and Pt wire as a counter. To compare, the same analyzes were carried out on a commercial electrocatalyst, Vulcan carbon with Pt particles.

RESULTS AND DISCUSSION

Fig. 1 shows the typical tubular formation of the multi-walled carbon nanotubes (MWCNT) taken from transmission electron microscopy (TEM). In addition, it is possible to observe the Pt nanoparticles evincing that the used methodology is appropriated to achieve a very good particle distribution.

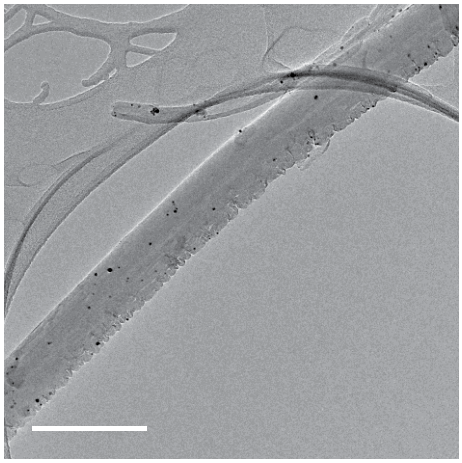

Fig. 1. Transmission Electron Microscopy micrograph of the low Pt loading material (LPt/CNT).

Table 1 shows the chemical elemental analysis performed by energy dispersion spectroscopy (EDS) using scanning electron microscopy (SEM). As can see, low metal loading was achieved around 2 wt%. Iron metal is attributed to the ferrocene catalyst used which remains inside the MWCNT.

Table 1. Chemical Elemental analysis by EDS

Element	Wt. %
Carbon	90.50
Iron	2.88
Oxygen	5.01
Platinum	1.17

The electrochemical results of the proposed material in the PEM fuel cell reactions is presented in Fig. 2. Regarding the hydrogen oxidation reaction (Fig. 2a) it is possible to observe that the Pt/CNT sample did not achieve a good activity compared to the commercial material (5%Pt over Vulcan). However, for the oxygen reduction reaction (Fig. 2b) the synthesized material demonstrates a higher limiting current. It is important to mention that as it is shown in Table 2, the Pt/CNT material has 4 times less Pt available to perform the reactions. However, the good distribution and size of the particles, as well as the interaction with the support (MWCNT) allows the material to provide better performance [6]. It is also noticed the onset potential is still low compared to the commercial material. Nevertheless, the behavior achieved opens a good opportunity to improve the design of the material with low Pt loading.

Table 2. Metal loading over the electrode

Sample	mg Pt/cm^2	Pt ratio
Low Pt CNT	0.016	1
5Pt Vulcan	0.067	4

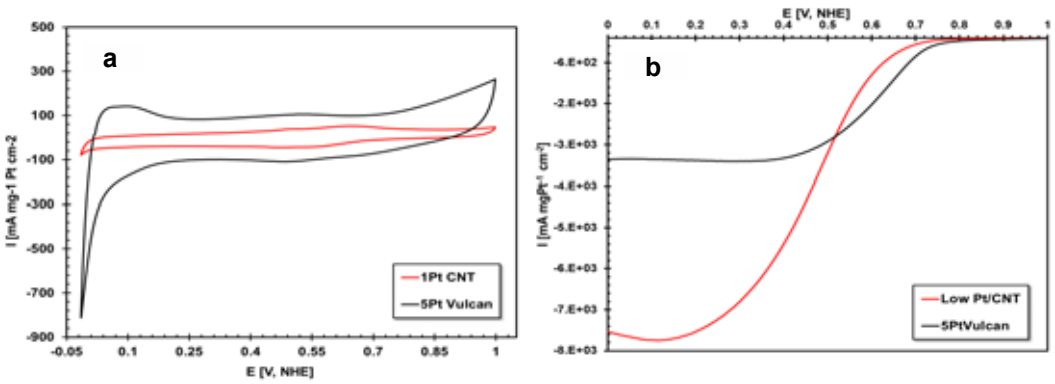

Fig. 2. Electrochemical evaluation using 0.5M H_2SO_4 as electrolyte: a) cyclic voltammetry, b) linear voltammetry

CONCLUSIONS

The Modified Chemical Vapor Deposition Method is suitable to produce MWCNT. The Low Pt/CNT system has shown a low activity (compared to commercial material) towards de hydrogen oxidation reaction. However, for the ORR low, Pt/CNT material exhibited a higher current density per mg of Pt, than the commercial material, this can be attributed to the good dispersion of Pt particles over the surface and the interaction with graphitic domains of carbon. Even though the onset potential is still lower, the behavior of the proposed materials opens a great opportunity for the development of affordable PEM-FC electrocatalyst with low Pt loading as well as good thermal and chemical stability. It is important to mention that different loading has been tested during the development of this research work, the complete set analysis will be presented at the conference.

ABSTRACT

In this study, the performance improvement of a proton exchange membrane fuel cell (PEMFC) by applying a magnetic field was revealed according to the catalyst loading. A unit H_2-air PEMFC was tested at catalyst loadings of 0.5 mg_{pt} cm^{-2} and 0.03 mg_{pt} cm^{-2}. The performance of a PEMFC increased by applying a magnetic field in both high and low catalyst loading conditions. However, the increasing rate in the performance was significantly higher in the high catalyst loading than in the low loading. The magnetic field effectively increased the catalyst utilization, and the performance improvement as a result of increased catalyst utilization was more effective in high catalyst loading. In conclusion, it is more effective to apply a magnetic field to PEMFCs at high catalyst loading than at low catalyst loading.

Keywords: PEMFC, Catalyst loading, Magnetic field, Performance

INTRODUCTION

Proton exchange membrane fuel cells (PEMFCs) are next-generation energy converters as an essential component of a hydrogen economy. A PEMFC has many advantages to be a promising energy source such as zero emissions and high efficiency. However, the low activity of a cathode oxygen reduction reaction (ORR) deteriorates the performance of PEMFCs, which hinders the commercialization of PEMFCs [1]. Therefore, the improvement of ORR performance is important for the commercialization of PEMFCs.

Among many efforts to enhance the ORR performance of PEMFCs, recently, an ORR activity improvement method using a magnetic field has been studied by several research groups. Oxygen is affected by the force of a magnetic field because oxygen is a paramagnetic material [2]. Therefore, a magnetic field can have a positive influence on the ORR of PEMFCs by enhancing the movement and transport of oxygen on an electrode surface. Several studies were reported to reveal the performance improvement by a magnetic field. Abdel-Rehim [3] studied the performance enhancement of an open cathode PEMFC stack by a magnetic field controlling the fan power of the air inlet. Ruksawong et al. [4] reported the performance improvement of a PEMFC by a magnetic field, and the improvement increased with an increase in the magnetic field density. However, the electrode condition of cathode catalysts has not been mainly discussed as a critical variable for the study. The performance improvement of PEMFCs by a magnetic field is mainly caused by the improvement of ORR activity. Since the ORR occurs on the cathode electrode, the performance improvement by a magnetic field is naturally affected by the electrode condition of a cathode catalyst.

In this study, the effect of catalyst loading on the performance improvement of a PEMFC by a magnetic field was investigated using a unit cell. The performance of a PEMFC was tested by varying the Pt/C catalyst loading of a cathode with and without a magnetic field. Based on this experimental study, the effect of catalyst loading was revealed, and the optimal catalyst loading for best performance improvement by a magnetic field was determined.

EXPERIMENTAL

In this study, a unit PEMFC with an active area of 9 cm^2 was used to determine the performance. Hydrogen and air were supplied to the anode and cathode, respectively. The relative humidity of both hydrogen and air was 80%, and the stoichiometries were 1.5 and 2.5 for hydrogen and air, respectively, based on the current density of 2 A cm^{-2}. The operating temperature and pressure were 80 °C and atmospheric pressure, respectively.

A magnetic field of 0.2 T density was applied to the PEMFC. The magnetic field was created by five neodymium (Nd-Fe-B) magnets at each side of the PEMFC. The Pt/C catalyst loading of the cathode electrode in the PEMFC was varied as 0.03 mg_{pt} cm^{-2} and 0.5 mg_{pt} cm^{-2}. The catalyst loadings were selected as the representative of high and low loading. Based on the variation of catalyst loading, the effect of the catalyst condition on the performance improvement by a magnetic field was revealed.

RESULTS AND DISCUSSION

Fig. 1 shows the variation in voltage and power density as a function of current density with and without a magnetic field. The voltages and corresponding power densities increased by applying a magnetic field in both high (0.5 mg_{pt} cm^{-2}) and low (0.03 mg_{pt} cm^{-2}) loadings. However, the amount of increment was notably different. The performance improvement using a magnetic field was much larger in the electrode condition of high loading than in low loading.

Fig. 2 shows the increasing rate of the PEMFC performance by applying a magnetic field according to the catalyst loading. The performance increasing rate of high loading PEMFC was significantly larger than that of low loading in all voltages. The magnetic field aided the transport and movement of oxygen, so the oxygen was better adsorbed on the catalyst surface in the magnetic field. In other words, the magnetic field effectively increased the catalyst utilization, and the performance improvement as a result of the increased catalyst utilization was more effective in high catalyst loading condition. In summary, it is effective to apply a magnetic field to PEMFCs at high catalyst loading conditions.

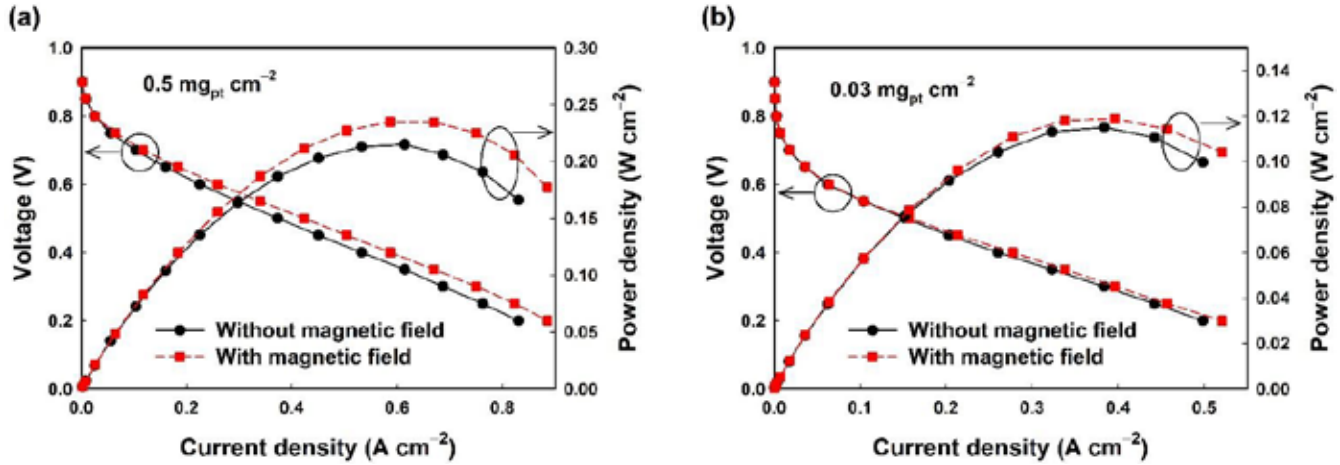

Fig. 1. Variation in voltage and power density as a function of current density according to the catalyst loading of (a) 0.5 mg_{pt} cm^{-2} and (b) 0.03 mg_{pt} cm^{-2} with and without a magnetic field.

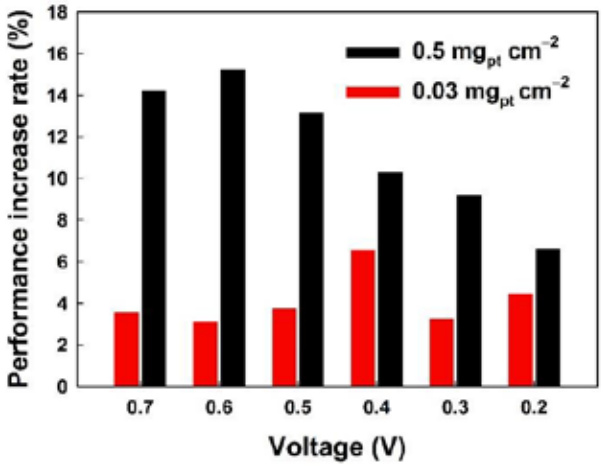

Fig. 2. The increase rate of PEMFC performance by applying a magnetic field according to catalyst loading.

CONCLUSIONS

In this study, the performance improvement of a PEMFC by a magnetic field was investigated according to the catalyst loading. The unit PEMFC tests were conducted at catalyst loadings of 0.5 mg_{pt} cm^{-2} and 0.03 mg_{pt} cm^{-2}. The performance of a PEMFC increased by applying a magnetic field in both high and low catalyst loadings. However, the amount of increment and increasing rate were much higher in the high catalyst loading than in the low loading because the magnetic field improved the catalyst utilization. In conclusion, the performance improvement by applying a magnetic field can be significantly increased with the increase in catalyst loading on an electrode.

ABSTRACT

Aluminum Alloy (AA 5052) is an inexpensive and lightweight metal that has been used in a variety of applications including as a bipolar plate in Proton Exchange Membrane Fuel Cells (PEMFC). The alloy has good electrical conductivity and low corrosion, corrosion rate will increase during PEMFC operation with increasing temperature. Inorganic dyes such as chromate are commonly used to reduce metal corrosion, unfortunately, they are toxic and have a negative impact on the environment. To solve this problem, chitosan as an organic solvent is green, cheap, non -toxic and environmentally friendly. Thickening electrophoresis (EPD) technique was used to coat the surface of AA 5052 with chitosan.. To measure the level of corrosion rate using electrochemical and weight los methods (in 0.5 M H_2SO_4 solution). Levels of AA 5052, with and without chitosan, were 0.1702 $mgcm^{-2}\ h^{-1}$ and 0.0552 $mgcm^{-2}\ h^{-1}$, respectively. Based on the polarization test, chitosan inhibitors can decrease the corrosion rate and will increase with increasing temperature.

Keywords: PEMFC, Inhibitor Chitosan, EPD, Corrosion rate

INTRODUCTION

Aluminum and its alloys have many advantages over other metals because of their high electrical conductivity, low cost and light weight [1]. The resistance of aluminum in a corrosive environment under certain conditions is due to the presence of an oxide layer on its surface [2]. Aluminum alloy 5052 (AA 5052) contains 97.2% - 97.8% aluminum (Al) and 2.2% - 2.8% magnesium (Mg). The addition of Mg to AA 5052 metal can increase its strength without reducing its ductility [1]. AA 5052 can be applied to aircraft, automotive, construction and bipolar plate components in Proton Exchange Membrane Fuel Cell (PEMFC) systems. The selection of AA 5052 as a bipolar plate is generally based on its properties namely, high conductivity, low cost and light metal) compared to other metals [3,4]. Generally PEMFCs are operated under acidic conditions at temperatures of 40 °C to 80 ° C (313 – 353 K) [5,6]. Yang, Guo & Liu [5] reported that acidic environmental conditions and relatively high operating temperatures can cause alloy AA 5052 to corrode [7].

In general, corrosion is defined as damage to metal surfaces caused by chemical reactions between the surface and the environment. Inorganic inhibitors such as chromate to combat corrosion. Unfortunately it has a negative impact on the environment due to its toxicity [9, 10]. Based on these facts, green organic inhibitors are the best alternative to prevent and reduce corrosion. Chitosan is an organic compound derived from chitin which has the potential as a corrosion inhibitor because it fulfills all the characteristics. Chitosan can be produced from chitin through hydrolysis and deacetylation processes containing amino (-NH2) and hydroxyl (-OH) groups both of which act as absorbents to inhibit the corrosion rate through the absorption process [11-14].

It is known that temperature plays an important role in the corrosion process, especially in PEMFC operation. Therefore, this study tried to explore the effect of temperature differences on the corrosion rate of AA 5052 alloy with and without chitosan in 0.5 M H_2SO_4 at different times and temperatures. The effects on corrosion rate and inhibition efficiency are discussed in detail along with the performance analysis (potentiodynamic polarization and activation energy analysis).

MATERIALS AND METHODS

Equipment and Materials

AA 5052 alloy with size of 20 mm x 10 mm x 2.5 mm was selected during this experiment. Chitosan (Merck, with standard analysis) was used as a green organic inhibitor. The corrosion rates of AA 5052 with and without chitosan were evaluated by using the potentiostate CorrTest CS350 to analyze the potentiodynamic polarization. The morphology and element compositions on the surface of AA 5052 with and without chitosan were analyzed by using a scanning electron microscope (SEM, Hitachi TM3000) equipped with energy dispersive X-ray spectroscopy (EDX,

Carl Zeiss EVO MA 10). Firstly, AA 5052 alloy was washed with acetone and polished by sand paper with grids of 200, 400, 600, 1000 and 2000. After that, AA 5052 alloy was washed with acid and base pickling solution, and then rinsed with deionized water. Cleaned AA 5052 alloy was perforated using a drill with a diameter of 2.5 mm. To hold the AA 5052 alloy, a polyvinyl chloride (PVC) cable was attached. Lastly, the AA 5052 alloy surface was smeared with epoxy, except for a 1.0 cm^{-2} of its surface. 0.5 % of chitosan solution was prepared using a total 0.15 g of chitosan that was diluted in 30 mL acetic acid (CH_3COOH). The mixed-solution was stirred until homogeneous by using a magnetic stirrer [14]. AA 5052 alloy was put into the electro phoresis deposition (EPD) cell that contained 0.5 % chitosan solution. The EPD process was performed at room temperature with AA 5052 as cathode and carbon felt as anode. The EPD process was conducted for 10, 20 and 30 minutes with an applied voltage of 20 V..Corrosion rate tests: Weight loss analysis AA 5052 with and without chitosan were immersed in 0.5 M H_2SO_4 for 72, 120 and 168 hours at room temperature [15].

Electrochemical method with potentiodynamic polarization

The corrosion rates of AA 5052 alloys with and without the chitosan was verified and analyzed using the potentiodynamic polarization method. This test was performed using the potentiostat CorrTest, model CS350 at temperature of 298 K, 313 K, 333 K and 353 K. Potentiodynamic polarization cell was arranged as three electrode configurations, in which theAA 5052 acted as the working electrode (WE), platinum (Pt) rod as the counter electrode (CE) and Ag/AgCl as the reference electrode (RE). The applied potential used was in the range of -0.9 V to -1.0 V with a scan rate of 2 mVs.

RESULTS AND DISCUSSION

Analysis of time effect on EPD process

The corrosion rate of AA5052 with and without chitosan increased with increasing immersion time in 0.5 M H2SO4 solution . The lowest corrosion rate without chitosan was obtained at 0.1491 mgcm-2h-1 at 72 hours. Meanwhile, after the EPD process, the lowest corrosion rate was found in the 20th minute (0.0181 mgcm-2h-1) followed by 10 minutes (0.0245 mgcm-2h) and 30 minutes (0.0398 mgcm-2h-1). This phenomenon can occur because the chitosan layer on the surface in the 10 minute EPD process has not yet been formed. Meanwhile, the chitosan layer is thicker in the 30 minute EPD process, so that the layer acts as an inhibitor that reduces current density; consequently, the absorption of chitosan is less homogeneous [16,17]. Overall, the corrosion rate of AA 5052 alloy with chitosan decreased at 120 hours to 168 hours of immersion time. In principle the protective layer reduces the contact between the alloy surface and the electrolyte [18].

Effect of temperature on corrosion rate and inhibition efficiency

The results showed that the corrosion rate of AA 5052 with and without chitosan increased with increasing temperature The corrosion rate of AA 5052 with chitosan-20 cm^{-2} $h^{-1}$was 0.25 mg cm^{-2} h^{-1}at 298 K then increased to 0.43 mg cm^{-2} h^{-1} (313 K), 0.62 mg cm^{-2} h^{-1} (333 K) and 1.38 mg cm^{-2} h^{-1} (353 K), increasing temperature accelerates anodic and cathodic reactions, reduces dissolved oxygen in solution, and also accelerates cathodic diffusion, consequently increasing the corrosion rate [19]. The highest inhibition efficiency was 42.31% at 298 K. As discussed above, the inhibition efficiency decreased with increasing temperature. This fact may be because the cathodic chitosan has physisorption properties [20] which reduce the electrostatic interaction between the chitosan and the surface of AA 5052; consequently, its inhibitory activity decreases.

Activation energy analysis

- Activation energy can be defined as the minimum amount of energy that is required to activate atoms or molecules to a condition in which they can undergo chemical reaction or physical conversion. Theoretically, the corrosion rate can also been analyzed using the activation energy (E_a) equation, as formulated by Arhenius [21]. AA 5052 whitout chitosan was lower (20.55 kJ mol^{-1}) compared to AA 5052 with chitosan (25.82 kJ mol^{-1}). The higher activation energy indicates that AA 5052 with chitosan was more difficult to corrode compared to AA 5052 without chitosan [21]. This fact showed that the corrosion in AA 5052 alloy can be reduced by using a chitosan inhibitor is as shown in Table 1.

-

Table 1. Values of activation energy (E_a) for AA 5052 alloys with and without chitosan

Sample AA 5052	Linear regression	$-E_a/R$	E_a (kJ mol^{-1})
Without Chitosan	y = -2471x + 7.457	-2471	20.55
With Chitosan	y = -3105x + 9.020	-3105	25.82

Potentiodynamic Polarization Analysis

Potentio-dynamic polarization tests provided the corrosion current density (I_{corr}) and the corrosion potential (E_{corr}) data. In general, the corrosion rates were determined based on the ASTM G102 standard. Firstly, the corrosion current density was tested through the electrochemical method [24], The potentiodynamic polarization can be transformed towards the corrosion potential to determine the corrosion current density. Table 2 shows the values of Tafel extra-polarization for AA 5052 with and without chitosan.

Overall, the Ecorr values for AA 5052 without chitosan were lower than those coated with chitosan at each temperature tested. For example, -0.4829 V vs Ag/AgCl Ecorr for AA 5052 without chitosan is lower than 0.5519 V vs Ag/AgCl Ecorr for AA 5052 with chitosan at the test temperature of 298 K. This fact reveals that chitosan predominantly protects the cathodic region [22]. The corrosion rate can be determined using the Icorr value. The higher the Icorr value, the higher the corrosion rate. Overall, the corrosion rate gradually increases with increasing temperature. The activation energy (Ea) of the particles increases with increasing temperature; consequently, the corrosion reaction becomes faster [19]. Furthermore, the highest IE of chitosan was observed at 95.12% at 298 K and then gradually decreased with increasing temperature tested [23]. This is due to the physisorption properties of chitosan, where the dominant adsorption reaction occurs on the cathodic side [24].

Table 2. Tafel of potentiodynamic polarization for AA 5052 with and without chitosan in 0.5 M H_2SO_4 at 298, 313, 333 and 353 K

Sample AA 5052	T (K)	E_{corr} (V vs Ag/AgCl)	I_{corr} (mA cm^{-2})	CR (mpy)	IE (%)
	298	-0.4829	144.8	62.96	-
Without Chitosan	313	-0.5880	490.0	213.12	-
	333	-0.6558	959.5	417.34	-
	353	-0.5925	2794.2	1215.31	-
	298	-0.5519	7.07	3.07	95.12
With Chitosan	313	-0.6277	88.29	38.40	81.98
	333	-0.6844	501.93	218.31	47.69
	353	-0.6345	2011.90	875.06	28.00

CONCLUSIONS

Chitosan has been successfully coated on aluminum alloy AA 5052 using the EPD method and the role of organic molecules as a green inhibitor to reduce the corrosion rate of the alloy has been studied. Based on the weight loss method, the optimum conditions for the EPD process were obtained at an exposure time of 20 minutes. Meanwhile, the corrosion rate for AA 5052 with and without chitosan at an immersion time of 168 hours was 0.0552 mg cm^{-2} h^{-1} and 0.1702 mg cm^{-2} h^{-1}, respectively. Increasing the temperature can decrease the inhibitory properties of chitosan.

ACKNOWLEDGEMEN

The authors would like to thank the financial support provided by the Universiti Kebangsaan Malaysia through the Petronas short project research grant and the University of Mercubuana for its good cooperation so that this research can be completed.

ABSTRACT

This study presents the design, integration, and validation of a PEMFC stack testing setup, which was realized at the Hynor Laboratory – IFE. The design of the testing setup, which includes an anode/cathode loop and a cooling, power conditioning, and control system, is described in detail. The setup is used for fuel cell stack testing (up to 20 kW power) using a system-like configuration, fuel cell system testing (up to 135 kW power) and the characterisation of its components, and fuel cell system operation using a hybrid configuration with Li-ion battery modules (up to 100 kW power). The integrated fuel cell testing setup is planned to be used for research investigations related to the utilisation of fuel cell technology in heavy duty and maritime applications.

Keywords: fuel cell stack, testing setup, PEM fuel cell

INTRODUCTION

Hydrogen technology coupled with polymer electrolyte membrane fuel cells (PEMFCs) has been recognised as a key technology that enables decarbonisation of the transport sector [1]. Even though PEMFC technology has reached the high technology readiness level and is currently being commercialised, the application of this technology in heavy duty vehicles and maritime requires further research, which will allow for smooth deployment. Fuel cell stack testing is an important stage in the development process of new stack designs and in the development of new fuel cell system configurations and architectures [2].

The PEMFC stack testing setup developed at IFE is a response to the current needs for stack and system testing and it is an open platform configuration that enables testing of stacks, balance of plant components, and complete systems.

EXPERIMENTAL SETUP

The PEMFC stack testing setup was integrated according to the developed detailed piping and instrumentation diagram (P&ID), a simplified version is depicted in Fig. 1 (a). The real view of the fuel cell stack testing setup available at Hynor Laboratory - IFE, including control system, is shown in Fig. 1 (b).

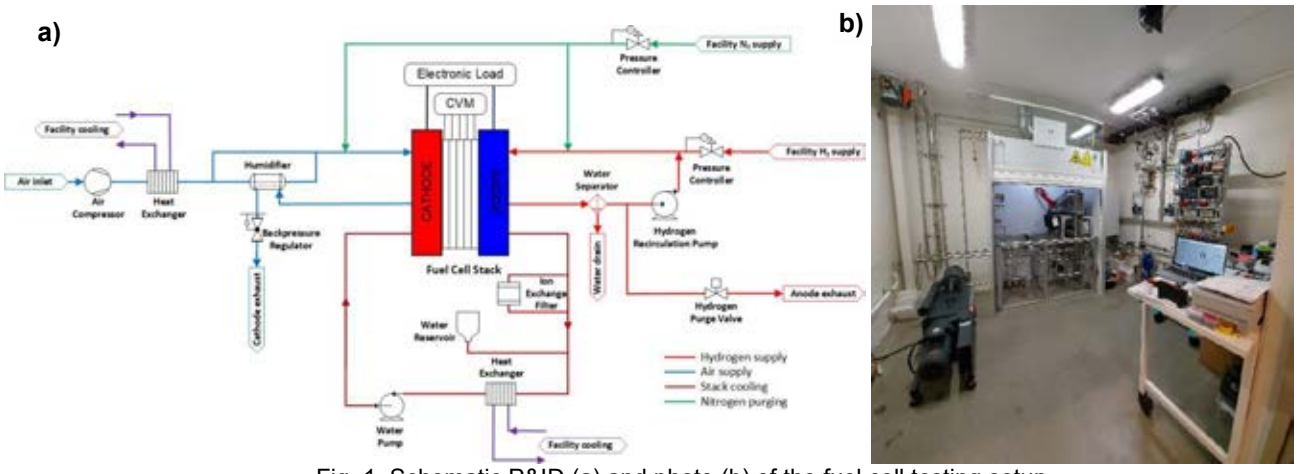

Fig. 1. Schematic P&ID (a) and photo (b) of the fuel cell testing setup.

Fuel cell stack

A PowerCell S2 type of fuel cell stack was integrated into the testing setup. Detailed technical specification of the applied fuel cell stack unit is presented in Table 1.

Table 1. Fuel cell stack technical specifications

Physical	Number of cells	150
	Electrode active area	195 cm^2
	Dimensions	148 x 484 x 293 mm (WxLxH)
	Weight	approx. 24.2 kg
Electrical	Nominal / maximum stack power	12.9 kW / 18.0 kW
	Nominal / maximum stack current	136.5 A (@ single cell voltage 0.63 V) / 195.0 A (@ single cell voltage 0.40 V)
	Minimum / nominal / maximum DC stack voltage	60.0 V / 94.5 V / 127.5 V (OCV @ 165.0-195.0 V)
Operating conditions	Anode	Hydrogen or reformate
	H_2 temperature / pressure / humidity	75 °C / 150-1200 $mbar_g$ / >40% RH
	Cathode	Air
	Air temperature / pressure / humidity	75 °C / 150-1000 $mbar_g$ / 60-80% RH
	Cooling	Liquid cooled (de-ionized water)
	Nominal stack temperature	70-75 °C
	Ambient operating conditions	2-70 °C / 0.8-1.5 bar_a / 0-100% RH (noncondensing)

Anode loop

The anode loop was operated in the dead-end mode with hydrogen recirculation. Hydrogen was supplied from the laboratory hydrogen storage to the setup at 5 barg pressure. The pressure was further reduced to the maximum of 1.2 barg before it was supplied to the stack. The pressure in the loop was regulated by a pressure controller (Bronkhorst). The parameters of the supplied hydrogen (humidity, pressure, temperature, and flow rate) were carefully controlled, and the stack outlet gas parameters (pressure and temperature) were carefully monitored. Recirculation of the anode gas was performed using a hydrogen pump (Busch). Gaseous impurities that may diffuse from the cathode side (e.g., nitrogen) and accumulate in the anode loop, as well as water vapour, were released using a purge valve. The valve was periodically opened to release the volume of gas enclosed in the fuel cell stack. The outlet gas was directed to the anode exhaust and evacuated outside laboratory building. For safety reasons the anode loop was flushed to remove residual air using nitrogen and hydrogen during system start-up and shutdown, respectively.

Cathode loop

The oxygen required for the reaction was obtained from air and delivered to the stack by an air compressor (Busch). Outlet air from the compressor was cooled to room temperature using a heat exchanger (AlfaNova) coupled with the facility's cooling system. The inlet air was humidified by a humidifier (FumaTech) before it reaches the stack, and the backpressure was controlled using a backpressure regulator (Equilibar). The parameters of the supplied air (humidity, pressure, temperature, and flow rate) were carefully regulated, and the stack outlet gas parameters (pressure and temperature) were precisely monitored. The cathode loop was flushed with nitrogen to remove potential gas impurities and liquid water during system start-up and shutdown, respectively.

Cooling loop

Heat is generated as a by-product during the operation of the fuel cell stack and used for stack self-heating and excess heat is transferred to the facility's cooling system via the cooling loop. The main component of the cooling loop was the water pump (DP-Pumps) that flows deionised water through the stack and heat exchanger (Alfa Nova), which connects the cooling loop of the stack to the facility's cooling system. The flow rate of the coolant was regulated, and its inlet/outlet conductivity, pressure, and temperature were measured to ensure suitable stack operating conditions, especially its temperature.

Power conditioning

The fuel cell testing setup was electrically connected to the DC-bus, which is part of the laboratory power conditioning system. The nonlinear stack DC voltage was regulated using a 20 kW DC/DC boost converter (Hot Platinum), which enables stack operation in the galvanostatic mode. Alternatively, the DC-bus was connected to the grid via a DC/AC inverter (Bitrode), which balances the DC-bus voltage. Another part of the power conditioning system is the cell voltage monitoring (CVM) unit (Smart Testsolutions), which was used to carefully monitor the voltage of each cell in the stack.

Control system

The operation of the testing setup components, signal measurements from integrated sensors, and control of the valves was performed using the control system. The system hardware is based on the cRIO chassis (National Instruments) equipped with digital/analog input/output modules and the software application used for communication and data logging was programmed using the LabView environment. The software application contains an embedded matrix with alarms and warnings, which ensures safe fuel cell stack operation and an immediate response in the case of operating parameters being out of range.

TESTING CAPABILITIES

The developed infrastructure was mainly used for PEMFC stack testing with a nominal power up to 20 kW in a system-like configuration. The instrumentation of the setup and its open platform configuration allows for the characterisation of various fuel cell system balance of plant components. The integration of the setup within the available laboratory power conditioning system facilitates the testing of fuel cell systems up to 135 kW and enables hybridisation with Li-ion battery modules with a power capacity up to 100 kW.

CONCLUSIONS

A PEMFC stack testing setup was successfully designed and integrated at IFE and is available in the Hynor Laboratory. The setup's validation process is ongoing, and the preliminary results obtained thus far are promising. These results confirmed that the design assumptions are correct, and the selection of the system components is appropriate to operate high power PEMFC stacks. The main setup specifications and functionalities are:

- PEMFC stack testing up to 20 kW nominal power in a system-like configuration.
- Characterisation of fuel cell system balance of plant components (e.g., air compressor/blower, humidifier, hydrogen recirculation pump, heat exchanger) and in situ system testing.
- Fuel cell system testing up to 135 kW power and system hybridisation with LI-ion battery modules with a power capacity up to 100 kW.

ACKNOWLEDGEMENT

This study was performed within MoZEES, a Norwegian Centre for Environment-friendly Energy Research, co-sponsored by the Research Council of Norway (Project no. 257653) including 40 partners from the research, industry, and public sectors. The financial support received from the Research Council of Norway (Project no. 294568) for the project "Hydrogen and Fuel Cell for Maritime Applications (H2Maritime)" is gratefully appreciated. The experimental study was partly executed in the national infrastructure Norwegian Fuel Cell and Hydrogen Centre and funded by the Research Council of Norway (Grant no. 245678/F50).

ABSTRACT

Polybenzimidazole (PBI) is a high-temperature polymer that is used for many purposes in polymer technology since its high hydrophilic nature and mechanic stability. Polyvinyl alcohol (PVA) has advantages, such as its easily modifiable structure and high ionic conductivity features. Polybenzimidazole and polyvinyl alcohol polymers were used as blend membrane structures with different percentage ratios such as 90:10, 70:30, 50:50 for proton exchange membrane fuel cell (PEMFC) applications. Firstly, PBI was synthesized by the solution polycondensation method which means that polyphosphoric acid was applied as both condensation agent (catalyst) and monomer solvent. The H-Nuclear Magnetic Resonance (H-NMR) was applied to identify the structural formation of the polymer. PVA and synthesized PBI polymers were dissolved in different solvents separately and both polymers were mixed by sol-gel method to prepare the blend membrane. The blend membrane was treated with phosphoric acid which was used as a phosphonation agent. The PBI/Phosphonated-PVA (PPVA) blend membrane was examined for evaluating the suitability for proton exchange membrane fuel cell (PEMFC) operations. The characterization tests, i. e; water uptake capacity, FT-IR Analysis, Ion-exchange capacity, Thermal Gravimetric Analysis measurements were applied to the synthesized blend membrane. The synthesized PBI membrane has 2.12 meq gr^{-1} Ionic exchange capacity (IEC) while PBI/PPVA-90:10 blend membrane has 4.15 meq gr^{-1} IEC value.

Keywords: Polybenzimidazole (PBI) polymer, PBI/PVA blend membrane, polyvinyl alcohol, PEMFC, Fuel cell applications

INTRODUCTION

Polymer exchange membranes were attracted a great deal of interest for fuel cell applications since their high energy efficiency at low temperature and low emission output [1, 2]. The polybenzimidazole polymer is known as a highly chemically/mechanical stable polymer which was selected as a basis polymer to obtain PEM blend membrane. However, PBI polymer needs to be improved since its inefficient proton conductivity under medium-temperature conditions. To obtain higher proton conductivity and water uptake features of a membrane PVA polymer was added to the membrane structure since its high ability of conductivity [3, 4]. A wide range of modified PBI polymers was studied thoroughly for PEMFC. For the purpose of attributing the proton conductivity of PBI, the sulfonation/phosphonation procedure is applied mostly before/ after the membrane preparation [5,6]. The PBI based composite or crosslinked acid-base membrane production methods are other applied techniques for PEMFC's [7,8]. Kerres et. al., ionically crosslinked PBI polymer by adding different types of cation-exchange ionomers and compared the results in terms of chemical/ thermal stability and fuel cell performance [9]. PBI polymer was synthesized by using the solution polycondensation method. The PBI/PVA blend polymer was produced according to the sol-gel method and the membrane was obtained by the casting method. The prepared PBI/PVA membrane was treated with dilute phosphoric acid in order to phosphonate the blend membranes. The characterization tests, i. e; water uptake capacity, FT-IR Analysis, Ion-exchange capacity, Thermal Gravimetric Analysis measurements were applied to the synthesized blend membrane. The H-Nuclear Magnetic Resonance (H-NMR) was applied to identify the structural formation of the synthesized polybenzimidazole polymer.

MATERIALS AND METHODS

3, 3''-Diaminobenzidine (Anhydrous DAB, $(NH_2)_2C_6H_3C_6H_3(NH_2)_2$, M_w: 214.27), and Isophthalic acid (Anhydrous IPA, C_6H_4-1,3-$(CO_2H)_2$, M_w: 166.13) were used as monomers for PBI synthesis and purchased from Akerman Group, Ankara, Turkey. The polyphosphoric acid (PPA, 99%) was used as a solvent and poly-condensation agent. N, N-Dimethylacetamide (DMAC, $CH_3CON(CH_3)_2$, 99.8%, Mw: 87.12) and Dimethyl sulfoxide (DMSO, $(CH_3)_2SO$, 99.8%, Mw: 78.13) were used as solvents for PBI and PVA polymers.

Polybenzimidazole Polymer Synthesis

The PBI synthesis solution polycondensation method is described as follows: PPA was heated to 120 °C for 4 hours under a nitrogen atmosphere for the dehydration process. The monomers were dehydrated as well before the polymerization stage. DAB was added to the pre-heated PPA in a ratio of 1:26.5 (wt.) and mixed with PPA at 120 °C for an hour. IPA was added to the system (as an equimolar quantity of the DAB) and mixed at 175 °C until the monomers were properly dissolved. After 4 hours, the reaction temperature was heated up to 300 °C and held under the nitrogen atmosphere for 20 hours. Then, the homogenous mixture was poured into cold de-ionized water to obtain

a solid dark purple coloured polymer. The solid polymer was washed and filtered continuously to be neutralized. The polymer was held into 10% of $NaHCO_3$ solution for a day to neutralize the polymer. PBI was dried in a vacuum drying at 60 °C for 3 days.

PBI/PVA Blend Membrane Preparation

PBI polymer was dissolved in DMAC (99%) solvent at 100 °C for 2 days and 5 wt. % of LiCl was added as a stabilizer. Separately, PVA polymer was mixed in DMSO solvent at 80 °C for 2 hours and 5 % of PVA solution was prepared. The blend membrane sol-gel method and casting method were described by Cali et al. [2]. The dissolved polymers were poured into the glass flask at a different percentage of 90:10, 70:30 and 50:50, then mixed at 100 °C for 48 hours and then, an ultrasonic homogenizer device was applied for 1 hour to homogenize the solution. The polymer solution was cast into a glass petri dish and then dried at 50 °C for 4 days.

PBI/PVA Blend Membrane Phosphonation

The blend PBI/PVA membranes were extracted from the petri dish and then, dried in an oven at 100 °C for a day. The dilute phosphoric acid solution (0.1 M) was prepared for the process. The blend membranes were soaked in the phosphoric acid solution at room temperature and held for a day. The excess phosphoric acid was cleaned out of the membranes and finally, membranes were dried in an oven at 100 °C for a day. The phosphonated blend membranes were named PBI/PPVA-90:10, PBI/PPVA-70:30 and PBI/PPVA-50:50.

Characterization Methods

Prepared PBI/PPVA blend membranes were weighted (Wdry) and their thickness value was measured at different points (Tdry). The measured samples were plunged in distilled water and kept overnight at 30 °C and 80 °C. The thickness of the samples was measured using a Sheen thickness measurement device [2]. Equation (1) illustrates the water uptake calculation of the samples.

$$\%WaterUptakeCapacity = \frac{m_{wet} - m_{dry}}{m_{dry}} x100 \quad (1)$$

FTIR analysis was employed by using a Jasco FT / IR-480 + instrument to obtain information about the chemical structure of membranes. The measurements were executed at a wavelength from 4000 to 400 cm^{-1} and a scanning speed of 4 cm^{-1}.

The NaCl solution was used to examine the Ion exchange capacity (IEC) of the PBI/PPVA blend membranes. The samples were held in NaCl solution (2 M) for 2 days at room temperature and then the classic titration method was operated. The solution, where membranes held, titrated with stock NaOH solution and then, IEC results were examined.

$$IEC = (V_{NaOH} \cdot M_{NaOH}) / W_{dry} \quad (2)$$

The thermal gravimetric analysis method was applied to evaluate the thermal stability of the PBI/PPVA blend membranes. Perkin Elmer Pyris 1 Thermogravimetric Analysis Device suitable for TS ISO EN 11358-1 accredited method was used in Middle East Technical University Research Lab. The TGA heating rate is 10 °C $minute^{-1}$ from room temperature to 900°C in air conditions.

A liquid H-proton Nuclear Magnetic Resonance Ultrashield TM 300 MHz device having a superconductive magnet, digital Bruker Biospin AVANCE 300 MHz ~7 Tesla, was used to identify the synthesized polybenzimidazole polymer structure.

RESULTS AND DISCUSSION

Fig.1. illustrates the weight loss of synthesized blend membranes at different temperatures. The synthesized PBI

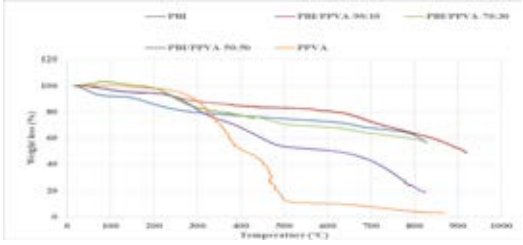

Fig. 1. TGA Results of the PBI/PPVA blend membranes

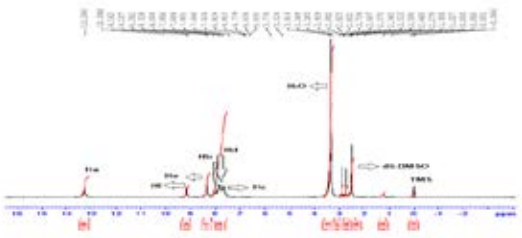

Fig. 2. H-NMR results of PBI polymer

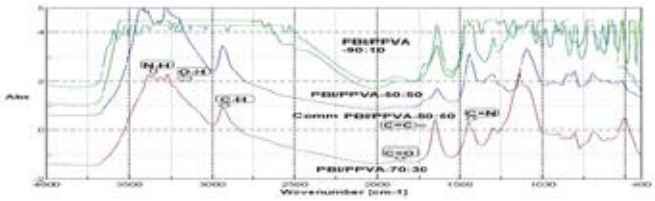

Fig. 3. FT-IR results of the synthesized membranes

membrane has the lowest weight loss (43%) amongst the blend membranes. PBI/PPVA-90:10 blend membrane has 51% weight loss after 700 °C. The dropping line around 100 °C is attributed to the water loss [10]. The phenyl group proton peaks of the synthesized polybenzimidazole polymer, which could be seen in Fig. 2., is at 7.42 and 9.16 ppm. The N-H proton absorption peak belonging to the PBI imidazole ring is at 13.266 ppm. The peaks at 2938 cm^{-1} at Fig.3 belongs to C-H asymmetric/ symmetrical vibration peaks of the PVA polymer. The characteristic phosphonation peak is at 1095 cm^{-1}. The Ion exchange capacity of the PBI membrane was found as 2.12 meq gr^{-1}. PBI/PPVA-90:10 and PBI/PPVA-50:50 membranes have the same IEC which found as 4.15 meq gr^{-1}. PBI/PPVA-70:30 blend membrane has 3.33 meq gr^{-1} IEC. Synthesized PBI membrane has no water uptake capacity at room temperature and 80 °C. PBI/PPVA-90:10 blend membrane has 5 % of water uptake capacity. The highest water uptake capacity (8 %) was calculated for PBI/PPVA-50:50 blend membrane.

CONCLUSION

Polybenzimidazole and polyvinyl alcohol polymers were used as blend membrane structures with different percentage ratios and blend membranes were phosphonated for proton exchange membrane fuel cell (PEMFC) applications. The ion exchange capacity of the PBI membrane was enhanced from 2.12 to 4.15 meq gr^{-1} by preparing PBI/PPVA-90:10 blend membrane. The highest water uptake capacity (8 %) was calculated for PBI/PPVA-50:50 blend membrane. The prepared PBI/PPVA blend membranes have great thermal stability according to TGA results. The structural formation of the PBI polymer was verified by H-NMR Analysis. Authors indicate that prepared PBI/PPVA blend membranes have greater properties compared to synthesized PBI membranes and they could be excellent candidates as proton exchange membranes.

ABSTRACT

This work attempts to innovatively develop a hydrogen/vanadium redox flow battery stack and improve the previous vanadium redox battery encountered by our team when the electrolyte leaks easily and the strong acid corrosion environment may cause the vanadium redox battery and the micro sensor to age or fail. Utilize MEMS to innovatively develop hydrogen concentration and conductivity micro sensors, and integrate the flexible five-in-one (voltage, current, temperature, flow and pressure) micro sensors developed by our team. Corrosion-resistant, thinner and miniaturized flexible seven-in-one micro sensor embedded in the hydrogen/vanadium redox flow battery for real-time microsensing and diagnosis.

Keywords: Hydrogen/vanadium redox flow battery, Flexible seven-in-one micro sensor, Real-time microsensing and diagnosis.

INTRODUCTION

Vanadium redox battery system is an emerging energy storage technology, which has many advantages in application, such as high efficiency, long life, high power and high safety. The latest literature points out that the hydrogen (H_2)/vanadium(V) redox flow battery has better energy density and efficiency than the vanadium redox battery, and has the advantages of low cost and light weight. Weng [1] et al. indicated that the theoretical energy of the hydrogen/vanadium redox flow battery is 5 times that of the vanadium redox battery, and the discharge voltage of the hydrogen/vanadium redox flow battery is about 1.76V, which is higher than the discharge voltage of its control system. In addition, the hydrogen concentration, conductivity, voltage, current, temperature, electrolyte flow and flow channel pressure inside the hydrogen/vanadium redox flow battery will affect its performance and life.

RESEARCH METHODS

The development of the flexible seven-in-one micro sensor mainly focuses on the newly developed micro hydrogen sensor and micro conductivity sensor and integrates the micro voltage, current, temperature, flow and pressure sensors of the past core technologies of our team. The production process of the flexible seven-in-one micro sensor is shown in Fig. 1. Simultaneous and synchronous development of hydrogen/vanadium flow batteries. Although the design and key components of the hydrogen/vanadium redox flow battery is similar to those of the vanadium redox battery, the design and material selection of the hydrogen/vanadium redox flow battery also need to be redesigned. The biggest difference between the flow battery is that half of the storage space of the hydrogen/vanadium redox flow battery is hydrogen, and the other half is vanadium electrolyte. Therefore, it is necessary to find a container suitable for storing hydrogen, and the electrolyte is a strong corrosive solution. Containers of suitable material and improved according to past experience.

Sensing principle of micro hydrogen sensor

This micro hydrogen sensor is a semiconductor type sensor. The sensing principle is to use the oxygen adsorption between the reducing gas and the surface of the gas-sensitive film. After oxygen atoms (O) are adsorbed on the surface of the gas-sensitive film, the electrons inside the material will tend to oxygen atoms form oxygen ions (O^-), which reduces the number of electrons inside the gas-sensitive film, which increases the resistance of the sensing material; when the surface of the gas-sensitive film and the reducing gases in the environment (such as CO, H_2, etc.) When in contact, the reducing gas will react with oxygen ions on the surface of the gas-sensitive film, releasing electrons back into the gas-sensing film, thereby reducing the overall resistance of the material.

Sensing principle of micro-conductivity sensor

Conductivity measurements were investigated using Alternating Current Impedance. The AC impedance analysis method obtains the impedance value of the electrochemical system by calculating between the AC voltage and the AC current, and then substitute the impedance valued into the Eq. (1) to obtain the conductivity value (Conductivity, σ):

$$\sigma = L/R \times A \quad (1)$$

where σ is the conductivity (S/cm), R is the membrane impedance (Ω), L is the membrane thickness (cm), and A is the electrode area (cm^2).

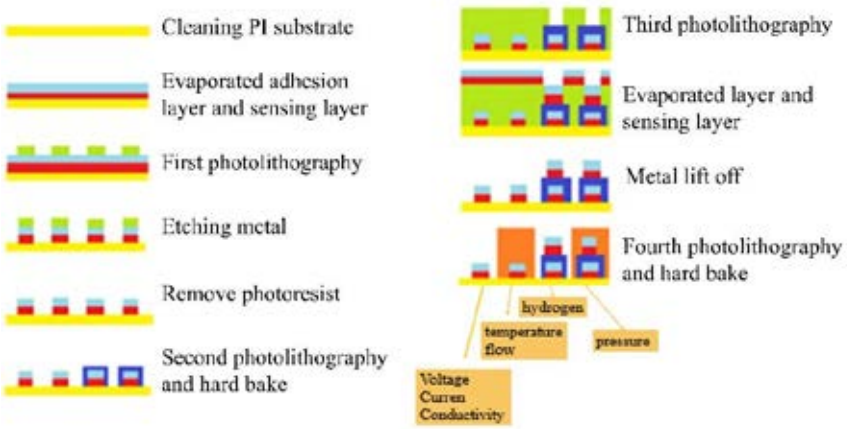

Fig. 1. Step diagram of the integration process of the flexible seven-in-one micro sensor.

RESULTS AND DISCUSSION

In this study, a flexible seven-in-one micro sensor was embedded in the hydrogen/vanadium redox flow battery of 100 hours of microscopic diagnosis of seven physical quantities, including hydrogen, conductivity, voltage, current, temperature, flow and pressure. The hydrogen/vanadium flow batteries of embedded microsensor and without embedded microsensor were tested separately, using the same reaction area size, the same flow channel design and the same operating conditions, and compared the performance difference between the two, and the long-term results were obtained. Effective real-time monitoring of local hydrogen, conductivity, voltage, current, temperature, flow and pressure distribution of the hydrogen/vanadium redox flow battery, and real-time feedback of internal information through a flexible seven-in-one micro sensor to analyze and discuss hydrogen, conductivity. The relationship between voltage, current, temperature, flow rate and pressure to allow users to instantly grasp the internal reaction and operating conditions of the battery, so that the hydrogen/vanadium redox flow battery can be quickly adjusted to the best operating parameters.

CONCLUSIONS

In response to the needs of real-time micro-diagnosis inside the hydrogen/vanadium redox flow battery, this work innovatively develops a flexible seven-in-one micro sensor using MEMS technology and embeds it inside the hydrogen/vanadium redox flow battery, so that it can real-time micro-sensing and diagnosis and real-time feedback of internal information, however, the hydrogen/vanadium redox flow battery can operate in the best condition, which can effectively improve the performance of hydrogen/vanadium redox flow battery and achieve the purpose of extending life.

ABSTRACT

Proton exchange membrane water electrolyzer (PEMWE) requires high operating voltage for hydrogen production, so it is easy to accelerate the decomposition of hydrogen molecules, and it is easy to cause PEMWE to age or fail. This research uses micro-electro-mechanical systems (MEMS) technology to innovatively develop the micro oxygen sensor inside PEMWE so as to know the oxygen production rate in real time. This information is one of the important information on PEMWE aging. The flexible six-in-one (voltage, current, temperature, humidity, flow and pressure) micro sensor developed by our team has been integrated into a flexible seven-in-one micro sensor. It embedded in the high voltage PEMWE to monitor oxygen, voltage, current, temperature, humidity, flow and pressure. And, we observe whether the high voltage PEMWE is aging or damaged so as to prolong its service life.

Keywords: MEMS, Flexible seven-in-one micro sensor, High voltage proton exchange membrane water electrolyzer.

INTRODUCTION

The seven important physical quantities of oxygen, voltage, current, temperature, humidity, flow and pressure inside PEMWE have a key impact on aging. As mentioned in [1], thermal stress has a significant effect on the degradation of polymer films. If the input voltage is higher, it is easy to generate a large amount of waste heat due to the resistance. The heat will increase the temperature of the system, which will accelerate the aging and performance degradation of PEMWE. Although increasing the operating temperature of PEMWE can improve performance. If the temperature is too high, it may cause damage to the membrane electrode assembly (MEA) and make water to evaporate into water vapor and cause aging. Therefore, how to find the best operating conditions and aging test and predict its life is the focus of this work.

RESEARCH METHODS

Process development and calibration of semiconductor-based flexible micro oxygen sensor

In the research, a semiconductor-based micro oxygen sensor was developed by using the MEMS technology. Use a sputtering machine sputtered tin dioxide (SnO_2) on the surface of the sensor as a gas-sensitive sensing layer, and sputtered platinum (Pt) as a catalyst layer afterwards. When the micro oxygen sensor is completed, the eight-channel fuel cell test machine is used for testing and calibration. The sensor is connected with precision data acquisition machine (NI PXI-1033). Then, the constant temperature and constant current oxygen is introduced, the resistance change is measured and captured.

Integrated process development of flexible seven-in-one micro sensor

(a) First, wash the PI film with acetone and methanol organic solutions respectively in order to increase the adhesion of metals. Then, use deionized water to remove residual methanol, remove surface dust and residual grease.
(b) Then use an E-beam evaporator to evaporate chromium (Cr) and gold (Au) as the adhesive layer and the sensing electrode layer.
(c) Use the photolithography processed to define the patterns of the micro oxygen, voltage, current, temperature, humidity, pressure and flow sensors.
(d) Use gold etching solution and chromium etching solution to wet etching.
(e) Coating photoresist, then defining the micro oxygen sensor pattern, sputtering tin dioxide and platinum on the micro oxygen sensor, and then cleaning off the photoresist mask.
(f) Coating LTC 9320 as a protective layer, and using the yellow light lithography process again to define the sensing area and pins of the micro voltage, current, humidity and pressure sensors so that they are exposed and not covered by the protective layer.
(g) Finally, coat LTC 9305 as the moisture-sensing film of the micro humidity sensor to complete the manufacturing process of the flexible seven-in-one micro sensor, as shown in Fig. 1.

Establish PEMWE technology

At present, parallel flow field is still one of the most common forms of PEMWE flow channel design. The advantages are that the deionized water is easy to enter and exit, the flow rate is faster and the piezoresistance is lower. The assembly pressure will affect the aging, and it is necessary to be careful to prevent the deformation and rupture of the bipolar plate and the collector plate due to uneven stress. On the other hand, the rotational speed of the external pump of PEMWE also has a great influence on its aging. When the performance is optimized, the flexible seven-in-one micro sensor, which is the focus on this research, is embedded to measure the internal physical quantities of PEMWE in real time.

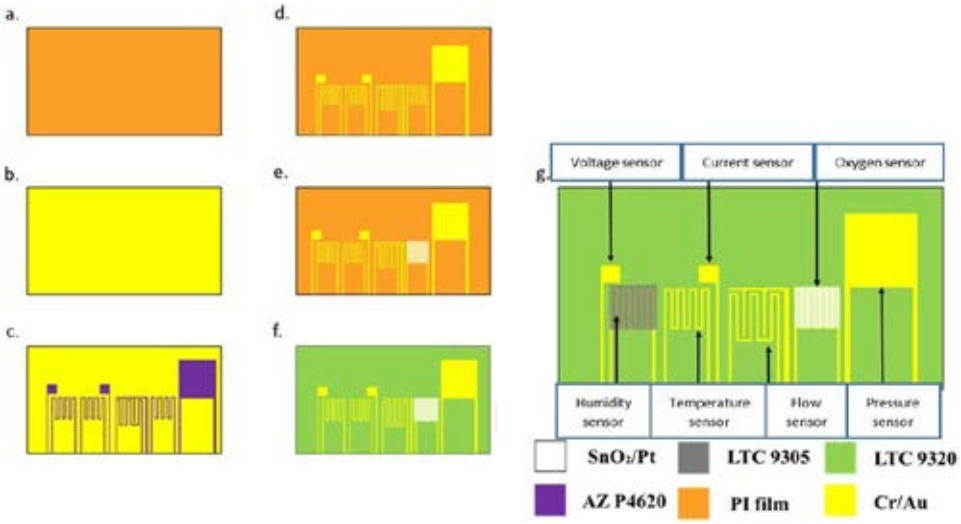

Fig. 1. Fabrication flowed chart of the flexible seven-in-one micro sensor.

RESULTS AND DISCUSSION

The flexible seven-in-one micro sensor is embedded in the PEMWE for 200 hours of accelerated aging test. Detect the distribution of oxygen, voltage, current, temperature, humidity, flow and pressure of PEMWE from activation to aging so as to know the relationship between these seven important physical quantities affecting each other.

CONCLUSIONS

In this research, a flexible seven-in-one micro sensor has been developed and embedded in PEMWE for 200-hour accelerated aging micro-monitoring, and the life prediction of PEMWE has been achieved. The sensor makes product development and application wider and verify its reliability at the same time.

ABSTRACT

In this paper, we report on the influence of different dispersion technologies on fuel cell performance. We present the complete process chain from dispersing the dry powder components in a liquid phase to final performance testing on the electrode level in order to identify process-structure-property relations. For comparing different dispersion technologies, we use both an ultrasound-based batch-type method and a continuously operable wet impact milling device that can be operated at elevated hydrostatic pressures of up to 245 MPa. We use analytical centrifugation to analyse the sedimentation behaviour of concentrated inks and the surfaces of the electrode layers are characterised by means of Atomic Force Microscopy (AFM). The results of the ink characterisation were visualised in self-developed transmittograms in the working group. In addition, we spray the inks and prepare electrodes for a final evaluation in a fuel cell. We found that ink dispersion by wet impact millling ends up in more stable formulations than when dispersion by ultrasound is applied. This is also reflected in the performance of the fuel cells, i.e., the electrodes made from inks generated by wet impact milling did perform better with regard to polarization curves than those made from inks generated by ultrasonic Sonotrode.

Keywords: PEMFC, Ink Preparation, Wet Impact Milling, Sonication, Transmittograms

INTRODUCTION

In the context of climate change, increasing globalisation and mobility as well as the growing industrialisation of emerging countries such as India and China, environmental protection is taking on unprecedented importance. Therefore, there is an increasing shift in thinking towards alternative drive systems, which also includes the fuel cell technology. Fuel cells are regarded as efficient and climate-neutral energy converters and could be one alternative to thermal engines in the future. Among the fuel cell types, the Polymer Electrolyte Fuel Cell (PEMFC) has advantages in efficiency, quiet operation, good reaction dynamics and low environmental impact [1].
The biggest obstacle to the market breakthrough of polymer fuel cells is the high cost of materials mainly as a result of the use of precious yet highly active metals such as platinum. Therefore, the main concern is to reduce the platinum loading by simultaneously increasing the performance or without adverse effects on the performance at least. Because of this, a better and more efficient utilization of platinum in the electrode should be sought. One of the possibilities to address this angle includes an improved and well-controlled dispersion of the ink preparation process which can have a detrimental effect on the final electrodes. A poor dispersion can potentially lead to inhomogeneous distribution and agglomeration of catalyst particles and thus to an uneven distribution of platinum on the electrodes.

The overall aim of this work is to investigate the whole process chain in PEMFC production from preparing inks from powders over the production of electrodes to final performance tests. To this end, we are mainly focusing on the preparation of FC inks by applying two different dispersion methods (see Fig. 1). Here, we are interested in the influential factors of ink preparation on the general process chain.

MATERIALS AND METHODS

Dispersions were prepared by a continuous and a batch device. For a potential continuous preparation, we used a wet impact milling device (Sugino Corp, Japan) and for ink preparation in a batch mode we used an ultrasonic device (Branson SFX Digitaler Sonifier). In the wet impact mill the dispersion is homogenised by collision with a static ceramic ball using an adjustable hydrostatic pressure in the range of 100 -245 MPa. By this method, the particles in the dispersion are subjected to varying and controllable shear forces and are hence homogenised. Additionally, we can repeat the processing several times by running several cycles. The dispersion in the lab-scale sonotrode occurs through ultrasonic waves. Here, the controllable parameters are the amplitude resulting in different dispersion intensities and time. The inks were characterised with an analytical centrifuge (LUMisizer, LUM GmbH) and the results were visualised in self-developed transmittograms in the working group by Bapat et al. [2],[3]. After preparing

the ink, we spray it onto a Polytetrafluoroethylene (PTFE) foil with an ultrasonic spray coater (PRISM 400, Ultra-Coat). For layer characterization, we measured the surface roughness and topology of the electrodes using atomic force microscopy (AFM). All layers were analyzed at nine different locations on the coated electrodes.

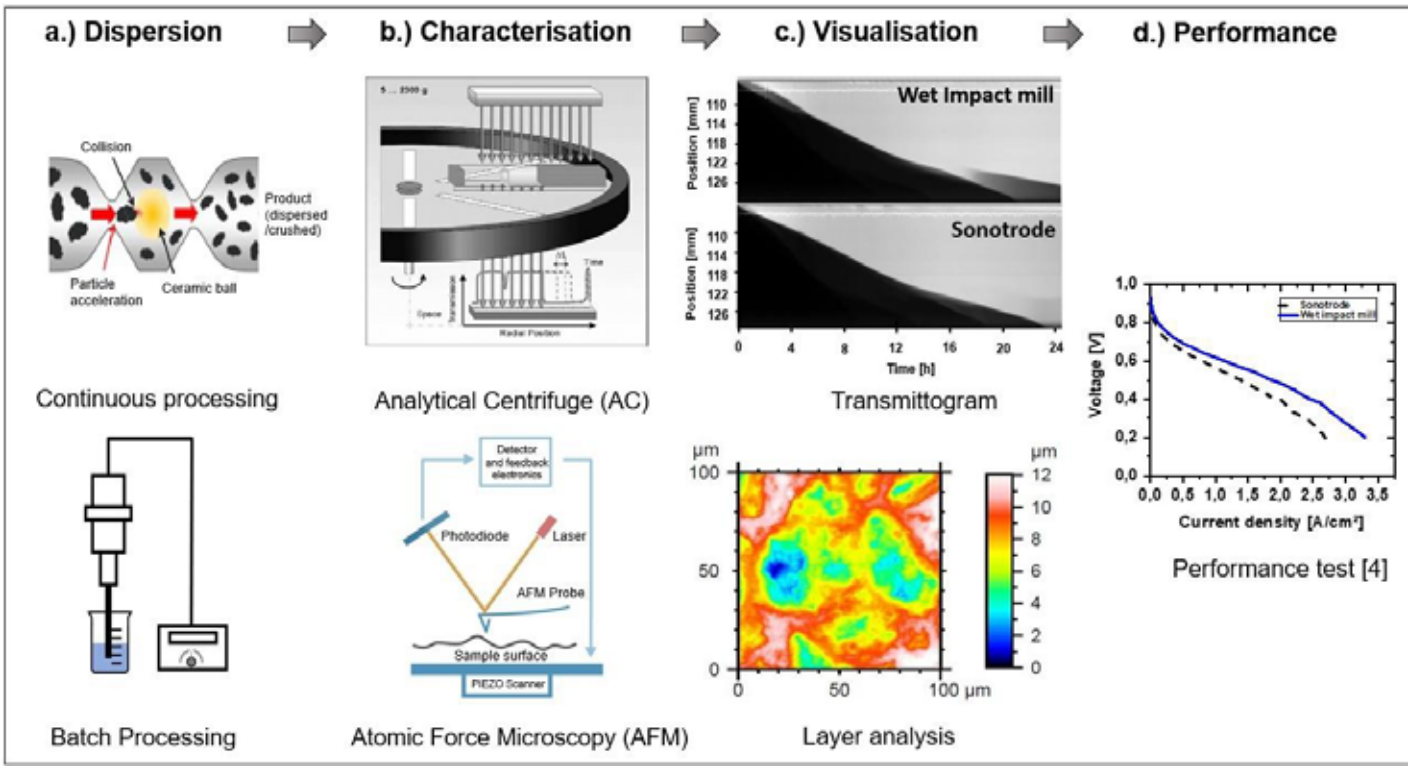

Fig.1: a.) Principle of the wet impact mill (particle acceleration at nozzle and collision at ceramic ball); principle of the ultrasonic sonotrode (dispersion by ultrasonic waves); b.) AC as the method of choice for characterising highly disperse FC inks; Atomic Force Microscopy (AFM) as a method to analyse the surface changes of the electrode layers; c.) Visualisation of the particle fractions via transmittograms after comminution/dispersion; resulting surface topography image after AFM analysis; d.) Performance test results on the fuel cell.

RESULTS AND DISCUSSION

As visualized by transmittograms (Fig. 1c.), we observed different sedimentation behaviour of the inks depending on the type of dispersion technology. The samples that were dispersed using both, the wet impact method and ultrasonic device show two distinguishable particle fractions which settle at different times. The fractions in the ink after wet impact milling are more pronounced than after using the ultrasound device. This is an indication that both devices crush and homogenise the particle agglomerations differently in the course of the dispersion procedure. While the wet impact milling seems to create a higher heterogeneity of particle assemblages suggesting a more intensive and efficient dispersion or comminution result, the ink after ultrasound treatment is more homogeneous with regard to particle assemblages. The number of particle assemblages and especially their settling time can be linked to size estimations. The longer the settling time for an assemblage is, the smaller are the particles within the settling fraction. As described previously by Bapat and Segets, transmittograms enable to deduce the behavior of particles in suspension. Moreover, they provide a size estimate. The sedimentation equivalent diameter of particles that reach the rotor position in a given time can be obtained from Stoke's law [3]. This is another hint towards a more efficient and intensive crushing by the wet impact milling.

Furthermore, from the transmittograms we can deduce that the dispersion with the wet impact method is more stable than the dispersion prepared via sonotrode. In the inks made by sonotrode, all particles settle completely shortly before about 24 hours, while for the inks made from the wet impact mill a full settling of all particles is not achieved, even within 24 hours (Fig. 1c).

Results of the layer analysis via AFM show that surfaces of both layers are uneven and inhomogeneous. The differences in height for both layers reach up to 10 micrometres (Fig. 2). One explanation for this observation are the features of the spraying process itself which is used for the generation of coated layers. The spray coater sprays in an X-Y grid with distinct spacing both in horizontal and vertical direction. This creates gaps between the coatings,

which leads to the observed differences in height and the surface roughness. In addition, we suspect that the spray coater does not spray constantly at the same rate, as there are slight blockages in the line. An additional factor is the point that the PTFE substrate material itself introduces an uneven and inhomogeneous surface which is to be coated during spray coating. This will be analyzed more quantitatively and systematically in future work but confirms the power of transmittograms derived from analytical centrifugation that are able to unravel clear changes of the ink properties with varying disperion procedures.

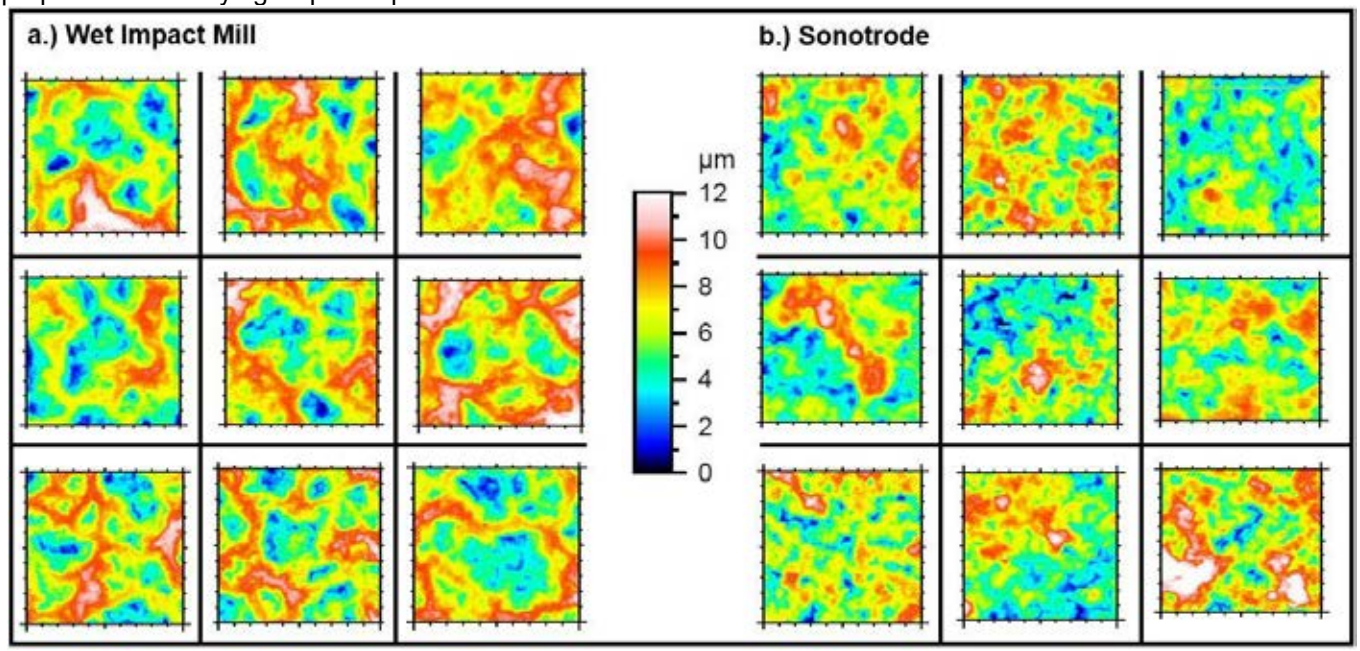

Fig.2 Investigation of the surface differences of the electrodes with AFM

However, compared to the dispersion produced by ultrasonic sonotrode, the MEA produced by wet-impact method delivers a comparable to slightly improved performance. Above all, the electrochemically active surface increases significantly. This can be recognised by the parallel shift of the characteristic curve (Fig. 1d).

In summary, with the help of transmittogram analysis we were able to link dispersion features with fuel cell performance data. We found that the stability of the inks is related to the performance which is a main outcome and feature of the respective dispersion technique applied. This is an outstanding starting point for establishing the initially mentioned process-structure-property relations and parameterize the PEMFC process chain. Individual process step interdependencies can be unravelled and used for a knowledge-driven and efficient production of FC electrodes while improving the environmental footprint through reduction of required amount of precious metals such as platinum.

INFLUENCE OF OPERATING PARAMETERS ON THE COLD START OF POLYMER ELECTROLYTE FUEL CELL SYSTEMS FOR TRANSPORTATION AND AEROSPACE APPLICATIONS

[1*] *Gema Montaner Ríos,* [2] *Johannes Schirmer*
[1] German Aerospace Center (DLR), Institute of Engineering Thermodynamics, Hein-Saß-Weg 22, 21129, Hamburg, Germany

ABSTRACT

Understanding the influence of operating parameters on the cold start of polymer electrolyte fuel cell (PEFC) is essential for the development of improved cold start strategies for transportation and aerospace applications. The effects of different operating parameters on the cold start performance at temperatures down to -30°C have been investigated using a 4-kW PEFC system. The results showed that the start-up temperature, coolant volume flow rate, cell voltage, cathode excess ratio and gas, make a significant impact on the cold start time and performance. The PEFC system was able to self start-up at -30°C, though it led to a standard slow cold start performance with three stages. The results indicate that lowering the start-up cell voltage and operating with oxygen enhance the cold start since more current and heat are generated, thus reducing ice formation. In addition, increasing the cathode excess ratio assists to overcome flooding issues once ice melts.

Keywords: Cold Start, Ice Formation, Operating Parameters, Polymer Electrolyte Fuel Cell (PEFC)

INTRODUCTION

The start-up of PEFC systems in winter scenarios is a remaining challenge for transportation and aerospace applications. At temperatures below 0°C, the water produced by the cathode reaction freeze, which may lead to shut-down and cause several degradations to the fuel cell. Experimental studies have been mostly carried out on single-cells and the influence of operating parameters on the cold start performance mostly focused on cell voltage and temperature [1, 2]. In this study, the influence of the start-up temperature, coolant volume flow rate, cell voltage, cathode excess ratio and gas on the cold start performance of a 4-kW PEFC system, and the interrelationship between these parameters have been investigated. The aim is, to develop a rapid, energy-efficient, and reliable cold start procedure that meets the technical targets for transportation fuel cell systems [2-4]. Establishing operating parameters that generate more heat and assist to evacuate more water to avoid freezing once the membrane is hydrated, as well as flooding after reaching 0°C, is expected to improve the cold start performance.

EXPERIMENTAL

Test bench

This investigation was conducted in a test rig developed in-house for testing PEFC systems at freezing temperatures. The 4-kW stack used consisted of 40 cells with 200 cm² of active cell area, graphite bipolar plates and liquid-cooled. The system was run without humidifiers but with H_2 recirculation, and the test rig was equipped with a programmable electronic load and NI programmable controllers. A schematic outline of this test rig is shown in Fig. 1.

Operating parameters

This work investigates the influence on the cold start performance of PEFC system of the following operating parameters: start-up temperature, coolant volume flow rate, voltage, cathode excess ratio and cathode gas. The value ranges of the tested operating parameters are given in Table 1.

Test protocol

After a conditioning test, the stack was purged with dry gases for 3 min. Then, the stack was cooled down to the test temperature and kept for a defined time. Next, the cold start test was run with the small cooling loop under the investigated operating parameters values. Finally, a polarization curve was conducted at standard conditions.

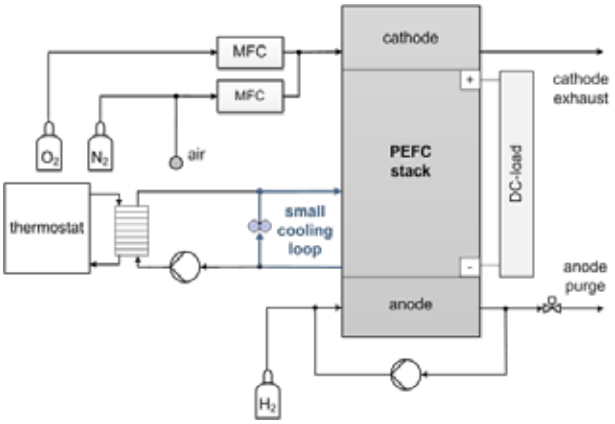

Fig. 1. Schematic outline of the 4-kW PEFC system developed test rig

Table 1. Operating parameters and value ranges tested

	Value
Start-up temperature (°C)	0 … -30
Coolant volume flow rate (g/s)	0 … 83.33
Cell voltage (V)	0.1 … 0.55
Cathode excess ratio	2.3 … 5.8
Cathode gas	air, oxygen

RESULTS AND DISCUSSION

As an example, the effects of start-up temperature, cell voltage, and cathode excess ratio on the cold start performance of the 4-kW PEFC system are briefly discussed below.

Effect of start-up temperature

The 4-kW PEFC system was able to start-up without external heat at temperatures down to -30°C. As expected, the lower the start-up temperature, the slower the cold start and less linear the performance was [5]. The cold start at -30°C led to a standard slow cold start performance with three stages: membrane hydration, ice formation, and ice melting and flooding [6].

Effect of cell voltage

Operating the fuel cell in potentiostatic mode can improve the cold start performance since the total heat generation rate depends nearly linearly on the current density [7]. The lower the cell voltage, the more current density and the more water is generated. Therefore, more heat is produced in the cells to warm up the stack more quickly, thus accelerating the cold start.

Effect of cathode excess ratio

Fig. 2 shows the effect of cathode excess ratio on the cold start performance of the 4-kW PEMFC system at -20°C. As illustrated in Fig. 2 (a), the higher the cathode excess ratio, the faster the cold start was. By increasing the cathode stoichiometry, the cold start performance is improved since higher oxygen excess ratio can generate more current and heat. Furthermore, a higher cathode excess ratio can remove more water, thus assisting to overcome the flooding phase that takes place once the ice formed melts, as shown in Fig. 2 (b).

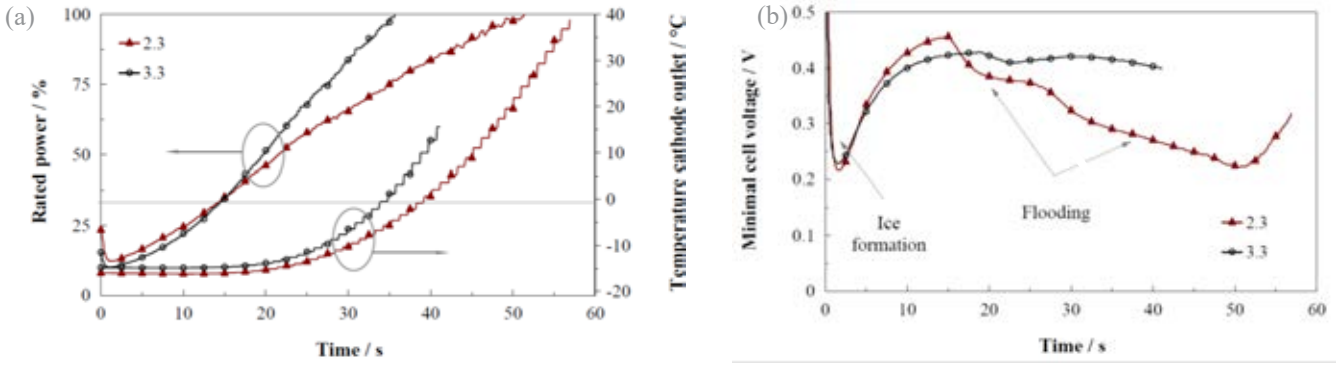

Fig. 2. Effect of cathode excess ratio (2.3 and 3.3) on the cold start of the 4-kW PEFC system performance at -20°C: (a) time-rated power and time-temperature cathode outlet; (b) time-minimal cell voltage

CONCLUSIONS

In this investigation, the effects of start-up temperature, coolant volume flow rate, cell voltage, cathode excess ratio and cathode gas on the cold start performance of PEFC fuel cell systems have been studied. The results of this experimental study can be summarized as follows:

- A self-start of the PEFC fuel cell systems was possible at temperatures down to -30°C. The startup temperature makes a significant impact on the cold startup time and on the cold start performance.
- The cell voltage has an enormous influence on the cold start time. Operating at lower cell voltage reduces the start-time since more waste heat is produced.
- Cold start performance can be improved by increasing the cathode excess ratio since more current and heat are produced, and more water is removed, thus assisting to overcome the flooding phase.

The remaining results obtained within this study will be presented and discussed in further detail during the conferences. Additionally, guidelines to optimize cold start strategies for transportation and aerospace applications will be provided.

ABSTRACT

Micro-stamping is a convenient sheet-metal forming technology providing small tolerances, surface accuracy, low-cost and fast production of thin metallic sheets. Compared to macro-forming operations, tribological changes in micro-forming processes are harshened. Tribological size effect should be considered for a better understanding of surface interaction on micro-scale. The objective of this study is to establish numerical and experimental models for micro-stamping of stainless steel blanks regarding the tribological size effect and determine the effects of feature size of the dies and stamping force onto friction, von-Mises stress, plastic strain, part thickness changes. Numerical models of micro-stamping process for the dies with 3 distinct channel sizes (250 µm, 750 µm and 2500 µm) were established in FEA package Ls-Dyna. Several coefficients of friction values were imposed and runs were performed. Micro-stamping were also conducted to verify the established FE models. It was noted that the dies with different channel sizes showed different magnitudes and distributions of von-Mises stress and plastic strain. In addition, different friction coefficients were encountered for the micro-stamping dies with 250 µm, 750 µm and 2500 µm channel sizes. The lower channel size the higher coefficient of friction was observed as a result of tribological size effect.

INTRODUCTION

The demand for miniaturization is incessantly growing with the technological developments in micro-electromechanics, electronic health care and automobile industries. The global micro electromechanical systems (MEMS) market size was estimated as big as $48.7 billion in 2018, and is forecasted to surpass $122.8 billion by 2026 [1]. Specifically, the market size for MEMS devices in biomedical applications in which micro components and mechanisms are involved is expected to reach $ 27.38 billion, by 2026 [2]. As a result of this demand, the research and industrial activities on mass manufacturing of micro-scale parts such as micro-gears, pumps, connector pins, miniature screws, contact springs have been a trend. In this respect, metal forming methods are preferred and adapted to microforming since these methods are appropriate for high production rates, and can provide high quality final product surface, and high strength with a low cost [3-6]. On the other hand, it is challenging to produce form micro-scale parts in big quantities and very tight tolerances compared to macro-scale process. Some of these challenges that need to be properly addressed are as follows; (1) Influence of size effect on material behavior, (2) Unknowns in contact mechanics, surface interactions and macro-scale tribology, (3) Lack of reliable modeling and simulation of micro-forming processes, (4) Machine and equipment problems [6,7]. Different from macro forming, in micro forming the ratio of surface area to volume of workpiece is high that causes size effect [8,9]. In addition, due to the higher ratio of surface area to volume, an increased level of friction and wear issues at the contact interface are experienced [10,11]. The friction at the tooling/workpiece interface in sheet metal forming operations determined the formability level of the sheets [12-14]. Thus, the energy and force required for forming sheets can be minimized and longer tool life and better surface quality of tool-workpiece can be provided via reduction of friction [12, 15, 16]. Therefore, the determination of coefficient of friction is critical, particularly in micro-scale [17]. FE based models needs to be integrated to the experiments for more reliable friction analysis. Quite a few studies are available in literature on the Hall-Petch equation-based grain size effect, however; limited number of studies investigated the tribological size effect and determination of coefficient of friction. Hu and Vollertsen carried out strip drawing tests and FEA to identify the tribological size effect [18]. They concluded that friction increased with miniaturization. Bin et al. investigated tribological size effect through cylinder compression tests and found that as tribological size effect encountered in lubricated condition whereas it is not observed in dry condition [19]. In another attempt by Peng et al, micro-scale soft punch stamping process, a rigid die and rubber as a flexible medium involves in only, was investigated with experiments and simulations. They noted that sheet blanks with smaller grain size are prone to attain higher formability. They noted that friction forces increase with miniaturization that leading to reduce formability [22].

Compared to micro strip/deep drawing and micro extrusion, micro-stamping is more prevalent technique in producing micro-parts and has not been investigated in detail, thus far. Current paper is therefore, dedicated for investigating tribological size effect via performing micro-stamping experiments with thin metallic sheet blanks and establishing FE models and their validation. It aims also to establish FE models and their validation.

EXPERIMENTAL

SS316L metallic sheet alloy with a thickness of 51µm (0.051mm) was chosen as material of interest for forming of blanks since SS316L offers low cost, electrical and thermal conductivity and easy formability [23, 24]. Total number of 36 SS316L sheet blanks were prepared in 30mm x 70mm dimensions. Rectangular strip blanks were preferred in the current study based on the previous research noting that the die corners cause tangential pressure in the blank and causes problems in numerical calculations [18, 25]. 3 different die pairs with different channel heights, 250, 750 and 2500 µm (representing the scale factors of X, 3X, and 10X) shown in Figure 1 were used to stamp the sheet strips. Each die pair was made from H13 tool steel with the dimensions of 40mm X 40 mm X 20 mm and had 67, 26, 9 arrays of micro channels, respectively. Blank holders used in the test setup were made from rubber material. Rubber blank holders protected the strips against the possible micro-cracks during the forming process. The optimum dimensions of blank holders were determined regarding the highest channel height that can be attained while avoiding the micro-cracks on the blank. The variables in micro-stampings was the blank holder dimensions and channel sizes of the dies used while the same sheet strip and blank holders materials were used in all experiments. Dies and blanks with almost the same roughness values were employed in experiments to minimize the effect of surface quality on results.

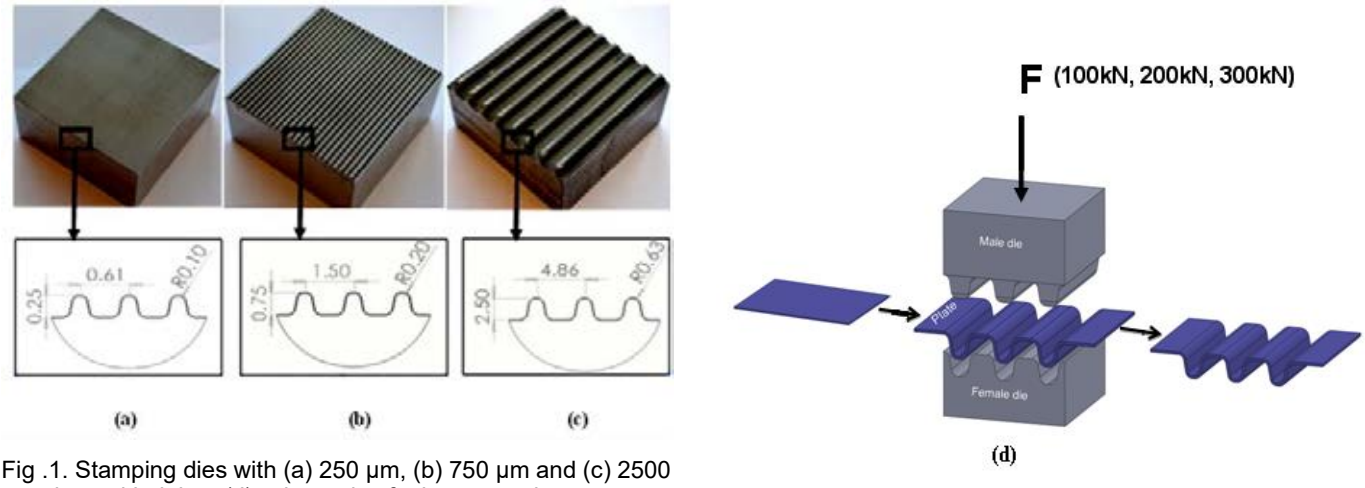

Fig .1. Stamping dies with (a) 250 µm, (b) 750 µm and (c) 2500 µm channel heights, (d) schematic of micro-stamping process

FE Model for Micro Stamping

The numerical simulations were preformed using commercial explicit/implicit finite element code Ls-Dyna for the micro-stamping processes employed three different channel sized dies (250 , 750 and 2500 µm). In order to simplify the analysis of stamping process and reduce the simulation time, 2-dimensional half models were built in Ls-Dyna. At first, die, blank, and blankholder geometries were prepared using SolidWorks CAD tool. Then, the models were prepared, as demonstrated in Figure 2 for finite element analyses. The FE models consisted of 37172, 28840 and 28613 4-node quadrilateral elements for the stampings with 250, 750 and 2500 µm channel height dies, respectively. Male and female dies were defined as rigid materials, whereas the blanks and blank holders were specified as deformable bodies. Elastic mechanical properties for blanks, male and female dies such as elasticity modulus, density and poisson ratio were acquired from literature as E=193 GPa, ρ = 7.99 g/m^3, υ = 0.31, respectively [27]. Power law material model with strength coefficient value (K) of 1058 and strain hardening exponent (n) of 0.28 were utilized for blanks. Blatz-Ko Rubber material model with mass density of 0.95 t/mm^3 and shear modulus of 28 N/mm^2 was used for blankholder. Coulomb friction model was defined for all contact surfaces. All contact conditions between upper (male) die and blank, lower (female) die and blank, blank and blankholder, blankholder and lower die (female) were selected as “2D Automatic Node to Surface” contact algorithm [28]. A very wide range of coefficients of friction values (µ= 0.001, 0.01, 0.02, 0.03, 0.04, 0.05, 0.1, 0.2 and 0.3) were employed in the simulations. The upper die was moved down with a constant stamping speed of 1 mm/s, and a blank holder force of 3000 N was applied on the blank holder. Finally, an implicit solver was imposed as a solution algorithm in the simulation due to allowing for much larger time steps.

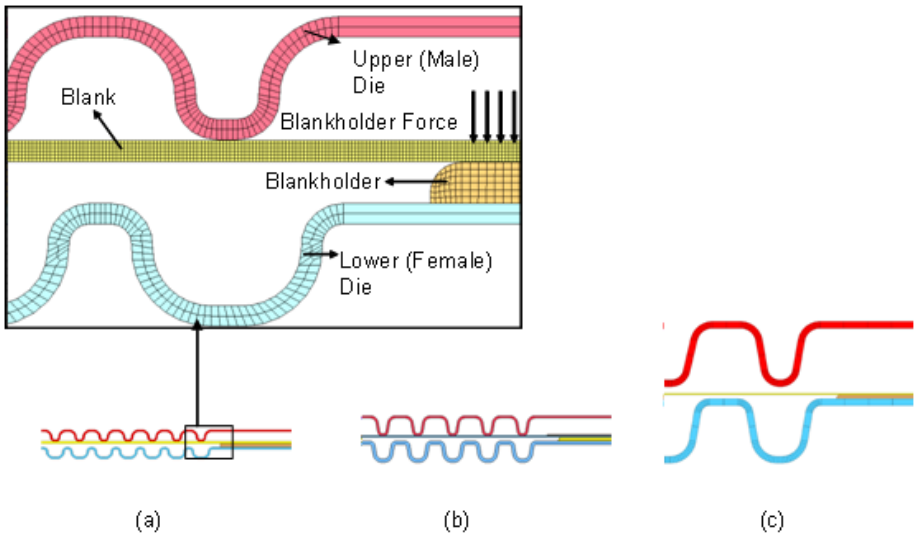

Fig.2. 2-D FE model of stamping process for the dies with the channel dimensions of (a) 250 µm, (b) 750 µm and (c) 2500 µm.

CONCLUSION

Formability and surface interactions between micro-stamped SS 316L sheet strips and micro-stamping dies were studied both experimentally and numerically. Channel height formation was taken as a measure for formability. Micro-stamping experiments were performed using three different dies with distinct channel height values (x, 3x, 10x) at different stamping force levels (100, 200, 300 kN) to investigate the tribological size effect. It was found that when the forming die dimensions get smaller the frictional conditions get harsher. Hence, tribological size effect was confirmed with the results. Interestingly, increasing force levels used in the experiments and simulations did not affect the coefficient of friction value in micro-forming of sheet strips with a certain die. On the other hand, plastic strain, equivalent stress so the formability levels were increased with increasing stamping force, as forecasted initially.

ABSTRACT

In this work, results of the synthesis and characterization of cationic hydrocarbon membranes with application in fuel cells will be presented. Semi-interpenetrating membranes based on PVA with sulfonated aromatic electrolyte polymer were prepared. In the polarization tests in a fuel cell prototype, the membrane with the best result obtained the value of open circuit potential and power equal to $0.8\,V$ and $7.5x10^{-2}\,W$, respectively, very close values when compared to Nafion®, an industrial membrane that reaches $0.8\,V$ and $9.0x10^{-2}\,W$, respectively, thus proving the applicability of the synthesized membrane in fuel cells.

Keywords: Electrolyte Polymers, Fuel Cells, Membranes, Polarization Curve

INTRODUCTION

Hydrocarbon electrolyte polymers have been good substitutes for the Nafion® membrane due to their low-cost synthesis, ease of insertion of hydrophilic groups, good proton conductivity and high chemical stability in some cases [1-4]. This work presents a new sulfonated indene-based electrolyte polymer applied in the synthesis of membranes with semi-interpenetrating structure, semi-IPNs, based on poly (vinyl alcohol) crosslinked with different crosslinking agents and tested in a fuel cell prototype.

MATERIALS AND METHODS

Poly (vinyl alcohol) - PVA Sigma Aldrich PM 130,000 g/mol and degree of hydrolysis 99% and ethanol Sigma Aldrich 98% were used in the synthesis of the membranes. The crosslinking agents used were Sigma Aldrich 99% citric acid, Sigma Aldrich 50% sulfosuccinic acid, Sigma Aldrich 50% 4-sulfophthalic acid. Poly(indene) sulfonated electrolyte polymer (SPInd) was synthesized as described by Brum and Colab [3–5]. Membranes were prepared by mixing 1.0 grams of PVA, 30% by weight of the crosslinking agents and 40% by weight of the SPInd polymer electrolyte [3,4]. For the characterization of the membranes, the following tests were performed: ion exchange capacity (IEC) at room temperature; degree of swelling at room temperature for 24 hours; degree of hydration; electrochemical impedance spectroscopy with humidified samples (sample area: 1.5 cm^2) [3,4]. In the fuel cell test, a hydrogen pressure of 1.5 psi and 3.0 psi of oxygen, cell area of 5.8 cm^2 and platinum catalyst 0.5 mg/cm^2 were used.

Units and Equations

Evaluation of the degree of swelling (WU): the degree of swelling measures the water absorption capacity of the membranes. The previously dried membrane sample is weighed and immersed in distilled water at room temperature for 24 hours, then it is removed from the aqueous medium, lightly dried to remove excess water, and weighed again. The value of the degree of swelling is calculated by the difference between then.

Ion exchange capacity (IEC): indicates the number of moles of the ion in 1.0 g of polymer. To perform this method, conventional titration is used, later the sample is placed in 1M NaCl solution for 24 hours. Then titrated with a 0.05M NaOH solution and using Eq. (1). Where V_{NaOH} is the volume of NaOH solution used to reach the equivalence point in the titration, M_{NaOH} is the molar concentration of the NaOH solution and M_{sample} is the mass of the sample, in grams:

$$IEC = (V_{NaOH} x M_{NaOH}) / M_{sample} \quad (1)$$

Hydration Degree (λ): indicates the degree of hydration of membranes, or number of H_2O molecules per an acidic hydrophilic group by Eq. (2).

$$IEC = (\%_{swelling})/(18/IEC) \quad (2)$$

Ionic conductivity (EIS): evaluates the resistance profile of isolated membranes and membranes in the prototype. It relates the ionic conductivity (δ) with the film thickness (l), the cross-sectional area (A) of the analyzed material, and the material resistance (R), the latter determined by electrochemical impedance spectroscopy (EIS), given by Eq.3. To perform this method, the membranes were conditioned in deionized water for 1h:

$$\delta = (1/R)x(1/A) \quad (3)$$

RESULTS AND DISCUSSION

Table 1 presents the values of ion exchange capacity, degree of swelling and hydration, and the description of each synthesized membrane. The only variation in the formulation of the membranes was the crosslinking agents. Membranes crosslinked with citric acid will be called M-AC, those with sulfophthalic acid (M-ASF) and sulfosuccinic acid (M-ASS).

Table 1. Values of ion exchange capacity, degree of swelling and hydration of synthesized membranes

Membranes	IEC (mEq/g)	Thickness (cm)	Swelling degree (%)	Hydration degree (λ)
M-AC	1.3	0.021	206	8.803
M-ASF	1.5	0.022	100	3,704
M-ASS	1.4	0.022	121	4.801

It can be seen that the IEC values were practically unchanged, but on the other hand, in the swelling values a significant variation is observed. This fact is attributed to the acidic character of the hydrophilic sulfonic groups (-SO_3H) having a strong influence as a catalyst in membrane esterification reactions, and crosslinking reactions [1,4]. The M-AC membrane has a hydrophilic carboxylic group (-COOH) and this fact explains the high swelling degree value, since the carboxylic acid group has a lower acidic character compared to the sulfonic group (BRUM, 2013). The values of the degree of hydration are almost double for the membrane with (-COOH), while those with group (-SO3H) had little difference. The M-ASF membrane has an aromatic group in its composition, and this group confers greater rigidity to the polymeric structure, which justifies the differences in swelling and hydration values of this membrane when compared to the M-ASF membrane.

Table 2 presents the results of the electrochemical impedance test. Citric acid and sulfosuccinic acid present a linear carbonic chain structure, with their major difference being the hydrophilic groups. This fact is observed by the proximity of the electrolyte resistance values, but with very different values in relation to conductivity.

Table 2. Resistance and conductivity values obtained by impedance

Membranes	Resistance (ohm)	Conductivity (S/cm)*
M-AC	9.20	$15.9x10^{-04}$
M-ASF	10.5	$5.77x10^{-04}$
M-ASS	3.47	$4.99x10^{-03}$
Nafion®	1.94	$5.529x10^{-03}$

*1.5 cm^2 area electrodes

From the resistance values it is observed that the M-ASS membrane presented the lowest value and, when compared to the M-AC membrane, the difference between the resistance values reaches more than 250%. This is due to the low ionic strength of the carboxylic groups, which is proven by the values of degree of hydration presented (Table 1). The M-ASF membrane, which presents only sulfonic hydrophilic groups in its composition, presented the highest resistance value and the lowest conductivity. This fact is associated with the presence of aromatic groups in the composition of this membrane from the structure of SPInd and the crosslinking agent sulfophthalic acid [1]. The aromatic groups tend to rearrange themselves in structures in the form of a half ladder and make the polymeric structure more rigid, thus impairing the ionic transport [3,4].

Figure 1 shows the polarization curves of the synthesized membranes obtained from the fuel cell performance test [2]. It can be seen that all the electrode/membrane/electrode sets presented the same open circuit value, around

0.8V, therefore, it is evident in the test only the influence of the tested membrane. The membrane that came closest to the Nafion® reference (power 9.20 x10^{-2} W) was the HC (power 7.49 x10^{-2} W) crosslinked with sulfosuccinic acid.

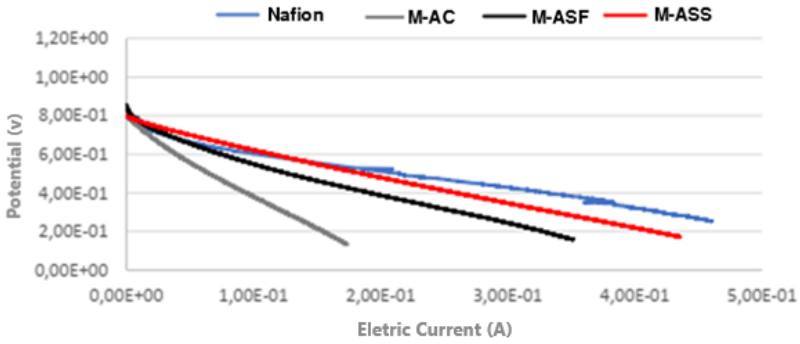

Fig.1. Polarization Curves of M-AC, M-ASF, M-ASS and Nafion® membranes

This result is corroborated by the conductivity values presented in Table 2. Although the HB membrane (power 5.56 x10^{-2} W) has in its composition only hydrophilic sulfonic groups, what may have influenced the reduction of proton transport was the presence of aromatic rings leaving the molecular structure of the semi-interpenetrating network more rigid, which impaired the transport of H_3O^+ species. Even with the presence of the polymer electrolyte SPInd, the HA membrane (power 2.31 x10^{-2} W) showed low performance compared to the other membranes.

CONCLUSIONS

Semi-interpenetrating PVA-based cationic membranes with poly(indene) sulfonated electrolyte polymer were prepared and presented homogeneous and stable films. The IEC values, degree of swelling and degree of hydration confirmed the esterification reaction and the structural differences between the membranes presented. Citric acid, sulfophthalic acid and sulfosuccinic acid were good crosslinking agents. The membrane that showed the best performance in a fuel cell test was the HC, crosslinked with sulfosuccinic acid.

ABSTRACT

Hydrogen mobility is becoming increasingly important and is seen as an alternative to electric and conventional mobility. As a student project the ThaiGer-H2-Racing Team at the University of Applied Sciences Stralsund has been working on hydrogen propulsion since 2007 and is building ultra-light prototype vehicles with fuel cells. Within the fuel cell system cooling is a crucial problem to be solved for future applications. We report on an experiment with a two-phase cooling system, which was developed for the fuel cell stack. An engineered liquid Novec 7000 from 3M was used as the cooling medium. The cooling medium evaporates in the fuel cell stack at about 45 °C and thus transports the heat to the outside. The cooling circuit is driven by the evaporation of the cooling medium and thermosiphon effect and therefore does not require an additional cooling pump. Since the cooling circuit is operated at a slight overpressure, the membranes in the stack are more uniformly compressed by the metallic bipolar plates, which might increase the performance of the stack. The two-phase cooling system was successfully tested in the new vehicle on a track. By saving the cooling pump and reducing the consumption, the overall efficiency of the fuel cell system was significantly improved.

Keywords: Two-phase cooling, Thermosiphon, Cooling System, Fuel Cell, 3M Novec

INTRODUCTION

In recent years' automobile manufacturers are recognizing the potential of hydrogen mobility and are launching series-produced vehicles on the market. The biggest players are Toyota and Hyundai, but German manufacturers are also following this trend and developing hydrogen vehicles and their own fuel cell systems. For weight reasons, the bipolar plates in such fuel cells are made of thin metal sheets. These usually consist of two metal foils welded together, in which the channels for the media supply (H2 and air) are stamped. The coolant flows through the interstitial space and removes the waste heat. The coolant used is usually an ethylene glycol/water mixture with corresponding cation and anion exchangers, which must have low electrical conductivity in the FC stack (<5 µS/cm at 25 °C), otherwise the water molecules will be split in the fuel cell, because a high voltage is applied across the bipolar plates. [1]

The ThaiGer-H2-Racing Team is a student team at the University of Applied Sciences in Stralsund, Germany, which has been developing and building hydrogen-powered prototype vehicles for over 14 years. These vehicles have excellent aerodynamics and are designed for highest efficiency. The team competes annually in the largest efficiency competition Shell Eco-marathon Europe, and won 1st place in the hydrogen-powered prototype category in 2017, 2018 and 2019. In 2019, the team achieved their best performance of 1083 km/m^3 of hydrogen, the equivalent of 3295 km on one litre of gasoline.

For Shell Eco-marathon 2022, the team has developed a new vehicle - ThaiGer 7. Compared to the previous model, the weight, aerodynamics and design have been improved, but above all the fuel cell (FC) system has been optimised for higher efficiency. The diaphragm pumps for the air supply were replaced by efficient side channel blowers developed in-house. In contrast to the water cooling system used in the old vehicle, a new type of two-phase cooling system was developed for the FC stack.

The two-phase cooling system requires a cooling medium with a boiling temperature below the desired operating temperature of the fuel cell (40-45°C). The medium must have a very high electrical resistance and must compatible with the used materials. In addition, low viscosity and low surface tension are advantageous for the cooling medium.

The engineered liquids from the company 3M, which are sold under the brand name Novec, were shortlisted as suitable liquids. These are the fluorine-based liquids, which are similar in structure to hydrocarbons, but in which the hydrogen atoms are replaced by the fluorine atoms. These liquids are relatively inert, non-flammable, non-inflammable and non-toxic. Typical applications for these fluids are ORC systems, thermosiphon systems, ion implanters, plasma etching, two-phase pumping systems and fuel cells. [2]

RESULTS AND DISCUSSION

Of all the Novec fluids, three were considered for the cooling system. Decisive for the selection is the boiling temperature, which must either correspond to the operating temperature in an open two-phase system or be below the desired operating temperature for a closed two-phase cooling system. Since the Novec liquids are relatively volatile, only a closed cooling system can be used. Table 1 summarizes the essential properties of selected media. Only Novec 7000 has the boiling point (34 °C) below the desired operating temperature of 45 °C. The water, Novec 7100 and Novec 649 have a higher boiling points, but are thermally more stable. The Novec liquids can be mixed with each other, but they do not form an azeotropic mixture, so that only the liquid with the lower boiling temperature would evaporate first. For this reason Novec 7000 was chosen for the experiments with the cooling system of the fuel cell.

Table 1. Comparison of cooling liquids [2, 3, 4]

	Unit	Water	3M Novec 7000	3M Novec 649	3M Novec 7100
Boiling Point (@ 1 atm)	°C	100	34	49	61

Thermal stability	°C	-	150	300	150
Thermal Conductivity	W/(m·K)	0.5984	0.075	0.059	0.0688

The fuel cell stack consists of 30 cells connected in series. The series connection is guaranteed by the metallic bipolar plates. The bipolar plates consist of two metallic stainless steel foils, in each of which the flow field for the hydrogen and the air are embossed. The interstitial space is filled with the cooling liquid, Novec 7000. When the liquid reaches boiling temperature, it boils at the hot spots occurring in the fuel cell during operation. The phase transition removes the heat from the bipolar plates. The warm cooling liquid rises together with the steam bubbles to the top of an expansion tank. There, the vapour condenses and releases the heat into the environment in a heat exchanger. Due to its higher density, the cooled medium sinks downwards through an aluminium tube to the inlet of the fuel cell stack. With the correct sizing of the plumbing the liquid in the cooling circuit is made to circulate by the evaporation and thermosiphon effect. This supersedes the circulation pump and reduces the system's self-consumption, thus increasing the efficiency.

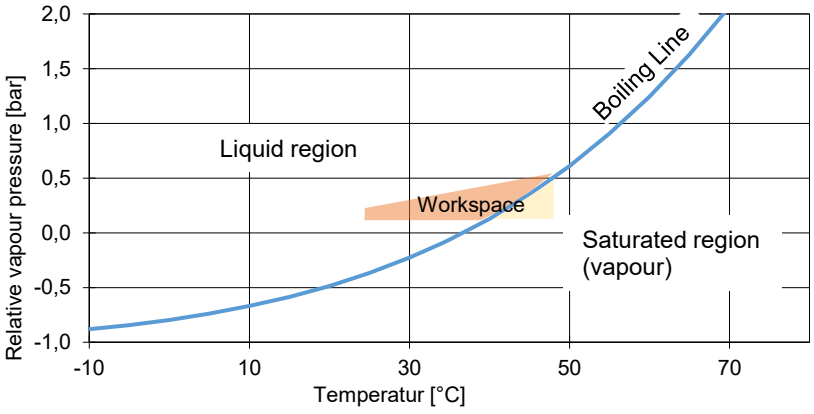

Fig. 1: Vapour diagram from Novec 7000 [5]

The steam curve of Novec 7000 is shown in the diagram (figure 1). The working area of the cooling system is shown in the diagram as a red area. The medium is present in the cooling system in two phases: liquid and as vapour. As the temperature rises, the volume of the cooling liquid increases significantly due to thermal expansion, since the

coefficient of expansion is about a factor of 10 higher than that of water. The expansion tank is equipped with a spring-loaded piston and has the task of compensating for the expansion, so that the pressure in the cooling system changes only in a very tight area and is about 0.4 bars. Due to this overpressure, the membranes in the stack are pressed more evenly by the metallic bipolar plates, which might increase the performance of the stack.

The assembled fuel cell system is shown in the figure 2. The expansion tank with spring-loaded piston is located above the FC stack. The expansion tank is made of an aluminium tube and serves together with the vertical recooling tube to dissipate the waste heat into the environment. The spring force, and thus the pressure in the cooling system, is adjusted by means of a screw. The pressure can be read on a digital pressure display (blue box on the top).

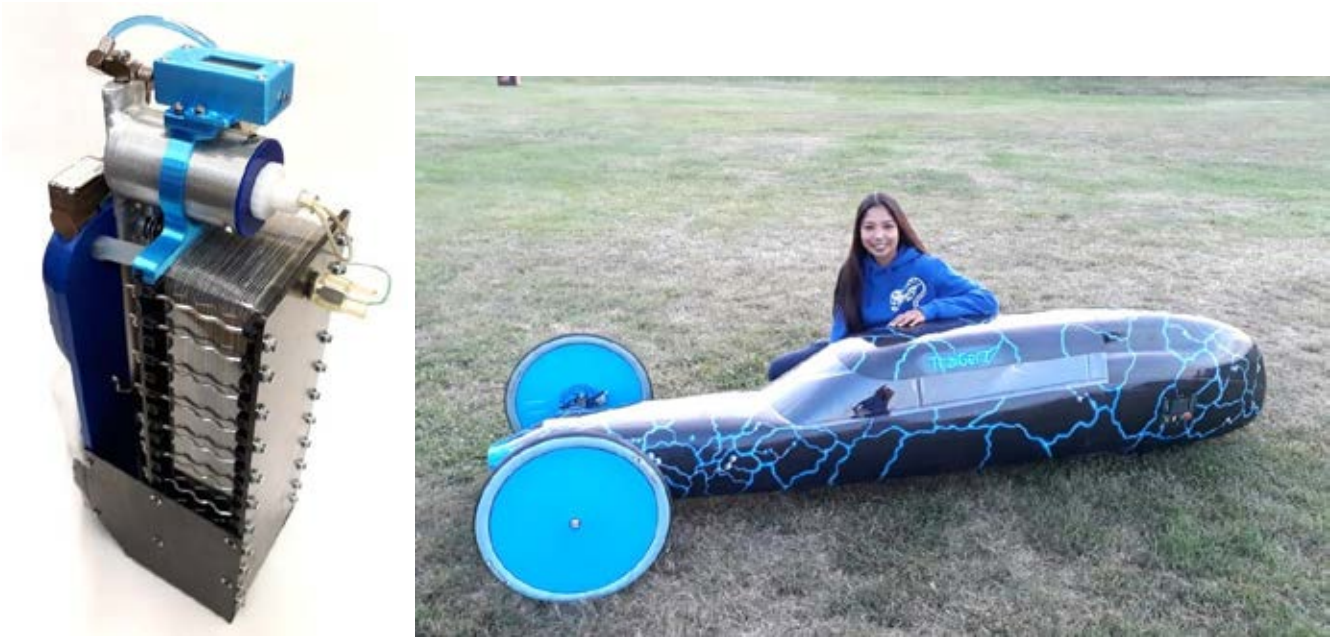

Fig. 2: Fuel cell system with the two-phase cooling (left); ThaiGer 7 vehicle with the author T. Bogdanske (right)

CONCLUSIONS

A passive two-phase cooling system was developed for the FC stack of an ultra-light vehicle. This is based on a light boiling liquid Novec 7000, which has a boiling temperature of 34 °C at ambient pressure. The overpressure in the cooling system of about 0.4 bar ensures an operating temperature of 45 °C. The overpressure ensures that the membranes in the fuel cell stack are compressed more evenly, which slightly increases the performance. Since the cooling circuit is driven by the evaporation and thermosiphon effect, no circulation pump is required for this closed cooling system. This saves power for the pump and increases system efficiency.

TWO-DIMENSIONAL SIMULATION OF COLD START PROCESS FOR PEMFC STACK WITH VARIOUS CURRENT LOADING MODES

*Jing Liu, * Tong Zhang*
School of Automotive Studies, Tongji University, Shanghai 201804, China

*Corresponding author e-mail: tzhang@tongji.edu.cn

ABSTRACT

Rapid cold start of proton exchange membrane fuel cell (PEMFC) stack is imperative for the widespread commercialization of fuel cell vehicles. In the present work, a two-dimensional transient cold start model of a PEMFC stack with coolant recirculation is developed to explore a fast start-up strategy and the corresponding required operating conditions. Five current loading modes are evaluated for the stack performance from – 20 °C, including three constant current loading modes and two current ramping loading modes. It is found that a linear current ramping strategy with a larger initial current density can generate more heat and facilitate rapid cold start without excessive voltage undershoot. Meanwhile, the cell voltage variation of the 20 cells during the cold start process is recorded and two end side cells show smaller output voltage due to lower cell temperature than that of the middle cells. In order to maintain cell voltage consistency, external heating or insulation is necessary for PEMFC stack cold start stably and successfully.

Keywords: PEMFC Stack, Cold Start, Current Loading Strategy

INTRODUCTION

Under the background of carbon neutrality, the development of proton exchange membrane fuel cell (PEMFC) obtained an unprecedented opportunity due to its characteristics of zero emission. However, the cold start problem brings a big challenge to PEMFC, which is one of the main obstacles to the promotion of fuel cell vehicles in cold zones [1]. During the cold start of PEMFC, the ice will block the diffusion path of reactant to the reaction site [2], which prevents electrochemical reactions from taking place and results in cold start failures.

In order to explore the multidisciplinary coupling process of PEMFC cold start, a number of cold start models of single cell or stack have been developed. Three-dimensional model is very useful to observe the ice distribution and temperature distribution. However, the computational domain is mainly limited in one single channel [3, 4] because of the limitation of computation resources [5]. Therefore, the characteristics of large-scale cell or stack can not be fully considered. One-dimensional models only consider through-plane direction of PEMFC stack without taking in-plane direction into account. Two-dimensional models are the extension of the one-dimensional models, which usually focus on the through-plane domain and long-the-channel domain. Comparatively speaking, the two-dimensional models require less computational cost, and the detailed transport phenomenon uniformity of ice distribution, consistency of voltage can also be taken into consideration. Thus, it can be an alternative way to investigate the cold start process of PEMFC stack. In addition, one of the most important parameters influencing the cold start process of PEMFC is coolant circulation. Nevertheless, rare multi-dimensional cold start model of PEMFC stack considers the coolant, and only the single cell model with straight flow channel has been studied to investigate the effect of coolant flow [3, 4]. Therefore, it is necessary to establish a two-dimensional large-scale cold start model considering coolant circulation, so as to study the cold start characteristics and evaluate various auxiliary start methods.

In this paper, a two-dimensional cold start model is developed for PEMFC stack. This study aims to investigate the effect of current loading strategies on the PEMFC stack cold start process with consideration of coolant circulation, which is closer to the actual working condition of PEMFC stack. Based on this model, an optimal current loading method is recommended.

MATHEMATICAL MODEL

A two-dimensional model for PEMFC stack cold start process with coolant circulation is established. Fig. 1 (a) shows the computational domain. N nodes is set along the channel and N is determined to be 5 in this study after the grid independency check. The cell number is set to be 20 to reflect the characteristics of the PEMFC stack [6]. The model is formulated based on the conservation equations of mass conservation, gas species transport, membrane water transport, liquid water transport, ice transport and energy [7]. Some basic assumptions are made as described in reference [7]. The coolant is assumed to be evenly distributed in each single cell.

$$\partial(\varepsilon(1-s_{\mathrm{lq}}-s_{\mathrm{ice}})\rho_{\mathrm{g}})/\partial t+\nabla\bullet(\rho_{\mathrm{g}}\vec{u}_{\mathrm{g}})=S_{\mathrm{m}} \quad (1)$$

$$\partial(\varepsilon(1-s_{lq}-s_{ice})\rho_g c_i)/\partial t=\partial^2(\rho_g D_i^{eff} c_i)/\partial x^2+S_i \quad (2)$$

$$[\rho_{MEM}/EW][\partial(\omega\lambda_{nf})/\partial t]=[\rho_{MEM}/EW][\partial^2(\omega^{1.5}D_{nf}\lambda_{nf})/\partial x^2]+S_{nmw} \quad (3)$$

$$[\rho_{MEM}/EW][\partial(\omega\lambda_f)/\partial t]=S_{fmw} \quad (4)$$

$$\partial(\varepsilon\rho_{lq}s_{lq})/\partial t=\partial^2(\rho_{lq}p_{lq}K_{lq}/\mu_{lq})/\partial x^2+S_{lq} \quad (5)$$

$$\partial(\varepsilon s_{ice}\rho_{ice})/\partial t=S_{ice} \quad (6)$$

$$\partial((\rho C_P)^{eff}T)/\partial t=\partial^2(k_T^{eff}T)/\partial x^2+S_T \quad (7)$$

In this model, the convective heat transfer rate between the end bipolar plate and environment is set as:

$$Q=h(T-T_{BP})A_{BP} \quad (8)$$

The inlet gas boundary condition is shown below:

$$u_{in,a}=(ST_aI_{ave}A_{cell})/(2Fc_{H_2}A_{ACH}),u_{in,c}=(ST_cI_{ave}A_{cell})/(2Fc_{O_2}A_{ACH}) \quad (9)$$

RESULTS AND DISCUSSION

Model validation

This two-dimensional model is validated by comparing the output voltage and temperature of coolant with experiment results of cold start process for PEMFC stack at -20 ºC [8]. The coolant inlet temperature is set as -17 ºC both in the experiment and the model. According to the Fig. 1(b) and (c), the output voltage, coolant inlet and outlet temperature of PEMFC stack model are in good agreement with the experiment data. And it is shown that this model can be used to predict the cold start performance of PEMFC stack reasonably.

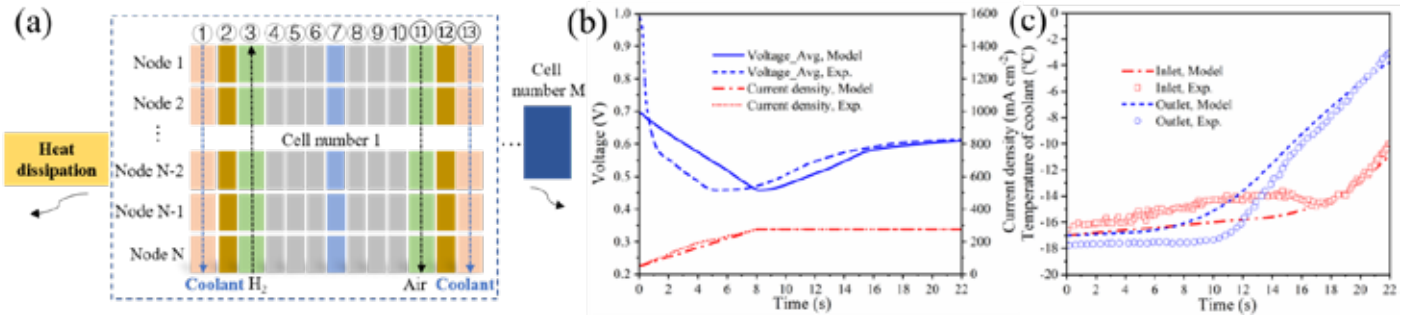

Fig. 1. (a) Schematic diagram of two-dimensional PEMFC stack model: ①ACF, ②ABP, ③ACH, ④AGDL, ⑤AMPL, ⑥ACL, ⑦MEM, ⑧CCL, ⑨CMPL, ⑩CGDL, ⑪CCH, ⑫CBP, ⑬CCF. (b) and (c) Comparison of model prediction with experimental results [8].

The output voltage and coolant inlet temperature of the PEMFC stack

This work aims to find out a proper current loading mode for rapid cold start process. Five different current loading modes are introduced in Table 1, including constant current and current ramping modes. The cell voltage and coolant inlet temperature are elucidating here to evaluate the effects of various current loading modes on PEMFC stack cold start process, as are shown in Fig. 2(a) and (b) respectively.

In regard to the three constant current cases, it is found that growth rate of the coolant inlet temperature in case 1 is the slowest. Because low current density can not provide sufficient heat to rise the PEMFC stack temperature rapidly. Increasing the start-up current density properly would favorable due to more heat generated. However, case 3 indicates that a large current density can result in too low output voltage to fail in cold start of PEMFC stack because of inadequate initial membrane water content. As to current ramping methods, case 4 shows lower cell voltage dropdown than that in case 2, which can avoid MEA degradation. Short cold start-up time and harmless to PEMFC stack are both imperative. Using a larger current ramping loading from 500 mA cm^{-2} to 700 mA cm^{-2}, the PEMFC stack can be successfully cold start-up in 19.5 s with the higher initial membrane water content.

Table 1. Detailed parameters of five current loading strategies.

	Current loading mode	Current density (mA cm^{-2})	Initial water content		Current loading mode	Current density (mA cm^{-2})	Initial water content
case 1	constant	100	3.2	case 4	ramping	50 – 400, 10 s	3.2
case 2	constant	400	3.2	case 5	ramping	500 – 700, 4 s	7
case 3	constant	500	3.2				

The cell voltage consistency of the PEMFC stack

Fig. 2(c) gives the output voltage variation of the 20 cells during the cold start of PEMFC stack in case 5, where the cell voltage is recorded when the coolant inlet temperature reaches 0 °C. It is obvious that the side cells (cell 1-4 and cell 17-20) have the lower output voltage than that of the middle cells. This is because the cells at both sides dissipate more heat to the environment, making it harder to warm up. Thus, it is necessary to make insulation or apply external heating to the cells at the both end sides of PEMFC stack to maintain cell voltage consistency and successful cold start-up.

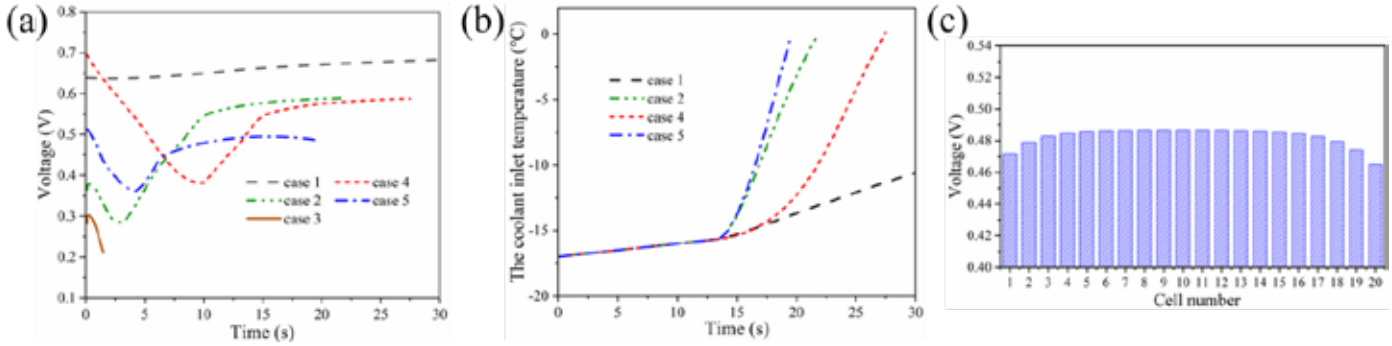

Fig. 2. (a) Average cell voltage for the five cases. (b) The coolant inlet temperature of PEMFC stack for the five cases. (c) Cell voltage variation of case 5 at start-up time t=19.5 s (the coolant inlet temperature T=0 °C).

CONCLUSIONS

A two-dimensional cold start model of the PEMFC stack with coolant recirculation is developed and a current ramping strategy is proposed for rapidly cold start-up. The constant current loading modes with a small start-up current density can not produce sufficient heat. Otherwise, the higher constant current density may cause too large voltage undershoot to cold start failure. As to current ramping mode, it can take advantage of sufficient heat generation and less voltage undershoot. The PEMFC stack mildly hydrated before cold start process can be successfully cold start-up in 19.5 s by using a current ramping loading from 500 mA cm^{-2} to 700 mA cm^{-2}. In addition, insulating or heating the cells at the both end sides of PEMFC stack is essential to retain voltage consistency and achieve cold starts.

AIR SUPPLY MODULE FOR PRESSURIZING FUEL CELLS IN AIRBORNE APPLICATIONS

[1] Daniel Frank, [1] Jonas Schröter, [1] Christiane Bauer, [1*] Caroline Willich
[1]Ulm University, Institute for Energy Conversion and Storage, Albert-Einstein-Allee 47, 89081 Ulm, Germany

ABSTRACT

In order to obtain high power and efficiency while operating PEM fuel cells in airborne applications, pressurizing the inlet air is a prerequisite. An air supply module and its control strategy was developed in order to provide air at optimal conditions for different ambient conditions (low pressure, temperature and humidity) and varying power demand. The system was successfully tested statically and dynamically and afterwards connected to a fuel cell system.

Keywords: PEM Fuel Cell, Air supply, Aviation

INTRODUCTION

Using PEM fuel cells for propulsion in aircrafts has attracted much attention in the last years [1][2]. However, the performance of fuel cells decreases significantly with decreasing pressures [3][4], so the fuel cell will perform worse at high altitudes unless it is pressurized. The pressurization of the fuel cell air in an all-electric aircraft should be achieved by means of an electrically driven compressor. Both the characteristic of the fuel cell and the compressor change with inlet conditions; therefore, the components need to be carefully matched for optimal airborne operation. The dynamic behavior of the system is especially important since both the load requirement and the ambient conditions change and influence the behavior of the two main components, fuel cell and compressor.

SYSTEM DESIGN

In order to provide the required quality and amount of air-feed to the fuel cell at the optimal pressure, temperature and humidity, the air supply system has to incorporate an air filter, an electric compressor, an intercooler and a humidifier before it enters the fuel cell and a valve is required after the fuel cell. In previously presented work [5] a preliminary architecture was designed and suitable components were identified. An enhanced architecture is shown in Figure 1.

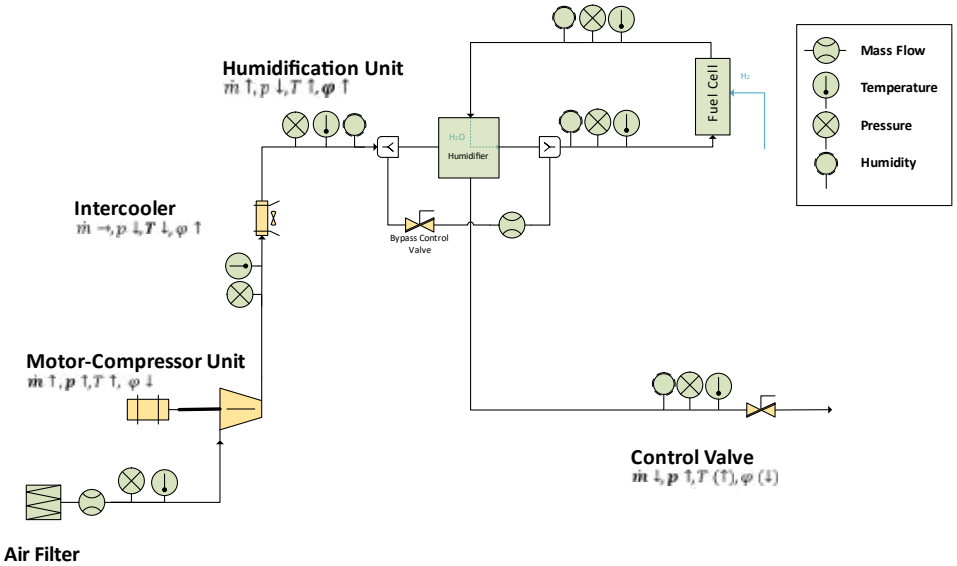

Figure 1: Enhanced Architecture of the developed air supply system

EXPERIMENTAL SETUP

After the design of the system, the air supply module was built up in a test-rig. Figure 2 shows the experimental installation. The setup uses a motor-compressor unit EK10AA (Rotrex, DK), a humidifier H50N (Fumatech, GER), an air filter FC F-0514-N (Freudenberg, GER) and two control valves APC (Hyundai Kefico, KOR) and was equipped with mass flow, pressure, temperature and humidity sensors.

The control of the air supply module was developed as well. With the help of the actuators compressor and throttle valve a decentralized control strategy for pressure and mass flow was developed, implemented and parameterized. The air temperature is controlled by means of intercooler coolant flow regulation. The humidity is controlled via the bypass control valve.

Figure 2: Experimental setup of the air supply module

RESULTS AND DISCUSSION

The compressor as the key component was in the first step tested inside an under-pressure chamber [6]. Figure 3 shows how the compressor characteristic shifts to lower outlet pressures and lower mass flow rates for low ambient pressures.

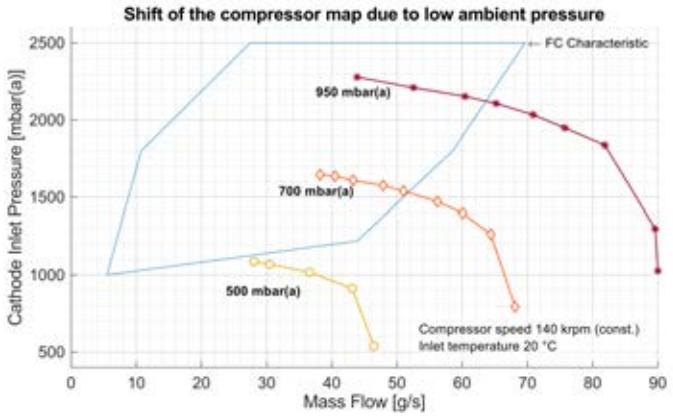

Figure 3: Shift of the compressor map due to low ambient pressure [5]

The dynamic behavior of the complete air supply system was then tested as well. Figure 4 shows an example of the pressure and mass flow provided by the system, where the air supply module performs a transition from a low power setpoint to a high power setpoint (1 → 6), as well as a transition from the high power setpoint to a setpoint with the minimum expected request (6 → 0). The figure shows the nominal operational characteristic of the fuel cell stack (300 cells, 68 kW peak), the compressor map and the trajectory of pressure and mass flow. It can be seen that the provided air stays within the preferred operational area, which is the overlap between the fuel cell map and the compressor map. In order to enable the system to perform transitions such as the beforehand mentioned (6 → 0), a surge avoidance strategy has been developed and implemented.

After successfully completing the tests, the air supply module was connected to a NM5 fuel cell stack (EKFC, GER) in cooperation with the German Aerospace Centre and the joint system was tested. The first coupled tests were successful, the functionality of the combined system was demonstrated, and measurement data will be presented.

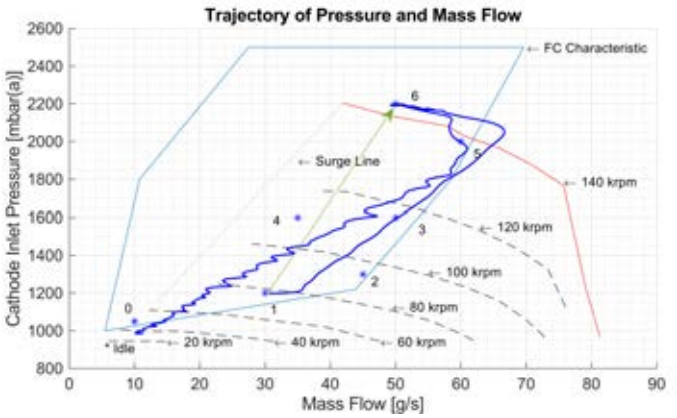

Figure 4: Exemplary transition between steady-state points of operation within the overlap between the fuel cell map and the compressor map at ambient pressure p_0 = 950 mbar

CONCLUSIONS

An air supply module for PEM fuel cells in airborne applications was designed, build and a control strategy was developed. The system was then successfully tested under static and dynamic operation. Afterwards the air supply module was connected to a fuel cell system and the combined system was tested as well.

ACKNOWLEDGEMENT

This work received funding from the German Ministry for Economic Affairs and Energy under grant number 20Y1701B, HighV, and grant number 20M1905D, Enable. The authors want to thank the German Aerospace Centre in Stuttgart for their support and cooperation with regard to the fuel cell.

ABSTRACT
The viability of graphene-based microporous layers for polymer electrolyte fuel cells is critically assessed through detailed characterisation of the morphology, microstructure, and transport properties. Microporous layer composition was optimised by the fabrication of several hybrid MPLs produced from various ratios of graphene to Vulcan carbon black. Single cell tests were performed at various operating conditions: between 25 % and 100% relative humidity, and at 80°C, in order to give a detailed understanding of the MEA performance over a range of conditions.

Keywords: Polymer Electrolyte Fuel Cells; Graphene; Gas Diffusion Layers; Hydrogen

INTRODUCTION
Polymer Electrolyte Fuel Cells (PEFCs) are electro-chemical energy conversion devices capable of providing sustainable transport, stationary and portable solutions, owing to their high-power density and fast start-up time and operation at relatively low temperatures [1]. Currently, liquid water management remains one of the largest barriers limiting fuel cell efficiency and the wide scale deployment of PEFC; this is due to the problem of liquid water accumulation in the electrode which limits reactant transport [2,3], and also membrane dehydration leading to ohmic losses [4,5]. The microporous layer (MPL) of PEFC is widely acknowledged as a crucial, performance enhancing component [6] largely due to enhancing the removal of liquid water and the subsequent reduction flooding. Moreover, the MPL may decrease ohmic losses by increasing the interfacial contact between the gas diffusion layer (GDL) and the catalyst layer, thus enhancing catalyst utilisation, and maintaining membrane hydration [7].
Although the MPL has significantly improved the conversion efficiency and performance of the fuel cell, it still requires optimisation to minimise potential losses from the MPL/catalyst layer interface and from inadequate oxygen mass transport. A recent trend has seen graphene being explored as an alternative to carbon black in the MPL. Graphene is a two-dimensional monolayer of graphitic carbon atoms, with good mechanical stiffness and elasticity, as well as extremely high electrical conductivity and thermal conductivity [8]. Graphene has previously been explored as an MPL material by a few researchers both as a freestanding MPL [9] and conventionally applied to carbon substrate [10,11,12,13]. Mixing graphene with carbon black, or a mixture of graphene with different morphologies has the potential for a synergetic effect on MPL morphology and microstructure, and thus optimising cell performance. The purpose of this research is to develop a greater understanding of how composition affects MPL microstructure and morphology, and ultimately identifying strategies to improve fuel cell efficiency. Here we present the fabrication and characterisation of novel MPLs produced from graphene-based materials. In this research, microporous layers were produced from Nanene (2D Tech, Cheltenham) which is a high-purity graphene, Vulcan XR72C carbon black, and a combination of the two materials.

METHODOLOGY
The fabricated dual-layer GDLs were used as the cathodic GDLs. Toray TGP H-60 carbon paper (10% wt. PTFE treated, Fisher Scientific) was used to produce the dual-layer GDLs. The carbon powder used in the MPL ink were Vulcan XC 72 R whereas the few-layer graphene (FLG) powder used in this study was Nanene provided by 2-DTech Ltd. The hydrophobicity was achieved from the addition of 60 wt. % polytetrafluoroethylene dispersion. Table 1 lists the MPL compositions following drying and thermal treatment. The carbon composition by weight and MPL loading was kept constant at 80 wt. % carbon and 20 wt. % PTFE and at 2.0 mg cm^{-2}.

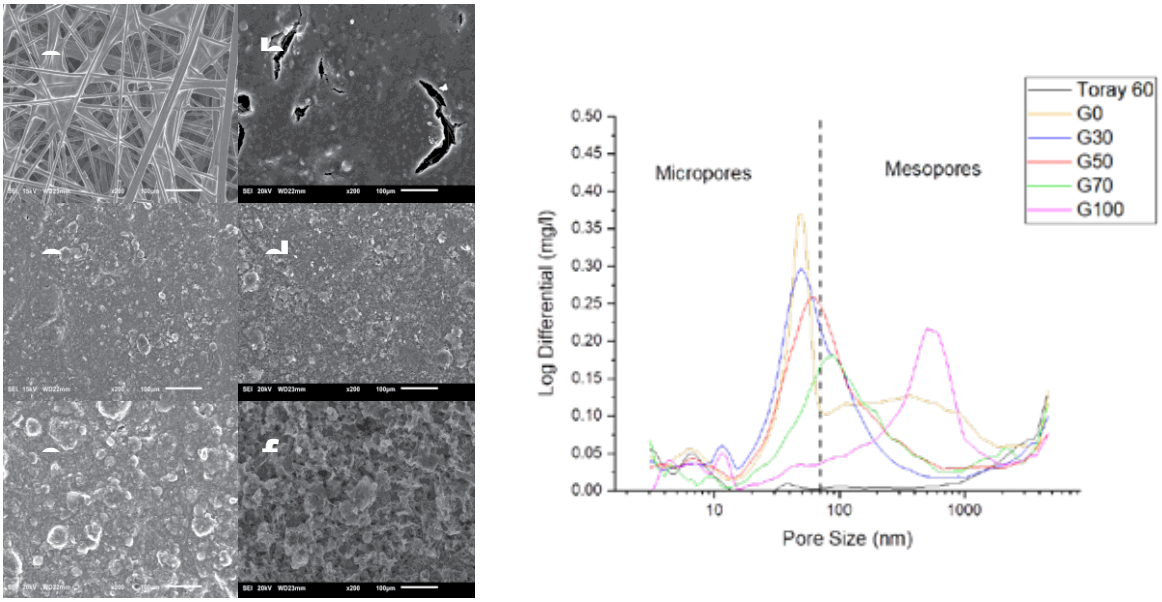

Table 1 Lists of the compositions of the microporous layer inks.

MPL	Vulcan Carbon black (wt.%)	Graphene nano-plates (GNP) (wt.%)	PTFE (wt. %)
G0	80	0	20
G30	56	24	20
G50	40	40	20
G70	24	56	20
G100	0	80	20

RESULTS AND DISCUSSION

Fig. 1a is a series of SEM micrographs showing the surface structure of the MPL coated and the uncoated Toray substrates; notable differences can be seen between the surface structure and morphology of the carbon black MPL and the graphene based.

The pore size distribution can be seen in Fig 1b, G0 (Vulcan MPL) has the typical pore profile of the conventional microporous layer: the majority of the pores are in the microporous region (50 nm). Conversely, G100 (GNP MPL) has a larger median pore size, with most pores occurring in the mesoporous region (500 nm). The inclusion of GNP to the MPL composition increases the average pore sizes in the MPL and leads to the formation of small mesopores in the layer. Interestingly, for the mixed composition MPLs, Vulcan is the dominant material in determining the average pore size. This is in line with the SEM micrographs which show that voids between the larger GNP are occupied by the smaller carbon black particles, and as such leads to the formation of micropores and reduction of mesoporous void space. G50 MPL has a desirable pore size distribution with a median pore size of 61nm, as it has an even distribution of micropores and mesopores. The adequate presence of micropores and mesopores may lead to enhanced performance at high relative humidity operation and current densities, thus enabling the simultaneous capillary wicking of liquid water to mitigate flooding at the cathode and improve reactant diffusion to the catalyst [14, 15].

(a) (b)

Fig. 1 (a) SEM micrographs of MPL coated and the uncoated GDLs (from top left): Toray H-060, G0, G30, G50, G70 and G100), (b) pore size distribution of the uncoated and coated GDLs by mercury intrusion porosimetry.

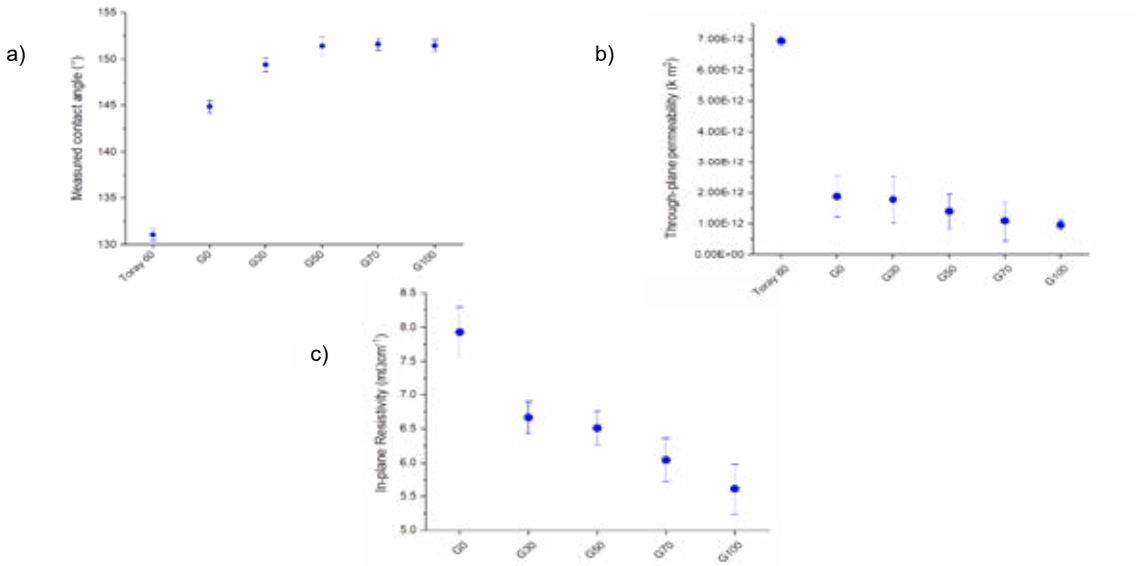

Figure 2: (a) The contact angle, (b) through-plane permeability and (c) in-plane electrical resistivity of the GDLs.

Fig 2(a) shows the contact angle measurements of the coated and uncoated GDLs. The uncoated carbon substrate is moderately hydrophobic (131˚) which is in good agreement with those reported in the literature (129 ± 9˚) [15]. Fig 2(a) indicates that G70 has the highest contact angle (~ 152˚). The inclusion of graphene in the MPL ink results in a higher contact angle; this is likely due to the horizontal stacking of the graphene nanoplates perpendicular to the water droplet. G0 has the lowest hydrophobicity with (145˚), although these values are not dissimilar and indicate that the determining factor in hydrophobicity is likely the PTFE (20 wt. %). The through-plane permeability decreases with graphene inclusion in the MPL; the graphene nanoplates lead to a greater resistance to air flow, this increase in resistance can be attributed to the morphology of the graphene flakes; their 2-dimenisonal geometry lends to dense, horizontal stacking of the graphene flakes in the MPL, which forms a sheet-like structure obstructing air flow in the through-plane direction. Similar findings are reported in [10].

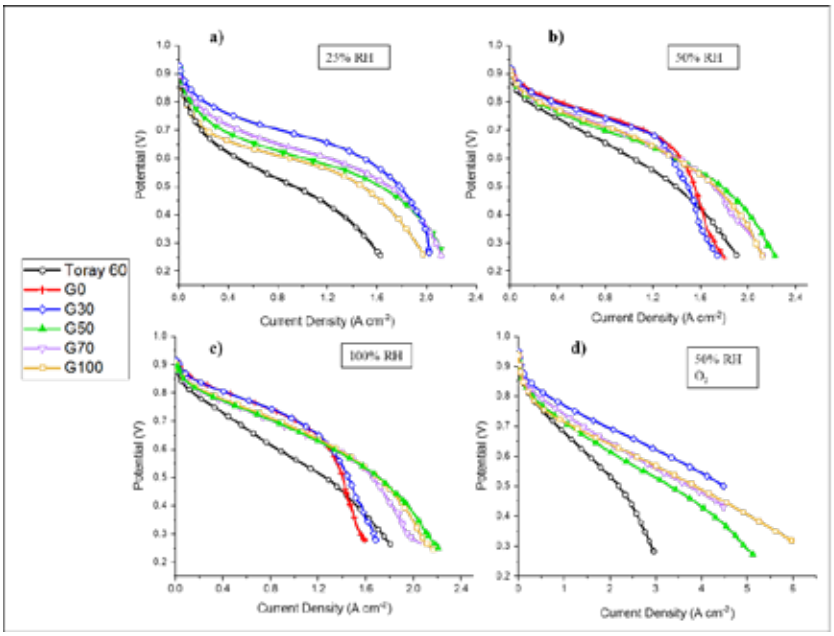

Figure 3: Polarisation curves of the MPL coated and uncoated GDLs at (a-c) 25%, 50%, and 100% relative humidity in air, and (d) 50% relative humidity in pure oxygen.

Polarisation curves were taken at 25%, 50% and 100% relative humidity in air, and 50% relative humidity in pure oxygen (Figs. 3a, b, c and d), at a constant cell temperature of 80°C. Fig 3a shows the polarisation curve of the GDLs at 25% relative humidity operation, where G30 MPL outperforms all the other MPLs. Under low humidity operating conditions, the ohmic losses caused by the membrane dry-out is the prevailing factor behind the degradation of the fuel cell. The high performance exhibited by G30 indicates that it is better than the other MPLs at retaining liquid water and preventing membrane dry-out. This is attributed to the larger proportion of micropores present in the G0 and G30 MPL that favour liquid water retention.

However, at 50% RH (fig 3b) G30 and the commercial G0 MPL start to experience significant potential drops at relatively high current density (> 1.2 A cm^{-2}). This is due to the inability of the above MPLs to reject excess liquid water produced at the cathode catalyst layer. This trend continues at 75% and 100% RH operation, where liquid water is more prevalent, thus it is clear that these performance losses are due to the inability of G0 and G30 to sufficiently divert liquid water away from the cathode catalyst layer. Larger inclusions of graphene in the MPL composition produce a higher limiting current density and greater power density in more humidified conditions (50%, 75% and 100% RH). Figs. 3b, c and d indicate that G50, G70 and G100 do not suffer the same potential drops that G0 and G30 experience in these conditions. It can be concluded that, under intermediate or high humidity conditions, the addition of 50% or above of GNP to the MPL has a positive impact on the fuel cell performance as evidenced from the lower mass transport losses and the increased limiting current density of the fuel cell.

CONCLUSIONS

Microporous layers were produced from graphene and carbon black, and a combination of the two materials in which the weight percentage of graphene was varied (0 %, 30%, 50%, 70% and 100%). The inclusion of graphene in the MPL was shown to increase the mean pore size, leading to the formation of mesopores in the layer. Polarisation curves were taken at different relative humidity operation. Inclusions of graphene at 50 wt. % and greater enhance fuel cell performance at higher relative humidity operation (50%, 75% and 100% RH), indicating that the addition of graphene in the microporous layer mitigates flooding and reduces mass transport losses.

ABSTRACT

In the field of metallic bipolar plates for PEMFCs, since coating technology can achieve improved resistance and surface properties without changing the base material, numerous studies have been conducted. The cost of the vacuum coating process and corrosion resistance and electrical conductivity of the coating materials are still under discussion. In order to improve the corrosion resistance of metallic bipolar plates, we select materials and technologies that are in the spotlight at ATF and conduct convergence research. The 3D laser cladding method was applied to the base material as metallic bipolar plate and the CrAl binary alloy was coated to evaluate its performance.

Keywords: PEMFC, Bipolar Plates, Corrosion, 3D Laser Cladding, Coatings

INTRODUCTION

The proton exchange membrane fuel cells (PEMFCs) directly convert chemical energy into electrical energy, so the conversion efficiency is high, and the by-products after the reaction are clean and reliable power is produced [6]. The bipolar plate is one of the key components because it supplies and cuts off fuel and air to each pole, exhausts the reaction products from the cell, and exchanges heat generated in the electrochemical reaction. However, metallic bipolar plates, the surface is corroded in the fuel cell environment in an acidic environment, and metal ions are eluted, which contaminates the catalyst and membrane, thereby reducing PEMFC performance [2],[3]. On the other hand, 3D laser coating technology using CrAl alloy powder is considered and have been developed to enhance the oxidation resistance as accident tolerant fuel (ATF) under loss of coolant accident (LOCA) conditions [4],[5],[6]. This technology has the characteristics of forming a local molten area to minimize the heat-affected zone and to minimize deformation and damage of the base material. It is also evaluated as an efficient and economical protective coating technology compared to the vacuum coating process [5],[6],[7]. In addition, it has been reported that CrAl alloy coating was very effective in enhancing the oxidation resistance of metals at high temperatures [8]. Since Cr_2O_3 and Al_2O_3 can form on the surface of CrAl, so the possibility of further increasing oxidation resistance has been confirmed. [4],[6]. In this study, nuclear convergence technology and materials were implemented and evaluated to solve the corrosion problem of metallic bipolar plates.

COATING METHODS

The selection of the coating materials was based on the physical properties such as thermal conductivity and expansion, melting points and phase transformation behavior. For plate-shaped substrates, laser cladding parameters such as laser power, specimen velocity, powder injection and gas flow have been systematically discussed in previous studies [4],[5],[6]. The continuous wave (CW) diode laser (wavelength of 1062 nm) with a maximum power of 300 W (PF-1500F) and a power supply (Pwp14Y04K). The continuous wave (CW) laser (wavelength of 1062 nm) was applied with power ranged 80 to 250 W (PF-1500F), and the scanning speed ranged was adjusted 12 to 15 mm/s for the surface coating on stainless steels 316L (SS316L). To prevent any oxidation during the process, an inert gas (Ar) was continuously blowing into the melted surface of specimen. SS316L Bare plates were cut to a size of 60 mm × 60 mm × 0.1 mm. The substrates were molded using etching techniques. The CrAl coatings were deposited on the SS316L Bipolar plate using 3D Laser cladding coating method with CrAl powder (0.85Cr-0.15Al) and cleaned sonically in ethanol and acetone solution.

CORROSION TESTS

In the case of PEMFC system, it operates in the operating temperature range of 80–120 °C and the hydrogen ion concentration in the range of 2–4. In addition, a wet fuel injection environment promotes corrosion of the metal bipolar plates [6],[8]. Damage to the passivation film occurs due to various causes such as temperature, humidity, and pH, and eventually, ionic dissolution of the base material is derived. In response, potentiodynamic polarization test was conducted to confirm the corrosion behavior of bare SS316L and CrAl coated substrates in a sulfuric acid environment

in the PEMFC environment was simulated ex-situ conditions (0.5 M H_2SO_4, 80℃) [1],[8]. Potentiodynamic polarization is a method to test the corrosion reaction of fuel cell bipolar plates using the LSV technique. Measuring the current value in operating voltage range of the fuel cell, it is possible to know the active and the passivation region. The electrochemical process of corrosion potential and passivation behavior is determined by the Butler-Volmer equation and the Tafel plot. The Butler-Volmer equation is expressed for a current that varies with an applied voltage when the overall reaction rate is governed by the charge transfer process [1],[9].

$$I = I_0 \left[exp\left(\frac{-\alpha F\eta}{RT}\right) - exp\left(\frac{(1-\alpha)F\eta}{RT}\right)\right] \quad (1)$$

I : Electrode current density

α : Charge transfer coefficient

F : Faraday constant

H : Activation over potential (defined as $E–E_{eq}$)

R : universal gas constant

T : absolute temperature

RESULTS AND DISCUSSION

Fig 1. (a),(c) are the SEM images of the CrAl coated SS316L by 3D Laser cladding method. The coating layer appears 2.5 ㎛ thickness and no crack and void are observed on the surface. For a more detailed study of the coating layer, (b) and (c) confirmed the EDS profiles from the base substrate to the coating layer.These results indicate that the CrAl coating is composed of two compositions, Cr and Al, without elution of the base material on the surface. Moreover, in Fig 2, the XRD results of the surface can prove that there are no defects in the coating. Only Cr and CrAl components are detected on the surface. Aluminum is not identified here because the CrAl alloy is a Cr-based solid solution structure.

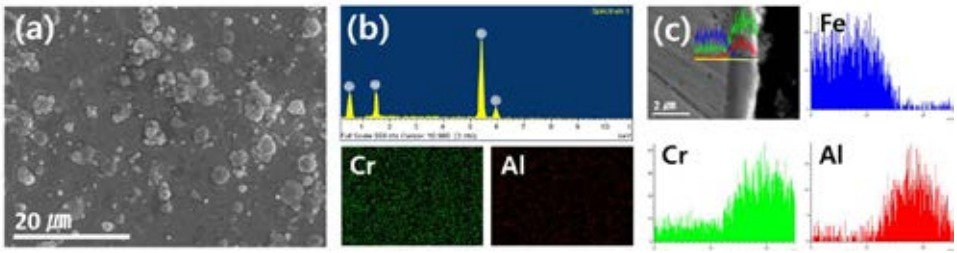

Fig 1. (a),(b) SEM image and EDS analysis of surface and (c) cross-sectional area

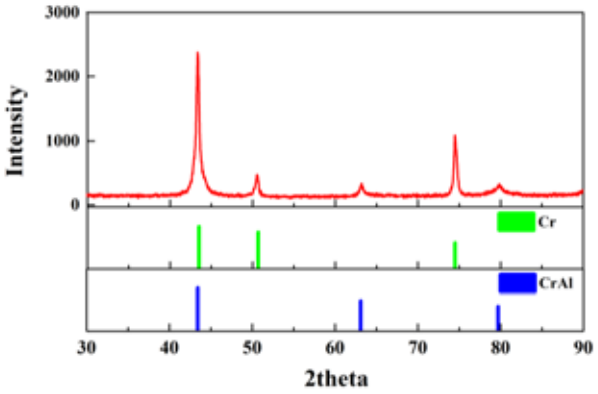

Fig 2. Surface XRD analysis of CrAl coated specimen

Potentiodynamic polarization curves of Bare SS316L (uncoated SS316L), CrAl on SS316L in the simulated acidic environment are shown in Fig 3. The corrosion behaviors of specimens are confirmed through the current value generated on the metal surface, and the potential at which the anode and cathode current become equal is expressed as the corrosion potential (E_{corr}). The corrosion potential means a potential value at which corrosion starts after the surface passivation film is formed. That is, the smaller the corrosion potential value, the greater the oxidation

tendency. the current density (I_{corr}) is larger, which means that the electron transfer due to the elution of ions is activated, which means that more corrosion occurs. In the LSV results, the corrosion potential value of the CrAl coated specimen was higher than that of stainless steel and the corrosion current was lower. These results showed that the CrAl coating had a positive effect on the corrosion inhibition properties compared to SS316L.

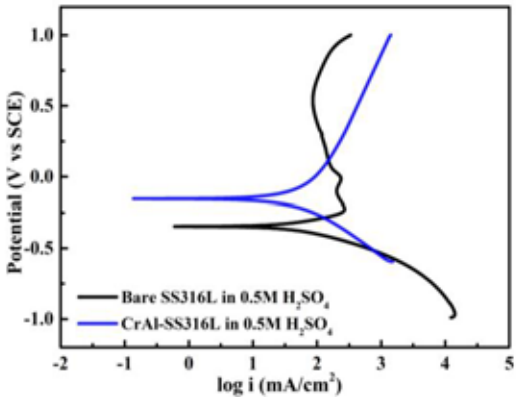

Fig 3. Polarization curves of bare SS316L and CrAl coated SS316L in 0.5 M H_2SO_4 solution at 80℃

CONCLUSIONS

3D Laser cladding coating technique is applied to CrAl on the surface of metal bipolar plates. The CrAl film as a protecting layer was successfully deposited on the SS316L bare substrate and uniform microstructure by laser cladding system. Moreover, In PEMFC acidic environment, CrAl coated SS316L was excellent high corrosion durability compared SS316L, which will form the basis for the electrochemical thin film process of the next generation of the bipolar plates for Fuel Cells. In this study, we demonstrated that ATF coating materials and coating Convergence techniques can also be applied in the fuel cell future industry. Especially, these studies could be open pathways to widely applied as bipolar plate and interconnector materials for fuel cells.

ABSTRACT

In view of the rapid depletion of fossil fuel sources and growing concerns on adverse environmental effects; including ozone depletion, global warming, sea-level rise and air-quality degradation. In last decade, there has been great endeavors to search for viable alternate energy resources. Fuel cells have shown great potential for energy production application because of their short start up time, low temperature operation and most importantly very little environmental cost of use. The present paper discusses the viability of using Organic Rankine Cycle (ORC) for waste heat recovery from Proton Exchange Membrane Fuel Cells (PEMFCs) is investigated. PEMFC and ORC system is modelled in Matlab® Simulink®. Thermodynamic property data of the working fluid is imported though Cool-Prop Python library. As the working fluid, suitability of multiple zeotropic mixtures is assessed. Finally, first law and second law thermodynamic analysis of the system is carried out. The developed ORC waste heat recovery system increased the overall power output of the system by 5.46 percent.

Keywords: PEMFC, Zeotropic, Matlab

INTRODUCTION

Polymer Electrolyte Membrane Fuel Cell (PEMFC) also called as Proto Exchange Membrane Fuel Cell (PMFC) are those fuel cells which were developed for the vehicles, and for the immobile fuel cell applications and transferable fuel cell applications. The thing that separate them from other cells are their low operating temperature and pressure and a specially made polymer electrolyte for the conduction of protons [1]. This technology will soon replace the old, alkaline type, batteries for the space shuttle application. These cells are clean energy as they have no impact on the environment. The wastage from these cells are water which is not harmful to the environment. Due to their high energy density these cells are now getting more and more sophisticated.

PMFC's are made of Built Electrode Assemblies also known as BEA which is composed of the electrolyte as medium for reaction, electrode (conductive material), catalyst to speed up the reaction and a diffused layer of gas. Catalyst, electrode and carbon are sprinkled or painted in the form of ink on to the solid electrolyte [2]. The hot pressing of the carbon paper is done on the inside to protect it and also to be used as an electrode. The TPB also known as the Triple Phase Boundary is a pivotal part, where all the part like catalyst, electrolyte and reactant mixes and thus the reaction starts [3]. The membrane of the cell should not be electrically conductive so that the half-cell reactions do not get mixed. The temperature of above 100 °C is desired, this to evaporate the water and management gets less critical.

SELECTION OF ZEOTROPIC MIXTURE

While selecting optimum zeotropic mixtures, not only thermodynamic properties are taken into account but the impact that they are going to inflict on environment is also considered. Some zeotropic mixture was befitting from the thermodynamic however they were rejected due to their hostile effect on environment. For thermodynamic viability, factor such as critical pressure and temperature were considered and for the environmental impact factors such as Global Warming Potential (GWP), toxicity, flammability and Ozone Depletion Potential (ODP) were taken into account. All the zeotropic mixtures were found to be non-flammable and nontoxic. [4].
The maximum temperature of the mixture on the turbine inlet is estimated around 343 K and pressure is estimated to be 3.0 MPa, therefore it is necessary to select those mixtures which fulfills this thermodynamic requirement because if the critical temperature of mixture is too high then it may not get become superheated. And further more compliance to the environmental safety standards is also considered necessary for selection. R-422 A and R-422 D were rejected due to their high GWP value. R-401 A was rejected due to its high ODP value. R-404 A was rejected due to its low critical temperature. A draw in terms of thermodynamic property is reached between R-407 C and 417 -A, but since 417-A had higher GWP value therefore final refrigerant selected is R-407C. Comparison summary is presented in Table 1.

Table 1 : Thermodynamic property and Environmental data of mixtures are shown.

Refrigerant	Critical temperature /K	Critical Pressure/MPa	Global Warming Potential (GWP)	Ozone Depletion Potential (ODP)
R 422 A	344	3.75	3144	0
R 404 A	345	4.9	2088	0
R 407 C	359	4.6	1774	0
R 417 A	361	4.03	2350	0
R 422 D	352.73	3.9	2730	0
R 401 A	380.4	4.6	1182	0.033

CONCLUSIONS

The use of Organic Rankine Cycle for waste heat recovery in PEMFCs is investigates in this paper. Models for the PEMFC and the Organic Rankine cycle were developed on Simulink and the performance of the system is studied under various input current values to the fuel cell.
As working fluid, zeotropic fluid R407C is used. The properties of the fluid at various stages of the cycle were calculated by implementing the Python Library of Cool Prop in MATLAB. The developed ORC waste heat recovery system increased the overall power output of the system by 5.46%.

NUMERICAL INVESTIGATION ON THE EFFECTS OF INHOMOGENEOUS GAS DIFFUSION LAYER AND IMPACT OF INTERFACIAL CONTACT RESISTANCE ON PERFORMANCE OF POLYMER ELECTROLYTE FUEL CELLS

ABSTRACT

A three-dimensional single-channel is modeled numerically to simulate homogeneous and inhomogeneous gas diffusion layer (GDL). The effect of interfacial contact resistance (ICR) between flow field ribs and GDL is also studied. The present study involves GDL being considered as a single component (homogeneous) in one case while in another case, GDL being considered with varying porosities to depict the inhomogeneity. The inhomogeneity in GDL is assumed to occur due to localized deformation induced due to non-uniform contact pressure. The study reveals increased availability of reactants at higher current loads in the case where ICR is assumed negligible. This study explains how the presence and absence of ICR impact reaction concentrations, water concentration, current density and polarization curve of polymer electrolyte fuel cells. It is observed in polarization curve that the presence of ICR has effect both in ohmic and mass transport region. This work involves considering 4 cases viz: homogeneous GDL, inhomogeneous GDL, homogeneous GDL with ICR and inhomogeneous GDL with ICR.

Keywords: PEM Fuel Cell, Gas Diffusion Layer, Interfacial Contact Resistance, Porosity, Cell Performance.

INTRODUCTION

Among the several components in PEMFC, gas diffusion layer (GDL) is a crucial component which facilitates the transportation of reactant gases and water and supports the catalyst layer (CL). It also provides electronic contact with the flow fields in fuel cells [1,2]. The behaviour of gas diffusion layer is known to change based on various physical properties like interfacial contact resistance (ICR) with flow field ribs, permeability, porosity and bulk resistance [3–6]. It is observed that inhomogeneous GDL has localized variations on these properties, impacting the performance of PEMFC. The GDL is a porous material and it often undergoes high compression during assembly, leading to variation in material and geometrical properties.

Various studies have been carried out on the transport behaviour and performance of PEM fuel cells [7–10]. However, it is observed that limited studies have been carried out while considering transport behaviour when taking the interfacial contact resistance into effect. The ohmic losses occurring due to interfacial contact resistance between GDL and the flow field plays a significant role in fuel cell performance. To this end, the numerical study by Chen et al. [11] showed the impact of interface contact resistance on a three-dimensional, single-cell, single serpentine flow channel fuel cell model. It is revealed that with the increase of ICR the polarization curves affects both the ohmic and concentration region at lower voltages. Li et al. [12] numerically investigated a two-dimensional, two-phase flow fuel cell model considering the effect of electrical contact resistance. They observed that cell performance significantly decreased when interfacial contact resistance was considered. Hence it is observed that ICR does impact on the performance and various properties in fuel cell. Thus it is necessary to consider ICR effect while conducting numerical investigation on PEMFC.

Studies related to homogeneous and inhomogeneous GDL occurring majorly during assembly operation have been carried out earlier. Wang et al. [9] developed 3D numerical model of PEM fuel cell considering inhomogeneous compression effects of GDL. The results revealed that higher compression is helpful in heat removal but reduces cell performance in contrast. Hence, it becomes evident to have optimum compression that can improve fuel cell performance. Padavu et al. [13] studied the transport behaviour of depth-dependent flow channels considering GDL as inhomogeneous. They illustrated that inhomogeneous GDL has slight reduction in performance of fuel cell compared to homogeneous GDL. This behaviour is predicted to occur due to improved hydrogen oxidation reaction and reduced oxygen reduction reaction in inhomogeneous GDL case. Jha et al. [8] studied the effect of varying GDL porosity of fuel cells, considering it to be as inhomogeneous GDL. Their results revealed that GDL with porosity of 0.5-0.6 provides better performance, while it is seen to reduce at higher current densities when porosity exceeds 0.6

Based on the aforementioned brief literature, numerical studies on transport characteristics and fuel cell performance have been investigated, with GDL considered as either homogeneous or inhomogeneous. Few other studies considered the impact of ICR in their numerical investigation. However, the effects of inhomogeneous GDL and ICR

are not considered together in the numerical investigation as observed from the available literature. Hence this study focuses on bridging the gap between the two cases.

NUMERICAL METHODOLOGY

A three-dimensional single channel, multiphase, steady state with homogeneous and inhomogeneous GDL has been considered in the present study. Table 1 lists the various geometrical parameters. The grid size considered along the x direction is 20, in y direction is 55 (through plane), and in z direction (along channel) is 480.

Table 1. Single channel geometrical parameters

Parameter	Value	Parameter	Value
Fuel Cell Length	50 mm	BPP Height	1.5 mm
Fuel Cell Width	2 mm	GDL Thickness	0.3 mm
Flow Channel Width	1 mm	Catalyst Thickness	0.015 mm
Rib Width	1 mm	Membrane Thickness	0.05 mm

The properties for homogeneous and inhomogeneous GDL like porosity, permeability and ICR values have been imported from ref [4]. The governing equations considered in present work are conservation of mass, momentum, species, energy and charge (both ionic and electronic). The present numerical investigation is carried out in ANSYS Fluent (2020 R2). The stoichiometry at anode is 1.5 and cathode is 2. The gas flow inlet at anode and cathode is calculated using the mentioned stoichiometry. Reference current density considered is 1.0 A/cm^2.

RESULTS AND DISCUSSION

The performance of PEMFC with four different cases viz; homogeneous GDL, inhomogeneous GDL, homogeneous GDL with ICR and inhomogeneous GDL with ICR has been depicted in Fig. 1(a) The current densities for all the four cases coincide with each other above 0.65 V cell voltage. It is shown that the current densities at 0.2 V for homogeneous GDL is 1.1886 A/cm^2, inhomogeneous GDL is 1.1637 A/cm^2, homogeneous GDL with ICR is 1.1725 A/cm^2 and inhomogeneous GDL with ICR is 1.1551 A/cm^2.

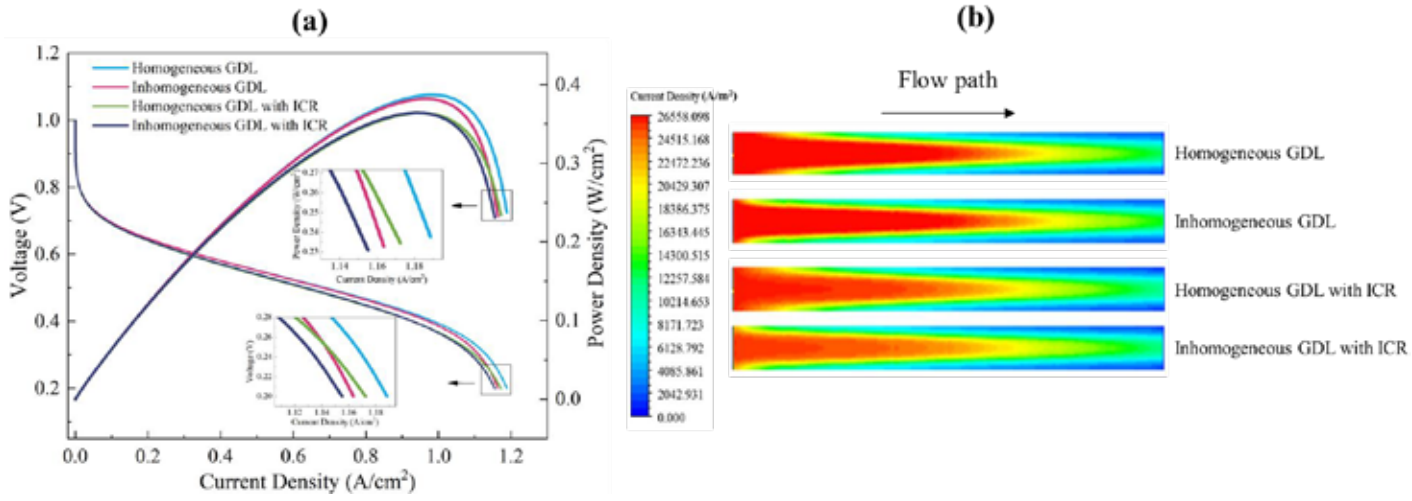

Fig. 1. (a) Cell performance of PEMFC at different cases, (b) Local current density at mid-section of membrane.

Similarly, power density at 0.2 V cell voltage for homogeneous GDL is 0.2377 W/cm^2, inhomogeneous GDL is 0.2327 W/cm^2, homogeneous GDL with ICR is 0.2345 W/cm^2 and inhomogeneous GDL with ICR is 0.2310 W/cm^2. Hence it is observed that the homogeneous GDL without ICR has maximum current density and power density. Whereas, inhomogeneous GDL with ICR has minimum current and power densities. The difference between considering ICR and absence of ICR is clearly visible in ohmic loss region and concentration loss region.

Results with respect to distribution of hydrogen mass fraction at anode, oxygen mass fraction at cathode, water mass fraction at cathode and current density at membrane show similar behavior (for reference local current density distribution is as shown in Fig. 1(b)). That is homogeneous GDL without ICR yields higher concentration of these species while inhomogeneous GDL with ICR yields lower. Therefore, it can be said that investigating transport

behaviour without ICR numerically is not the correct approach which can be considered as ideal case. In reality investigating with the effects of ICR and inhomogeneous GDL yields the correct results.

CONCLUSIONS

In this study, the impact of interfacial contact resistance with homogeneous and inhomogeneous GDL is investigated numerically. It involves investigating three-dimensional, steady state, multiphase, single flow channel transport behaviour. A PEFC with homogeneous without ICR provides best performance while PEFC with inhomogeneous with ICR results lower performance. Literature studies show that most of the numerical investigation are carried without considering ICR which is not the ideal approach since fuel cell performance is affected by resistance. Hence it is evident to consider ICR effects which helps in predicting realistic PEFC performance.

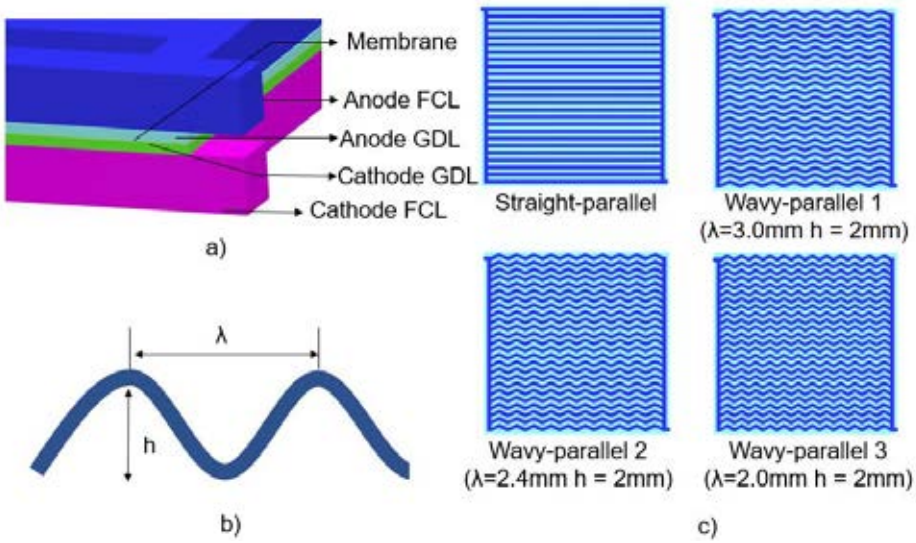
ABSTRACT

Polymer electrolyte membrane fuel cell (PEMFC) is one of the emerging fuel sources which have the potential to replace the conventional fossil fuels continuously endangering the earths climate system. The purpose of this paper is to evaluate the performance and the reliability of PEMFCs with straight channel in comparison to three wavy channels in the basis of polarization curve, pressure drop and velocity on cathode channel. The higher pressure drop of wavy channels facilitates the water removal and improve the cell efficiency. Eventually the wavy channel with short wavelengths showed the best performance.

Keywords: Fuel Cell, Flow Channel, Wavelength, Pressure Drop, Water Accumulation.

INTRODUCTION

The performance of the PEMFCs mostly depends on the design of the flow channels as it determines the supply of adequate amount of oxygen and hydrogen on the diffusion layers while keeping the back pressures as low as possible for both flow channels for the sake of cell efficiency [1]. There exist a number of experiments [2-4] and simulations [5,6] to investigate the effect of flow field using various channel designs. Anyanwu et al. [2] compared the performance of a serpentine, interdigitated, parallel with straight and 2 wavy channels under different relative humidity and found that the high relative humidity enhanced the cell performance while wavy parallel channels showed the best performance considering pressure drop, cell performance and structural integrity. Cooper et al. [3] changed the dimensions of flow channel for an interdigitated and a parallel flow in order to obtain a design guideline for both configurations using statistical analysis. The effect of flow channel on water flooding and hydrodynamics also investigated experimentally [4], where serpentine flow channel showed more stable cell performance, less water accumulation and high pressure drop compared to an interdigitated and a parallel flow channel. The numerical analysis carried out by Atyabi et al. [5] showed that the higher-pressure drops lead to more uniform distribution of oxygen and better water management for wavy flow channel in comparison to straight parallel channel which results in high power densities. In the present study, as shown in Fig. 1, the flow characteristics and performance are investigated and compared for the PEMFCs with 1 straight channel and 3 wavy channels with different wave lengths, in terms of the cell performance, pressure drop and velocity of gas.



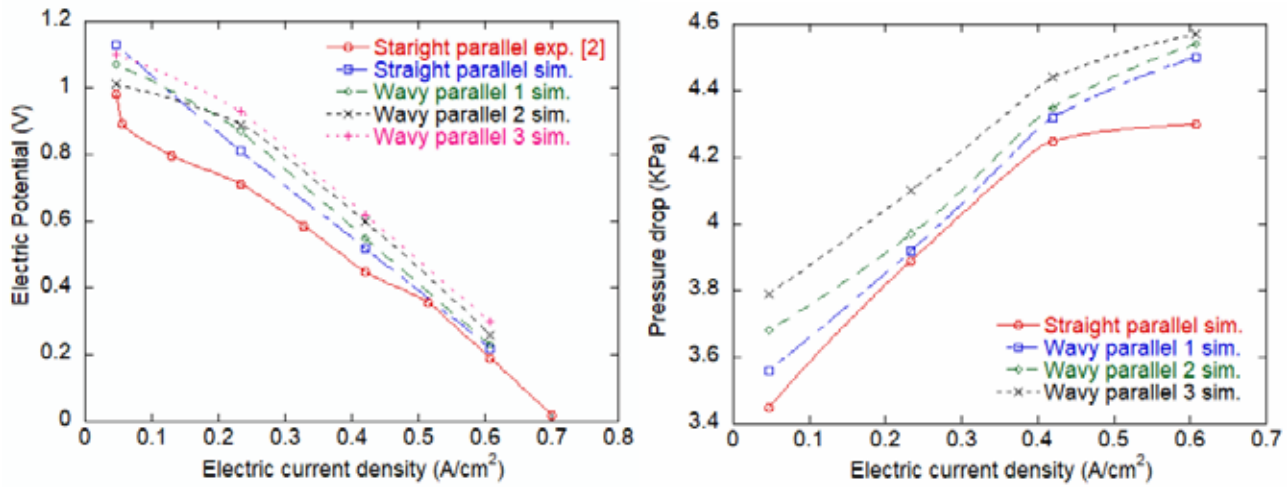


Fig. 1. a) Schematic view of PEMFC, b) parameters of wavy channel and c) front view of 1 straight and 3 wavy channels.

GEOMETRY AND MODEL IMPLEMENTATION

Fig. 1(a) shows the schematic view of PEMFC with parallel or sinusoidal flow field including gas flow channel layers (FCLs), gas diffusion layers (GDLs) and membrane, in which the area of the fuel cell is 25cm^2 (5cm×5cm) and channel dimension is 1 mm x 1mm. And (b) and (c) illustrate the parameters of sinusoidal wavy channel and the front view of 1 straight and 3 wavy channels, respectively. A mixture multiphase model of steady and laminar flow, which can solve simultaneously electrochemical reaction and heat transfer, was employed for gas flow channel and porous diffusion layers while solid membrane with ionic transport was considered in the membrane part. SIMCENTER STAR-CCM+ 16.04 was used for 3-D modeling and simulation of PEMFCs. A structured and directed mesh was generated (quadrilateral for straight channel and polygonal mesh for wavy channel). Catalyst layers were assumed as an infinite thin layer and not included in the mesh system, as suggested in previous research [7]. The relative humidity of the fuel cell was set to be maintained at 40%, and accordingly the mole fraction of hydrogen, oxygen, nitrogen and water vapor were reflected in the simulation conditions.

RESULTS AND DISCUSSION

a) b)

Fig. 2. a) Polarization curve and b) pressure drop at cathode channel at different current densities

The polarization curve along the electric current density for four different shapes of flow channel as shown in Fig. 2(a), where only the case of straight channel is validated through comparison with the experiment [2]. Although the overall trend of the slope looks similar to the experiment, the overestimation of the electric potential related to lack of bipolar plate seems to be made in the present simulation. Regardless of the higher conductivity, it has been observed that bipolar plates tend to decrease the potential of the entire cell by increasing ohmic losses. The case of wavy parallel 3 indicates the best performance among the flow channels. Fig. 2(b) shows the pressure drop on the cathode flow channel for different current densities. The pressure drop contributes the enhancement of cell performance by increasing the convective flow and removing the resultant water efficiently [2, 5]. It is understood that the pressure drop increases as the wavelengths decreases, and thus the velocity of gas also becomes high as shown in Fig.3. Therefore, it is seen that the diffusion through GDL is higher for wavy channels with short wavelength [5].

CONCLUSIONS

In this study, 4 different flow fields (1 straight and 3 wavy) in the channel of PEMFC were investigated using CFD simulation. The numerical result for the straight parallel channel was validated with the experiment. The wavier channel (wavy channel 3) showed the overall best performance while conventional straight channel acted as the worst candidate for large fuel cell stacks. The adequate pressure drops and relatively high velocity helps the wavier flow channel to increase the reaction rate and avoid water flooding inside the channel.

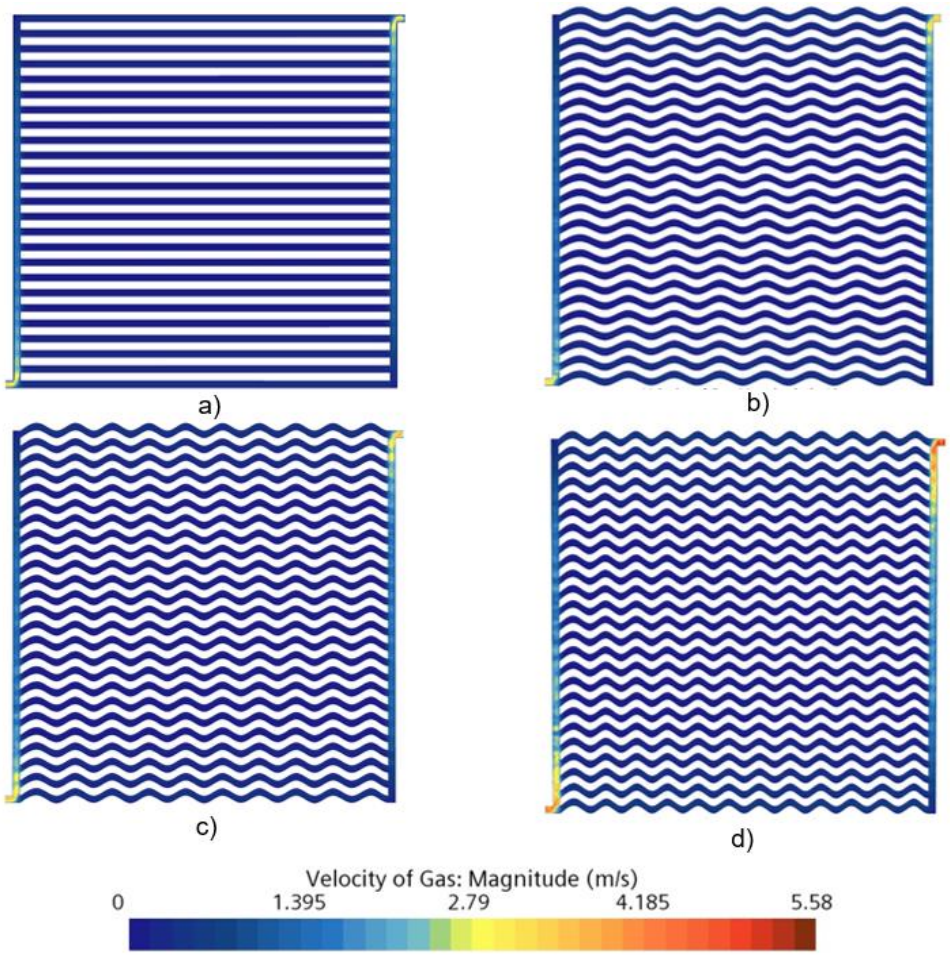

Fig. 3. a) Velocity distribution along the cathode channel for a) straight parallel, b) wavy parallel 1, c) wavy parallel 2 and d) wavy parallel 3

ABSTRACT

Flooding is one of the major issues in polymer electrolyte fuel cells (PEFCs), especially under high current density operation. Therefore, gas diffusion layers (GDLs) coated with hydrophobic microporous layers (MPLs) are usually employed to decrease water saturation at the cathode side of the cell. In this study, fluorinated carbon powders are synthesized to create superhydrophobic microporous layers to facilitate water management and prevent flooding. Fluorinated carbons are synthesized by a solvothermal method and characterized by various technics techniques. Then, either fluorinated carbon or commercially available carbon black are formed into a slurry and screen printed onto a commercial GDL to form MPLs. These MPLs are then characterized by water contact angle measurements, air permeability tests, and oxygen transport resistance measurement. Furthermore, their performance in a PEFC is evaluated using I-V measurements in a PEFC under various conditions. The results indicate that fluorinated carbon based MPLs are superhydrophobic, leading to lower oxygen transport resistance and significantly higher fuel cell efficiency compared to conventional carbon black.

Keywords: PEFC, Microporous Layer, Fluorinated Carbon Powder, Superhydrophobicity

INTRODUCTION

Polymer electrolyte fuel cell systems (PEFCs) running on hydrogen are one of the most promising clean energy conversion technologies for a carbon-neutral society. Gas diffusion layers (GDLs) are employed at both electrodes to transport reaction gases and remove the products. At the cathode side of the PEFC, under the high current density operation, excessive water accumulation inside of the gas diffusion media hinders the transportation of oxygen to the catalyst layer [1,2]. This phenomenon decreases the PEFC performance significantly. To overcome this, GDLs are usually coated with a hydrophobic microporous layer (MPL) comprising carbon black and a polytetrafluoroethylene (PTFE) binder [3,4]. However, the use of PTFE can negatively impact the conductivity and gas diffusion properties of the MPL. In this study, we synthesize superhydrophobic fluorinated carbon (SHFC) as an alternative MPL material with a view to improve the water-repelling properties of the MPL.

EXPERIMENTAL

Superhydrophobic fluorinated carbon powder was synthesized by reacting fluorinated alcohol with sodium metal at elevated temperature in a sealed PTFE crucible [5]. After the reaction, the product was already carbonized. The product powder was washed in an ethanol / water mixture for 24 hours. The product was then vacuum-filtered and dried at 65°C. The yield was ~20%. Superhydrophobic fluorinated carbon was characterized by X-ray photoelectron spectroscopy (XPS, PHI 5000 Versa probe (II) ULVAC) to prove fluorination of carbon and morphologic structure of carbon was observed by scanning electron microscopy (FE-SEM, JSM-7900F). Furthermore, thermal stability of SHFC was analyzed by thermogravimetric analysis (Rigaku Thermo plus EVO2 TG8121) under the air

RESULTS AND DISCUSSION

Fig 1. shows a scanning electron microscopy (SEM) image of the fluorinated carbon. The morphology comprises spheroidal nanostructures with an average particle size of around 100 µm.

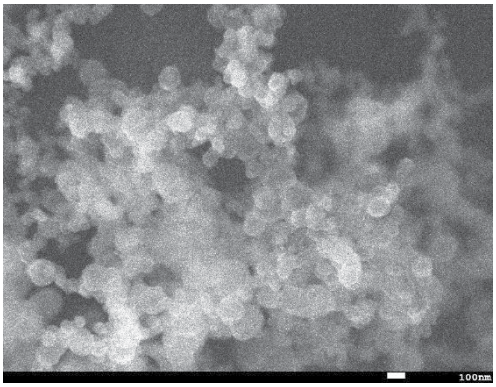

Fig. 1. SEM images of superhydrophobic fluorinated carbon

X-ray photoelectron spectroscopy (XPS) revealed an atomic concentration of ~89 at% carbon, ~10 at% fluorine, and ~1 at% oxygen, with trace amounts of sodium contamination. XPS also indicated that the fluorine atoms are mainly covalently bonded to carbon. Energy dispersive X-ray analysis (EDX) revealed lower fluorine content (2 at%) compared to XPS, suggesting that fluorination occurs mainly near the surface of the particles. X-ray diffraction (XRD) showed that SHFC is largely non-crystalline. From the XRD, EDX and TEM results, it is concluded that small amounts of sodium fluoride are trapped in the structure of the SHFC, which could not be removed by extensive washing in water and ethanol.

The synthesized SHFC powder was then coated onto a GDL substrate and employed as an MPL material, using PTFE as a binder. Water contact angle measurement results revealed that superhydrophobic fluorinated carbon based MPL has a water contact angle of around 151° while the identically prepared carbon black based MPL has a water contact angle of 130°.

Single fuel cell performance tests were conducted at 100% relative humidity conditions and two different cell temperatures (45° and 80°) (Fig.2). Compared to carbon black, the SHFC-based MPLs showed significantly higher I-V performance in the high current density region, suggesting improved water management due to the hydrophobic nature of the MPL material.

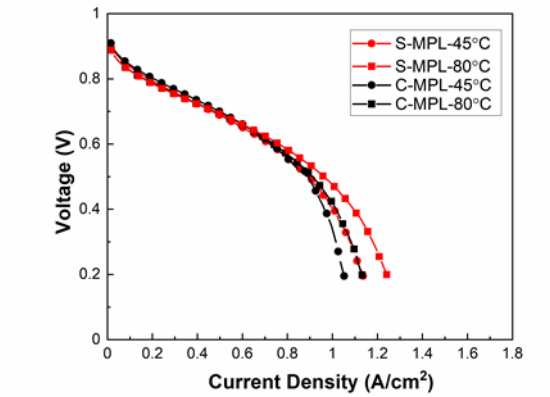

Fig.2. Single fuel cell performance test results of superhydrophobic fluorinated carbon (S-MPL) and conventional carbon black based MPL (C-MPL)

CONCLUSIONS

In this paper, fluorinated carbon was synthesized with a solvothermal method and used as MPL material to create superhydrophobic MPL with low PTFE loading. Its performance was evaluated and compared with conventional carbon black based MPL. Results indicate that it is possible to increase the hydrophobicity of the MPL by employing fluorinated carbons as an MPL material. Superhydrophobic fluorinated carbon based MPL with 5 wt% PTFE binder shows a much higher hydrophobicity than conventional carbon black based MPL. Due to the superhydrophobicity of superhydrophobic fluorinated carbon based MPL, its water-repellent characteristic increased significantly, which has led to higher fuel cell performance under high relative humidity conditions.

ABSTRACT

Liquid water flooding in low-temperature proton exchange membrane fuel cells (LT-PEMFCs) is one of the key issues, significantly reducing its performance. This study investigates the impact of water flooding on the reactant transport across the porous domain, active surface area of the catalyst layer (CL), and membrane water content. The main objective of this work is to estimate the LT-PEMFC performance in the mass transport region using a 3-D, multiphase, non-isothermal, physics-based model. The model is validated using the data obtained from experiments performed on a 32 cm^2 area LT-PEMFC with the hybrid flow configuration. The results show that the multiphase model with a root mean square current density error of 39 mA/cm^2 is in good agreement with the experimental results compared to the single-phase model with an RMS current density error of 60 mA/cm^2. The substantial drop in O_2 mass fraction from 0.95 at the flow channels to 0.14 at the CL at 0.4 V cell potential indicates a reduction in reactant transport due to the liquid water. On the other hand, water generation helps to improve water content inside the membrane, which increases the membrane's ionic conductivity from 1.5 to 5.3 S/m with a decrease in cell potential.

Keywords: Low-Temperature Proton Exchange Membrane Fuel Cell, 3-D Physics-Based Model, Multiphase Flow, COMSOL Multiphysics

INTRODUCTION

Low-temperature proton exchange membrane fuel cells (LT-PEMFCs) have emerged as a clean energy solution in the transportation sector and as backup power generators in deep space missions. For higher current density operations, the mass transport limitation is one of the major hurdles in the LT-PEMFC performance enhancement. It arises from the liquid water generated during the electrochemical reactions, which hinders the reaction sites of the catalyst layer (CL) and oxygen transport in the gas diffusion layer (GDL) [1]. The liquid water flooding may accelerate the degradation of the membrane electrode assembly (MEA) due to the hydrophobic material loss and platinum dissociation [2]. Though 1-D [3] and 2-D [4] models are quite simplified and quick, they are not useful for understanding water dynamics inside the cell while altering the flow configurations. Meng et al. [5] observed that the single-phase model over-predicts the cell performance by 20% compared to the multiphase single-channel model. However, this performance disparity requires a detailed analysis from the experimental and a detailed modeling perspective. In most of the studies, the full-fledged multiphase model containing the flow configuration is not studied and validated with the experimental results.

The current study aims at estimating the LT-PEMFC performance in the mass transport region considering multiphase phenomena. Using the governing equations and correlations from the numerical and experimental studies in the literature, we develop a comprehensive 3-D, multiphase, non-isothermal, steady-state physics-based model of the LT-PEMFC that can closely predict the experimental results. A hybrid flow configuration is used for the anode and cathode sides of the LT-PEMFC. The simulations are performed using the COMSOL Multiphysics, and the experiments are conducted on the LT-PEMFC to validate the model. The cell performance is characterized through the polarization curve, concentration profile, and water content across the flow channel, GDL, and CL.

MATHEMATICAL MODEL OF THE LT-PEMFC

The computational domain of the LT-PEMFC is comprised of the membrane, GDL, CL, and flow channels on the cathode and anode sides. The physics-based model is developed coupling the fundamental phenomena such as electrochemical reactions, transport of reactant species, porous media flow, heat generation, liquid water transport, and charge transfer. Fig. 1 shows the computational domain and cross-section of the LT-PEMFC. The total area of the cell is 32 cm^2, with a channel length of 55 mm and a channel width of 1 mm. The thickness of the GDL, CL, and membrane is 0.4 mm, 0.02 mm, and 0.127 mm, respectively. Primary operating parameters used in the experiments and physics-based model are shown in Table 1. The remaining parameters like diffusivity, relative permeability, active surface area, ionomer water diffusion and water drag coefficient are calculated from the liquid water saturation correlations [3, 4].

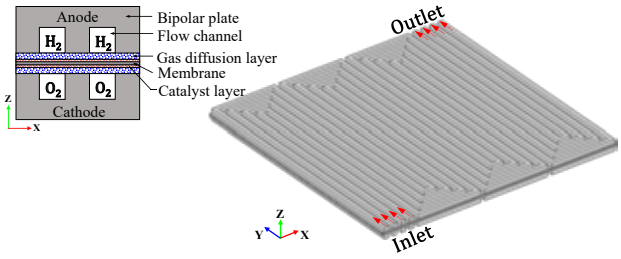

Table 1 Parameters used for the LT-PEMFC model

Parameter	Symbol	Value
Operating temperature, pressure	*T, P*	40[°C], 1[atm]
Relative humidity	*RH*	75 %
Porosity of GDL, CL	ε	0.4, 0.3
Inlet mass flow rate of H_2 and O_2	$\dot{m}$	2, 3 [lpm]

Fig. 1 Computational domain and cross-section of the LT-PEMFC

Governing Equations

For brevity, equations are not included in the text. However, they are described here with relevant references. Porous media flow using the Brinkman equation and gaseous species transport using Fick's law of diffusion are implemented for the GDLs, CLs, and flow channels [3]. The ionic conductivity of the Nafion® membrane is calculated using the power-law with Arrhenius temperature correction [6]. The current conservation equations are used for the ionic and electronic phases with the modified Butler-Volmer equation to obtain the I-V relation and mass transportation losses [4]. The heat transfer in various components of the HT-PEMFC is computed through the energy equation, including the heat generation due to electrochemical reaction and internal resistance. The water transport across the membrane is modeled combining the back diffusion due to concentration gradient and electro-osmotic drag due to potential gradient [3]. Darcy's law with the differential relation between the capillary pressure and saturation is implemented for the liquid water transport inside the cathode [3].

RESULTS AND DISCUSSION

Based on the computational geometry and operating parameters, the actual cell with a hybrid flow configuration is manufactured and assembled in the lab. Fig. 2(a) compares the polarization curve of the present multiphase model, single-phase model, and the experiments. The validation study suggests that the present multiphase model with an RMS current density error of 39 mA/cm^2 estimates the LT-PEMFC performance better than the single-phase model with an RMSE of 60 mA/cm^2. The maximum relative error in the current density is 4% with multiphase model and 12.5% with single-phase model. The results show that the multiphase model closely approximates the mass transport region identified between 0.6 and 0.4 V cell potential. An increment in water content inside the membrane is observed in Fig. 2(b) with a decrease in cell potential due to rapid electrochemical reactions and resultant water generation. The rise in water content enhances the ionic conductivity of the membrane from 1.5 S/m at 1 V to 5.3 S/m at 0.4 V cell potential, lowering the ohmic overpotential of the cell. At the same time, the increased water generation adversely affects the overall cell performance by impeding the reactant transport.

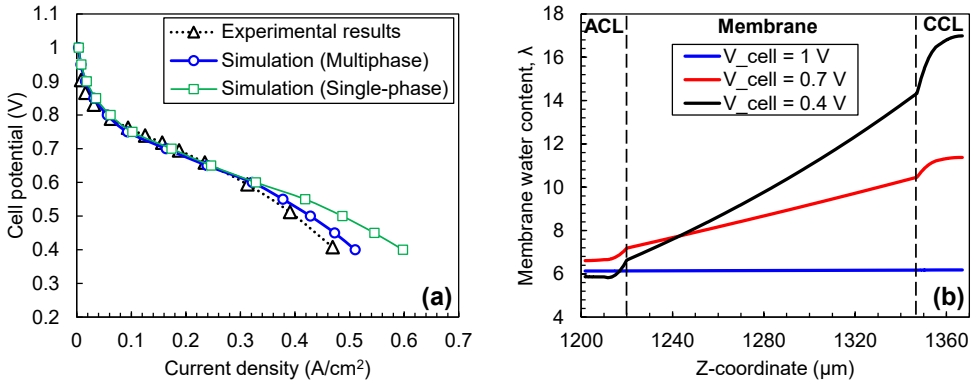

Fig. 2 (a) Validation of the present multiphase model with experimental results (b) Water content across the MEA at different potentials

The O_2 mass fraction and liquid water saturation on the cathode side of the LT-PEMFC are shown in Fig. 3. It is observed that the oxygen mass fraction substantially drops from 0.95 at the flow channels (Fig. 3(a)) to 0.14 at the CL (Fig. 3(b)) at 0.4 V cell potential. At lower cell potential (higher current density), the rapid electrochemical reactions consume a large quantity of oxygen and generate water. Some water moves towards the anode side due to back-diffusion. The remained liquid water floods the porous media and covers the reaction sites of the CL, as shown in

Fig. 3(c), which leads to performance deterioration of the LT-PEMFC. AA' line shows the central portion of the cell at which the water saturation is depicted.

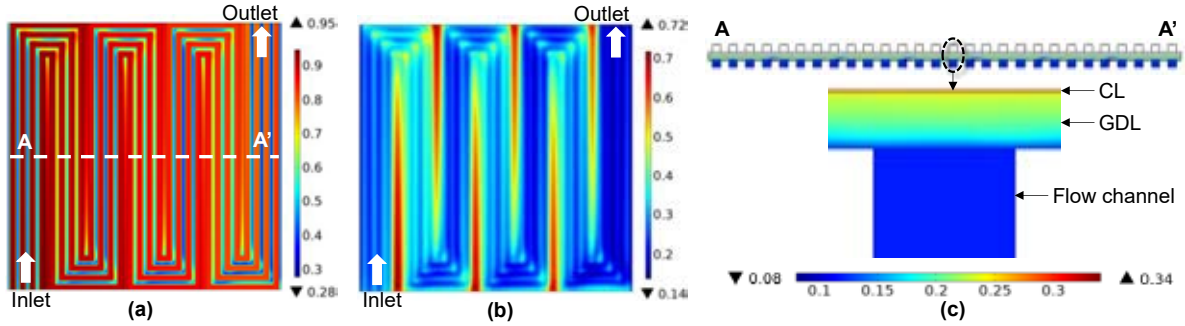

Fig. 3 (a) O_2 mass fraction at the flow channel-GDL interface (b) O_2 mass fraction at the GDL-CL interface (c) liquid water saturation at AA' section for 0.4 V cell potential

CONCLUSIONS

In the present study, a 3-D, non-isothermal, multiphase, steady-state physics-based model of the LT-PEMFC is developed to study the performance in the mass transport region considering the electrochemical reactions, transport phenomena, porous media flow, heat generation, liquid water transport, and charge transfer. The effect of liquid water flooding is analyzed on the crucial parameters like the active surface area of CL, porosity, permeability, water content, and diffusivity of the reactants. The validation study confirms that the present model estimates the LT-PEMFC performance with greater accuracy than the single-phase model. A significant reduction in the O_2 mass fraction from the flow channels (0.95) to the CL (0.14) suggests the liquid water impeding the reactant transport and deteriorating the LT-PEMFC performance. The liquid water can be effectively removed from the cell by implementing different flow configurations, increasing the hydrophobicity of GDL, and raising the operating temperature and reactant flow rate. The findings from this work can be used to design an efficient flow configuration, which enhances the LT-PEMFC performance. The developed model will be used to study the membrane deformation due to the shrinking-swelling under the humidification and thermal cycling and GDL-CL deformation due to clamping force.

ABSTRACT

Porous carbon materials have been more attractive and promising ones since their outstanding properties such as high surface area, accessible active sites, mass transport, diffusion. This study aims to synthesize bio-carbon based catalysts via the microwave method and KOH activation agent. By the reason of the abundant of Peanut shells in Turkey besides being an important agricultural by-product, they were used as a carbon source in this study. The obtained carbon was analyzed by Brunauer - Emmett - Teller (BET), X-ray diffraction (XRD), Raman spectroscopy.

Keywords: Porous Carbon, Electrocatalyst, Biomass, Peanut Shell.

INTRODUCTION

Peanut shell has an important potential in the world (6.49 million tons/year) and in Turkey (24.50 thousand tons/year) [1]. Considering that the values are high, it can be evaluated that peanut shell is an important waste plant biomass resource. Peanut shells have a high carbon content and are a suitable raw material for carbon synthesis [2]. Carbon materials play an important role in the development of alternative, clean and sustainable energy technologies. Bio-carbon-based materials can be a good alternative to commercial carbon materials when used as catalysts in various fields because of their high surface area, abundant porous structure, low cost, and environmentally friendly nature [3-9].

Although there are a lot of methods used in the synthesis of biomass-derived carbon materials, the microwave-assisted chemical activation method is commonly preferred in recent times due to its important advantages such as high carbon yield, improved porous carbon quality and high energy efficiency. Furthermore, it is an environmentally friendly method because of minimizing the formations and emissions of hazardous materials [10]. The objective of this research is to develop carbon-based catalysts with less expensive and simple experimental methods by employing peanut shells as a natural carbon source instead of fossil sources. Microwave assisted chemical activation method was applied as method.

EXPERIMENTAL

Materials and Chemicals

Peanut shells (PS) belonging to Osmaniye region in Turkey were used. Potassium hydroxide (KOH), isopropanol, hydrochloric acid (HCl) and sulfuric acid (H_2SO_4) Sigma-Aldrich and Merck Chemicals brands were used.

Synthesis of Porous Carbon

The experimental scheme for synthesis of porous carbon from peanut shells is given in Figure 1. After the peanut shell was washed with copious amounts of distilled water (DW) as firstly, it was dried at 105°C. The particle sizes were reduced by grating, and then pulverized in a mortar. The obtained peanut powder was mixed with a H_2SO_4 solution having a volume of 50 ml and molarity of 9 in a magnetic stirrer at room temperature during 48 hours. At the end of this duration, powder is filtered and was washed with DW. The filtered sample was mixed with the sample (1:3 - sample:KOH) and it was kept in the microwave at 700 W for 5 minutes. It was finally washed with hot and cold DW and 2M HCl until pH neutral. The resulting product was named PS-PC1. In order to reveal the effect of sonication process, it was further PS-PC1 sample was washed with isopropanol and distilled water and probe sonication having a time of 60 min was applied in solution of 10% H_2SO_4. This resulting product was named PS-PC2.

Fig 1. Synthesis of porous carbon from peanut shells

RESULTS AND DISCUSSION

The PS-PC samples properties obtained from PS were investigated by various characterizations. Firstly, the carbon content of the peanut shell was found as 48.19% via elemental analysis. Raman spectroscopy, XRD and BET analysis were used to show and compare the sonication and microwave treated porous carbon structures. Fig. 2a and b shows the Raman spectra and XRD pattern of both types of porous carbons (PS-PC1 and PS-PC2), respectively.

According to the Raman spectroscopy, as the D-band shows the C–C bond stretching vibrations (sp^3 vibrations) in the structure, the G band shows C=C bond in-plane stretching vibrations (sp^2 vibrations). The default peak values for carbon structures are 1340 and 1580 cm^{-1} for D and G bands, respectively. As is apparent from Fig.2a, while the low-intensity peak values in the D-band for PS-PC1 and PS-PC2 are 1340 and 1343 cm^{-1}, respectively, the peak values in G band are 1584 and1580 cm^{-1}. It is seen that these results are corresponded with literature [11]. The results of XRD patterns shown in Fig. 2b confirm the amorphous nature. Fig. 2b shows XRD spectrum peaks that are around 22.6°, indicating the lower graphitization degree of the sample. 43°4 indicates the availability of honeycomb-like structures formation in PS-PC carbons [12-13].

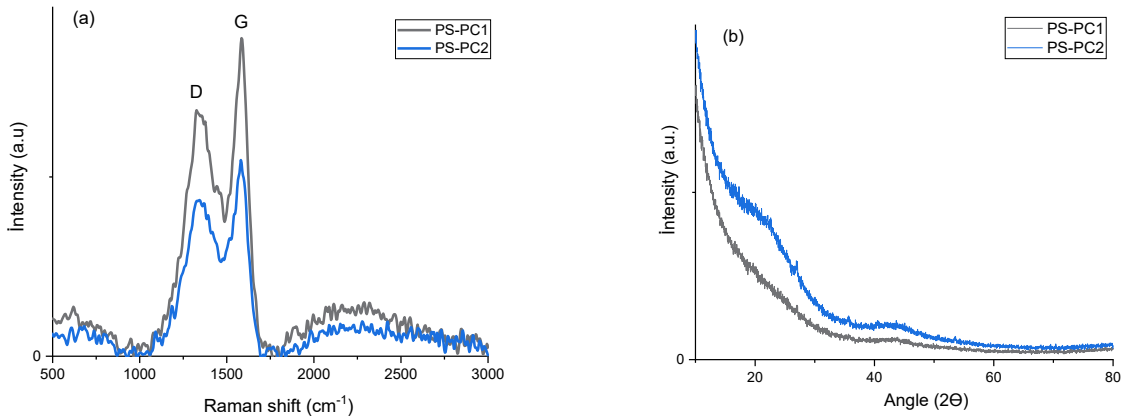

Fig 2. (a) Raman spectra; and (b) XRD pattern of PS-PC1 and PS-PC2

The specific surface area, porosity volume and pore size for PS-PC1 and PS-PC2 are given in Table 1. The surface area of PS-PC2 was higher than PS-PC1. It can be said that the sonication process has positive effect on the surface area.

Table 1. BET surface area, total pore volume and pore size of PS-PC1 and PS-PC2.

Sample Name	Surface Area [m^2g^{-1}]	Total Pore Volume [cm^3g^{-1}]	Pore Size [Å]
PS-PC1	1052.66	0.70	26.4
PS-PC2	1155.81	0.76	26.3

CONCLUSIONS

In the presented study, it was aimed to obtain a carbon source from peanut shell with two different techniques. Porous carbons were successfully synthesized using peanut shells by acid-treatment and chemical activation methods. The main conclusions can be given briefly as follows:

- Porous carbons with a high surface area were synthesized.
- The probe ultrasonication process had a significant effect on the specific surface area of porous carbon.
- Materials with rich porosity have an elevated specific surface area (SBET) leading to high active place density.

Consequently, the porous carbons obtained from peanut shells, which are a renewable biomass source, can be used in fuel cells and energy storage devices.

ABSTRACT

This study presents the synthesis of porous carbon from the sugarcane bagasse precursor. Carbon material obtained from sugarcane bagasse was synthesized by two different methods. In the first method, Sugarcane was carbonized without pretreatment and then impregnated with KOH. In the second method, It was activated with KOH. The surface areas of the prepared carbon materials were determined by Brunauer Emmet-Teller and the vibrational modes of the material properties were examined by Raman Spectrum analysis. The specific surface area of porous carbons was found at 646.96 m^2/g and 566.96 m^2/g, respectively.

Keywords: Biomass, Sugarcane Bagasse, Porous Carbon

INTRODUCTION

The interest in materials obtained from renewable resources is constantly increasing owing to the search for new materials in the energy sector and the increasing environmental awareness of both the industry and the public. More efficient and environmentally friendly energy solutions stand out with the use of renewable energy sources. Among renewable energy sources, biomass is a renewable resource that covers a wide variety of materials with significant energy potential [1,2]. Moreover, biomass-derived carbon materials show unique chemical, mechanical and thermal stability with high surface area. Sugarcane Bagasse *(Saccharum officinarum) (SB)* is biomass that plays an important role in the development of sustainable processes and the production of value-added materials due to its diversity of biomass composition and high carbon content.

SB is fibrous lignocellulosic biomass that consists of a cheap and very rich carbon source [3]. SB composes of approximately 48% cellulose, 29% hemicellulose, 24% lignin, moisture and less than 2% ash [4,5,6]. The cellulose-hemicellulose-lignin complex is degraded during pretreatment. Therefore, pretreatment of lignocellulosic materials is necessary. With the pyrolysis process, functional groups containing large amounts of oxygen in cellulose and hemicellulose are easily converted to H_2O, CO and CO_2, producing microporous carbon [7,8]. Thus, biobased carbon materials can be produced efficiently from this material. However, the production of material from sugarcane can be highly variable due to several factors such as local farming conditions, harvesting practices (i.e. equipment type, process, season, sunlight, harvest time, fertilizers and weather), storage conditions, age, environmental problems and pretreatment processes [9].

In this study, it is aimed to compare some similarities and differences affecting the properties of both pre-treated and untreated carbon materials obtained from SB precursors.

MATERIALS AND METHODS

Materials and Sample Preparation

In the experimental studies, sugarcane supplied from Kocaeli was used. After the sugarcane was firstly peeled and shredded, it was dried at a temperature of 105°C for 1 week in the oven in order to remove the water and unwanted volatile components. The dried product was sifted to obtain at average particle size of 1 mm. The obtained samples finally were stored in glass bottles at the room temperature and dry place.

Carbon Material Synthesis from Sugarcane Precursor

The synthetic scheme of porous carbon from sugarcane biomass employed to produce the target carbon is shown in Fig. 1. SB was firstly carbonized with a tube furnace at 400 °C for 2 h with an increment in temperature of 5 °C/min under the N_2 atmosphere at 0.2 L/min. The obtained biochar precursor was impregnated with KOH solution (C: KOH, 1:3 wt%) by stirring at 25 °C for 12 h, and then the mixture was treated under the hydrothermal condition at 120 °C for 6 h. After this process, the mixture was dried, which was followed by pyrolysis at 750 °C with a temperature rise of 5 °C/min under N_2 atmosphere at 0.2 L/min for 2 hours. The final product (SB-PC-1) was washed several times separately with HCl solution (0.1 M) and deionized water until the pH value was approximately 7. Carbon material was also

synthesized under the same conditions after SB fiber was further purified by a three-step acid-alkali-acid technique to compare (SB-PC-2).

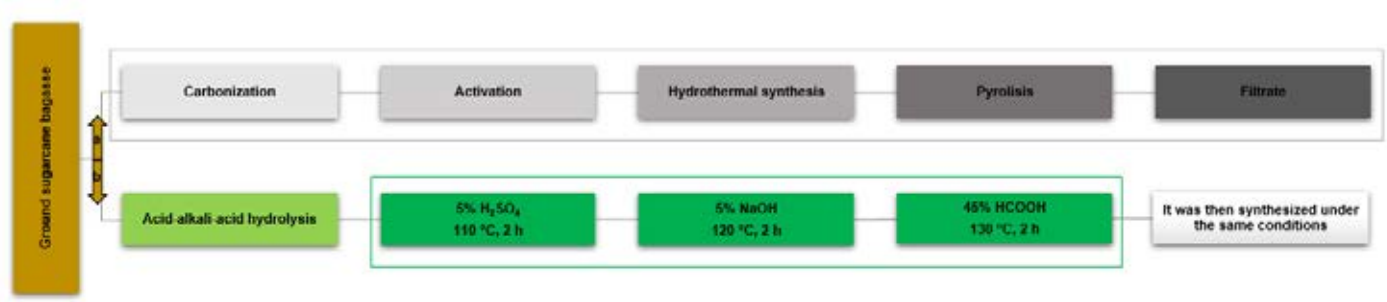

Fig. 1. Illustration of the synthesis scheme of porous carbon from sugarcane biomass a) SB-PC-1 b) SB-PC-2

RESULTS AND DISCUSSION

In this study, elemental analysis was firstly performed to evaluate the composition, properties and suitability of SB biomass. The carbon content of the crude SB biomass was 40.49%. A porosity was occurred on the carbon materials because of Chemical activation using KOH. SB-PC-1 and SB-PC-2 samples were characterized by Raman analysis to exhibit the vibration modes of material characteristics. Raman spectra of the prepared SB-PC samples are shown in Fig. 2. As is apparent from the Fig. 2, the samples have the sharpness band in value of 1576-1584 cm^{-1}, and this is known as G band been composed of sp^2 bonded carbon. Also in Fig. 2., it can be seen a distinct band around 1335-1355 cm^{-1}. This band shows a D band that is composed of sp^3 bonded carbon. Moreover, I_D/I_G value reflects the level of disorder in graphitic structure. A higher I_D/I_G value signifies a higher disorder, whereas a lower value shows less disorder in the graphitic plane [10]. The I_D/I_G ratio of SB-PC-2 is higher than SB-PC-1, indicating that the pre-treatment increases the defect of the material. The specific surface areas of SB-PC-1 and SB-PC-2 were found to be 648 m^2/g and 566.96 m^2/g, respectively, using BET analysis.

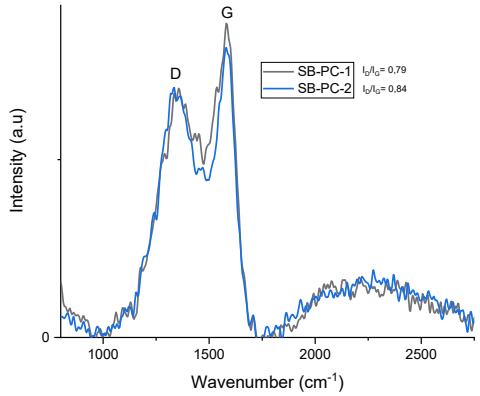

Fig. 2. Raman spectra of SB-PC-1 and SB-PC-2 samples

CONCLUSIONS

In the presented study, a simple and cost-effective hydrothermal assisted way to prepare porous carbon from sugarcane bagasse has been developed. This study highlights the benefit of pre-treatment for the preparation of porous carbon with a tuned surface chemistry that improves biochar properties. Sugarcane raw fiber was hydrolyzed by a three-step acid-alkaline-acid technique and so disorder in graphitic structure increased. The presence of defects aids in the transmission of electrolyte ions and increases transmission efficiency. In conclusion, the synthesized carbon materials can be applied in fuel cells and energy storage devices as a renewable, cost-effective and environmentally friendly electrocatalyst material.

ABSTRACT

Microfluidic fuel cells (MFCs) have received a great deal of attention in the last two decades for their high utility and versatility in portable electronics devices. Microfluidic-fuel cell technology used a liquid electrolyte, which show a great advantage compared to cells that include conventional polymer membranes (physical barrier). To date, different MFC configurations have been designed, in which ethanol have been used as fuel, however the implementation of high electrocatalysts materials is still the key for improvement performance of real devices applications.

The present work shows high performance in a MFC with ethanol as fuel, the excellent performance is due to use Pd-M (M= Co) based aerogels anode electrode, within the configuration of a microfluidic cell system. The use of hybrid aerogels allows the use of low catalyst masses of just 0.1 mg/cm^2 to generate current densities close to 400 mA cm^{-2}.

Keywords: Unsupported Aerogel, Microwave Heating, Microfluidic Fuel Cell, Nanotechnology, Electrocatalyst.

INTRODUCTION

Microfluidic fuel cells have the advantage of being portable and of carrying out small-scale processes what it offers high efficiency of energy conversion. The development of this type of devices allows to incorporate the ethanol oxidation (EO) for diverse technological applications on a small scale. Miniaturizing the cell may reduce fabrication costs. A study has recently presented a novel microfluidic fuel cell (MFC) that incorporates the innovation of using a laminar flow instead of the conventional solid membrane to separate the fuel and oxidant. Hence, the membrane-related issues are eliminated in this new MFC, which also offers savings in the manufacturing costs. However, it is still necessary to develop effective materials for this type of small devices [1].

Catalysts for different fuels have been continuously developed to optimize their power output and fuel utilization, with notable improvements achieved. Noble metals are potential hydrogen-storage materials that have been extensively studied due to its high efficiency, non-toxicity and stability. Particularly, Pd is widely used in anodes for EO [2]. The synergistic effect of metallic phase and oxyphilic properties of the Pd surface provides active sites for adsorption and dissociation of formic acid besides providing promoters of oxygen-containing species at low potentials [3]. There are a great number of Pd-based catalysts in the bibliography, however improving its activity is still a matter of fact to be implemented in fuel cells. Mesoporous materials with low density and greater number of active sites such as aerogels would allow to use less mass of catalyst and, at the same time, to provide a high catalytic activity [4]–[7]. Noble metal aerogels have approximately 90% air and very low content of the active metal which reduces the cost of the catalysts [8]. These innovative materials are commonly obtained by sol gel process and supercritical drying , however other techniques such as lyophilization allows promising aerogel qualities.

In this work, Pd-Co aerogels are synthetized by means of a totally innovative methodology based in microwaved heating during the sol-gel process, followed by lyophilization drying. The optimization of the synthesis process of the aerogels is performed to obtain the best performance in a microfluidic fuel cell for ethanol electrooxidation.

EXPERIMENTAL

Aerogels samples were obtained by a sol-gel methodology by microwave heating and lyophilization drying. The electrocatalytic activity of the Pd-Co aerogels towards EO were tested by Cyclic Voltammetry (CV) in a 0.5 M of ethanol in 0.5 M KOH as electrolyte. As for the electrocatalytic activity in half-cell configuration, at potential range between 0 and 1.4 V vs RHE was explored. The results were also compared with the electrocatalytic activity of a commercial reference (Pd/C 20%, Sigma Aldrich). For the MFC, Pd-Co aerogel samples were deposited on Toray carbon paper-060 (TCP) with a transversal area of 0.02 cm^2.The electrocatalyst loading was 0.1 mg for cm^2 anode and cathode electrode. Linear Sweep Voltammetry (LSV) was performed injecting 0.5 M ethanol with KOH as electrolyte in the anode with the evaluated catalyst; and 0.5 M H_2SO_4 in the cathode with commercial Pt/C as previous studies reported its best performance. A flow rate of 200 µL min-1 was used in the tests.

RESULTS AND DISCUSSION

A microfluidic fuel cell (Figure 1) was used for testing samples to verify their real activity under real operating conditions, using 0.5 M ethanol with 0.5 M KOH as electrolyte for the anodic reaction. Pd-Co materials have been tested and compared with the commercial Pd/C catalysts used as reference material in order to put into perspective the effectiveness of the best catalyst obtained using this novel methodology. LSV is a specific electrochemical protocol to discriminate the catalytic activity of the materials present in the anode surface. The microcell works by pumping 200 µL min^{-1} of the electrolyte fuel into the anode, and 200 µL min^{-1} of only 0.5 M H_2SO_4 into the Pt/C cathode. The polarization curves were obtained for stable open circuit voltage (OCV) and values registered for the samples were until 0.9 V. The power density obtained shows favourable results for the aerogel obtained by microwaved assisted sol-gel process. Small bubbles could be detected on the anode during the experiment, corresponding to the generation of hydrogen. The current density of the aerogel is up to almost three times higher than the commercial Pd/C catalyst, thus corroborating again the superior performance of the aerogels obtained in this work.

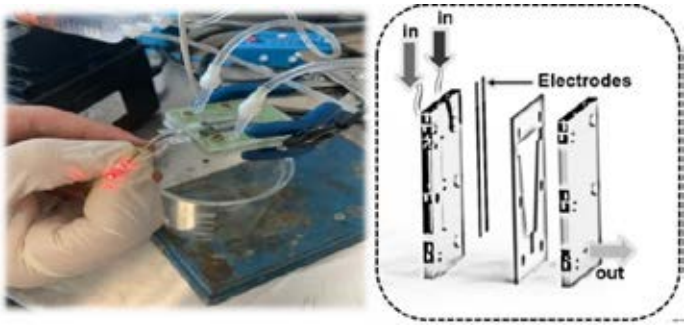

Figure 1. Scheme of the microfluidic system using the Pd-Co aerogels obtained in this work.

CONCLUSIONS

The use of microwave heating during the synthesis, followed by lyophilization as the drying step, allows obtaining Pd-Co aerogels with particle size smaller than 10 nm in anchored chains, favouring the ethanol oxidation. The Pd-Co aerogel sample showed a three times superior performance in a microfluidic fuel cell than a commercial Pd/C catalyst, reaching current densities of up to 118.3 mA cm^{-2}.

ABSTRACT

The polymer composite bipolar plates based on commercially available and self-prepared graphite and epoxy resin were obtained. The electrical conductivity, gas permeability, and other characteristics of materials were measured. The percolation behavior of the composites was analyzed. The own-designed bipolar plates were prepared using compression molding technique. The in-situ tests in fuel cells' stations were performed.

Keywords: Bipolar Plates, Polymer Composites, Thermally Expanded Graphite, Electroconductive Fillers, PEM Fuel Cells

INTRODUCTION

Recently the European Commission proclaimed the new hydrogen strategy to reach the climate-neutrality in Europe (basically by reducing CO_2 emissions) by 2050 by using renewable energy [1]. Hydrogen fuel cells (FCs) are one of the key alternative, eco-friendly, zero-emission, and effective energy sources [2]. Among important components of fuel cells such as membrane, catalysts, gas diffusion layers, and the bipolar plates (BPs) play a significant role in the fuel cells' operation (homogeneous distribution of gases, current collection, prevention of water flooding, heat management, etc.) [3]. Consequently, such often mutually exclusive requirements for BPs as high electrical and thermal conductivity, flexural strength, toughness, high electrochemical stability, low gases permeation, and lightness are indispensable [4], [5]. In light of that, the polymer composites BPs have undeniable advantages over graphite and metal BPs [6]–[8]. They are lightweight and corrosion-resistant as graphite BPs and yet have a reduced thickness, high conductivity, and mechanical properties as metal ones. To overcome the disadvantage of low performance, the developing of effective nonporous materials for BPs with high electrical and thermal conductivity, high mechanical and chemical resistivity, etc., is an actual challenge nowadays. In the present research efforts were made to obtain bipolar plates based on polymer composites by hot compression molding to achieve the demanded goals. Moreover, the properties of polymer composites series filled with different graphite fillers, are analysed.

MATERIALS AND METHODS

Polymer composite bipolar plates preparation

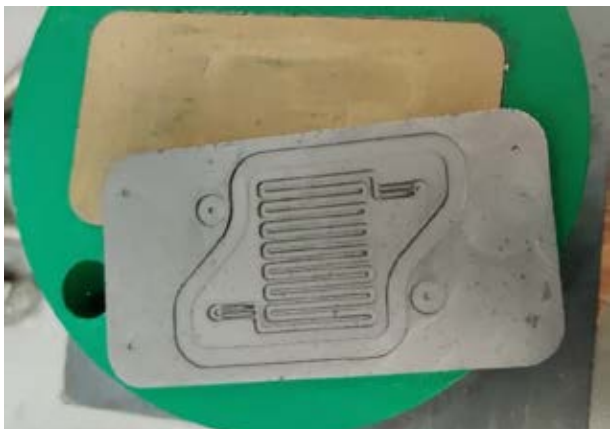

Fig. 1. Polymer composite bipolar plate based on carbon-filler obtained by hot compression molding.

Polymer BPs based on carbon fillers and epoxy resin were obtained using compression molding technique. The different materials as own-prepared thermally expanded graphite (TEG) (size particles ~500 μm), natural graphite (NG) (size particles ~17 μm), and synthetic graphite (SG) (size particles ~55 μm), were used as fillers. The filler content was varied from 2 to 60 vol.%. In order to obtain a good interface between the matrix and the fillers, among of increasing the quantity of latter, obtain the uniform dispersed materials, and, as a results, improve the mechanical characteristics of composites the filler particles were covered with epoxy resin in the dispersion. The pellets (with diameter 3 cm and thickness 0.1-0.3 cm), as well as bipolar plates (Fig. 1) were formed at 100 ºC at the 80 kN. The polymer composite with the best properties will be used for the manufacturing of the bipolar plates (Fig. 1).

Characterization of the polymer composite bipolar plates

The electrical conductivity of polymer composites was characterized using the impedance spectroscopy. Gas permeability of the materials were analyzed with electrochemical method and tested using linear sweep voltammetry. The bulk density and surface tension of the composites were measured.

The prepared polymer composite bipolar plates were characterized in a single cell with active area of 5 cm^2. Membrane electrode assembly consist of Nafion membrane, and two gas diffusion electrodes with 0.3 (mgPt cm^{-2}). The operating conditions for all experiments were: temperature 70 ºC; 0.5/0.5 bar of O_2 /H_2 or air/H_2 (piston pressure 8 bar), and 100 % relative humidity.

RESULTS AND DISCUSSION

The fillers' content affects the final materials' properties, such as the electrical conductivity, mechanical characteristics, etc. The influence of different carbon fillers (own-prepared TEG, synthetic and natural graphite) and variable content of them on the polymer composites' electrical conductivity is analyzed (Fig. 2). Moreover, the percolation behavior of such fillers in the bulk of epoxy resin matrix is studied (Fig. 2b).

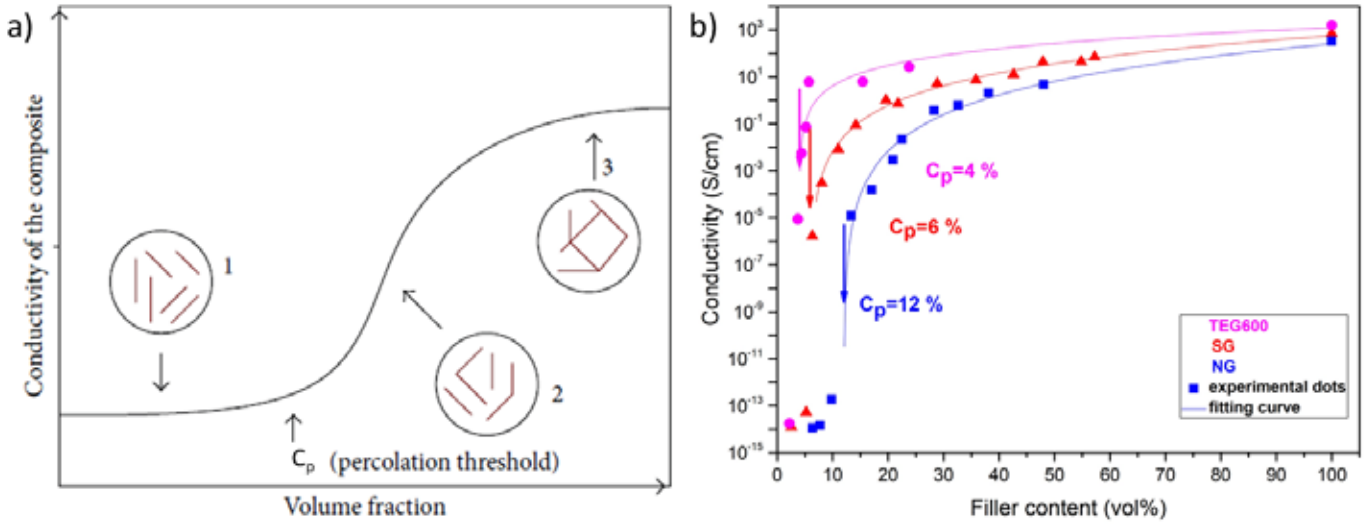

Fig. 2.Schematic percolation curves (a) [9], and experimental and fitted percolation curves for three different series (b).

Fig. 2a shows schematic percolation curves with 3 different regions of the fillers' particles packing [9]. The percolation threshold (C_p) is the critical filler volume fraction, where the electrical conductivity starts to increase due to the direct contact between the fillers' particles. Fig. 2b demonstrates that at the filler content around 60 vol.% the level of the electrical conductivity increases to 100 S/cm. The percolation threshold for the epoxy resin composites with TEG, SG, and NG are equal to 4.0, 6.0 and 12.0 vol.%, respectively. This effect shows that the TEG already forms electrically conductive percolation cluster at 4.0 vol.%. The critical index of electrical conductivity (t), calculated from the scaling relation derivate from Kirkpatrick's equation [10], are equal to 2.0, 4.4, and 3.6 for TEG, SG, and NG, respectively. The critical indexes from 1.6 to 2 correspond to standard 3D fillers' percolation [11]. The critical indexes higher than 2 indicate, on the electrical conductivity, which is realized due to the tunneling effect. It could mean that the SG and NG has less direct contact between the particles and covered with the thin polymer layer.
The polymer composites bipolar plates with own design of flow fields are prepared using epoxy resin and different carbon fillers (Fig. 1). The prepared BPs reaches the DOE target in terms of electrical conductivity (>100 S cm^{-1}) and gas permeability (<1.3x10^{-14} Std cm^3 s^{-1} cm^{-2} Pa^{-1}) with values of 150 (S cm^{-2}) and 2.8x10^{-14} (cm^3 s^{-1} cm cm^{-2} Pa^{-1}), respectively. The performance of membrane electrode assemblies in prepared BPs is tested in-situ in the fuel cell station. The tests' results are comparable to the literature.

CONCLUSIONS

The epoxy resin composites with different carbon-based fillers were obtained. The polymer composites BPs were formed using compression molding. The electrical conductivity, gas permeability, bulk density, etc., of the materials were analyzed. The percolation behavior of the different fillers in the bulk of the polymer matrix were studied. The critical filler volume fraction and the critical index of conductivity were calculated. The prepared BPs were tested in the fuel cell station.

ABSTRACT

The Pt-CeO_2-C thin film catalyst was prepared by magnetron co-sputtering in Ar+O_2 atmosphere. The electrochemical surface area (ECSA) of thin film catalysts was tested in half-cell rotating disk electrode (RDE) system and showed 2.5 times higher than that for pure platinum. When Pt-CeO_2-C deposited directly on polymer-electrolyte membrane, creates a porous structure. The Pt-CeO_2-C catalyst coated membrane (CCM) was further measured in single-cell and exhibited only 21% power density loss during the accelerated stress test (AST).

Keywords: Thin Film, Catalyst, Porous Structure, Fuel Cell

INTRODUCTION

In order to reduce global dependency on fossil fuels, many renewable energy sources are being widely developed, such as wind, rain and solar energies [1]. Among them, hydrogen represents one of the most prospective forms because it is easier to store and it can be simply generated through electrolysis of water. One of the most efficient methods of utilizing hydrogen is through the proton exchange membrane fuel cells (PEMFCs) [2].
At the present stage of PEMFCs technology, platinum catalyst shows the highest performance for both anode and cathode. However, the high cost together with a rare resource of Pt severely limits the widespread fuel cell commercialization. It is thus urgent to reduce the Pt content in a cathode catalyst while maintaining its high performance. There are two major strategies for cost-effective and high-performance catalysts. One is to lower Pt content in the catalysts through doping other low-cost elements, without compromising performance. The other one is to increase the active area of Pt catalyst through the development of highly porous nanostructures.
CeO_2 has been studied for years due to its unique feature – the Ce^{3+}/Ce^{4+} redox couple ability. This makes CeO_2 a prospective substance either as a support or as an active catalyst. In our previous studies, we showed that we are able to produce high surface area catalyst by sputtering CeO_2 into carbon support in Ar+O_2 atmosphere [3]. During the sputtering process, the nuclei of CeO_2 form islands on the carbon-based substrate. The substrate surface area between those islands is etched with oxygen by forming gaseous products such as CO and CO_2. The carbon below CeO_2 nuclei is prevented from oxygen etching, resulting in the formation of porous columnar structure.
Herein, we investigate the thin film catalysts prepared by simultaneous co-sputtering of Pt, CeO_2 and C in Ar+O_2 atmosphere as cathode catalyst for PEMFCs. The catalyst thin films were deposited directly onto the polymer-electrolyte membrane in order to achieve a highly porous surface structure. Thus, the catalyst combines both strategies for cost-effective fuel cell catalysts i.e. it contains a low amount of platinum and has a high surface area. Except for high activity, such catalyst showed high stability.

MATERIALS AND METHODS

Magnetron sputtering

Pt-CeO_2-C and Pt thin film catalysts with 70 nm thickness were prepared using magnetron co-sputtering. The Pt (SAFINA, 99.99%,101.6 mm x 2 mm) target and C target (Kurt J. Lesker, 99.99%, 4.00" Dia. x 0.250" Thick) were faced the substrate under the angle of 45° (target-to-substrate distance is 15.5 cm). In turn, the CeO_2 target (Kurt J. Lesker, 99.99%, 4.00" Dia. x 0.250" Thick) is mounted in front of the substrate holder. The sputtering pressure was kept constant at 0.15 Pa with the Ar:O_2 ratio of 100:1. Powers on Pt, C, and CeO_2 magnetrons were set at 20 W, 300 W, and 65 W, respectively.

Structure characterization

The thickness and roughness of the as-deposited catalysts were determined by atomic force microscope (AFM, Bruker MultiMode 8) operated in tapping mode. SCANASYST-AIR probes (Bruker) were used with a nominal tip radius of 2 nm. Image processing was carried out using the NanoScope 1.5 software.
The microstructure of thin film catalyst coated membrane (Nafion® NR-212, Fuel Cell Store) was measured by scanning electron microscopy (SEM, Tescan MIRA III) operated at 30 keV beam energy. The cross-sections were prepared by focused ion beam (FIB, Tescan LIRA).

Half-cell electrochemical measurements

Thin film Pt and Pt-CeO_2-C catalysts were deposited on a glassy carbon electrode (Dia.5mm, 0.196cm^2). Cyclic voltammetry was done in an electrochemical cell with a typical three-electrode setup containing the sample as a working electrode (WE), a platinum wire (Safina, 99.99%) as a counter electrode (CE) and a saturated Hg/Hg_2SO_4 (Monokrystaly, RME 122) as a reference electrode (RE). Cyclic voltammograms (CV) were captured between 0.05-1 V_{RHE} at a scan rate of 50 mV/s in N_2 saturated 0.5 M H_2SO_4 solution. Electrochemically active surface area (ECSA) was calculated from the H_2 desorption/adsorption peaks.

Single-cell membrane electrode assembly (MEA) measurements

The membrane electrode assembly (MEA) contained thin film catalyst deposited on a Nafion membrane (20 × 20mm, Fuel Cell Store) as the cathode and commercially available gas diffusion layers (GDL) supported Pt catalyst (FuelCellStore, 0.3 mg/cm^2 40% Platinum on Vulcan) as the anode. Measurements were performed at 80 °C, 50 kPa gas backpressure and with the 1.2:2 constant ratio of H_2/O_2 flow. Accelerated stress test (AST) was performed at 500 mV/s scan rate in the range of 1-1.5 V_{RHE}.

RESULTS AND DISCUSSION

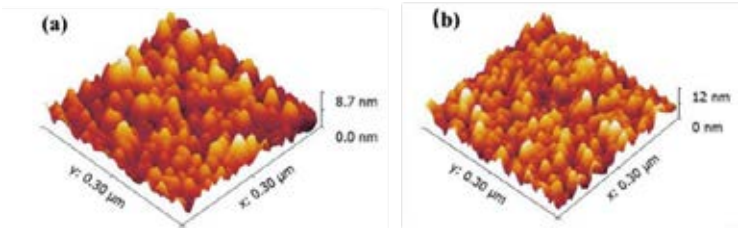

Fig.1 AFM images of (a) pure Pt and (b) Pt-CeO_2-C thin films

Fig.1 represents 3D AFM images of as-deposited Pt and Pt-CeO_2-C thin films. The average roughness (Ra) parameters calculated from the corresponding images are 1 nm and 1.5 nm for Pt and Pt-CeO_2-C, respectively. One can also observe that the Pt-CeO_2-C film surface is composed of smaller grains than the pure Pt film, which can be attributed to the CeO_2 and C doping effect.

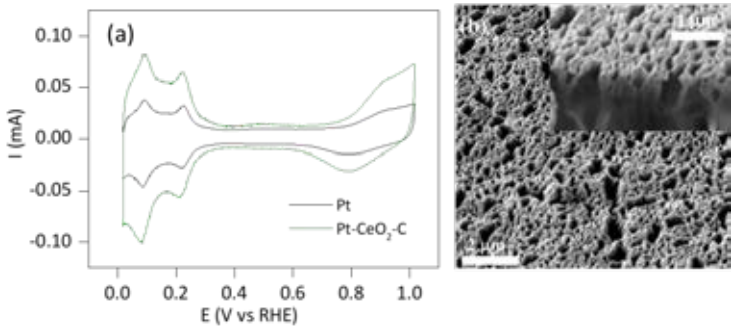

Fig.2. (a) Cyclic voltammetry curves of Pt and Pt-CeO_2-C catalysts. (b) Top and cross-section view SEM images of Pt-CeO_2-C catalyst deposited on Nafion membrane

Cyclic voltammetry (CV) was then applied to determine an electrochemically active surface area (ECSA) of the investigated samples. The CV curves of pure Pt and Pt-CeO_2-C thin film catalysts are shown in Fig 2a. Both CVs consist of the hydrogen oxidation/reduction and the platinum oxidation/reduction regions separated by the double layer potential region which is typical for polycrystalline platinum [4]. The ECSA of Pt-CeO_2-C thin film calculated from corresponding CV is 2.5 times higher than that for the pure Pt thin film. The higher ECSA for Pt-CeO_2-C can be explained by the formation of the so-called Pt-skeleton structure with higher concentration of low-coordinated Pt atoms due to CeO_2 leaching from the surface [5]. Fig. 2b shows SEM image of CCM. The highly porous surface of deposited layer can be explained by simultaneous membrane etching during the sputtering process [6]. The cross-section view from the inset of Fig. 2b, indicates that co-sputtering thin film deposited on membrane creates pores with about 1µm depth.

The Pt-CeO_2-C thin film with 21 µg·cm^{-2} Pt loading was then deposited on the Nafion membrane as cathode and commercial Pt/C catalysts with 300 µg·cm^{-2} as anode for testing in single cell. The commercial catalyst for both cathode and anode side were tested as reference. Polarization curves together with the power density (PD)

characteristics of investigated cathode catalyst are shown in Fig. 3. The specific power density of catalysts during 4000 cycles of AST are summarised in Table 1.

Table 1. The specific power density of catalysts during ADT

	Specific Power Density ($W \cdot g^{-1}$ Pt)	
Cycles	Commercial Pt/C	Pt-CeO_2-C
0	3.3	9.8
1000	1.8	8.9
2000	1.3	8.6
3000	1.0	8.5
4000	0.9	8.0

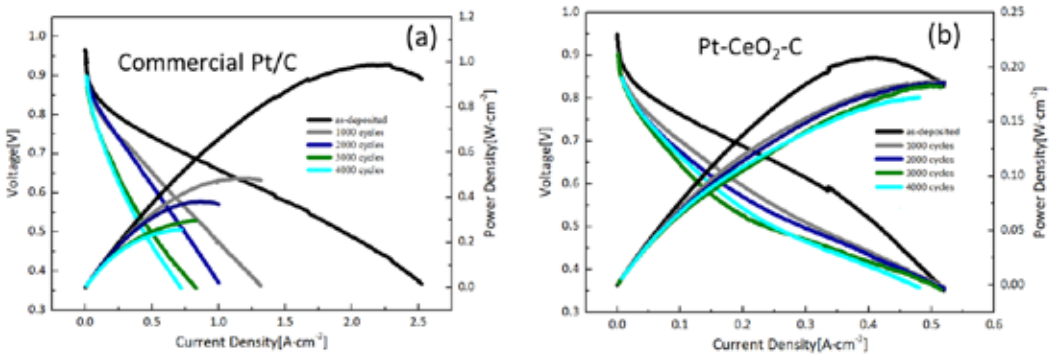

Fig.3. Polarization curves together with the power density of catalyst during AST

CONCLUSIONS

In this study, we developed Pt-CeO_2-C thin film catalyst prepared by magnetron co-sputtering in Ar+O_2 atmosphere. It showed 2.5 times higher ECSA than the pure Pt thin film catalyst. When deposited directly onto Nafion membrane, the porous structure with about 1 μm depth pores was achieved. Moreover, such catalyst showed only 21% power density loss after 4000 cycles durability test. Overall, the described results confirm the potential of using Pt-CeO_2-C catalyst as cathode in PEMFCs.

EXPERIMENTAL VALIDATION OF A 2-D MULTI-LAYER MODEL FOR FUEL CELL DIAGNOSIS USING MAGNETO-TOMOGRAPHY

[1] Antony Plait, [1] Frédéric Dubas*
[1]FEMTO-ST Institute, FCLAB, Univ. Bourgogne Franche-Comté, CNRS, 90000, Belfort, France

ABSTRACT

This paper focuses on the fuel cell (FC) diagnosis by using the magneto-tomography, which involves mapping the magnetic field produced by any electric device. Since the magnetic field and the current density are directly related, this study could describe the (ab)normal operation of a FC. For this purpose, a two-dimensional (2-D) multi-layer model based on the Maxwell-Fourier methods is developed. In order to validate the model developed for the FC diagnosis, an experimental bench was set up to emulate the FC operating mode. The purely analytical model is validated since the average difference between analytical results and experimental measurements is about 7%.

Keywords: Fuel Cell, Magnetic Field, Magneto-Tomography, Experimental Validation, Diagnostic.

INTRODUCTION

Many factors (e.g., obstruction of the gas diffusion layers, temperature hotspot, ...) can affect the current density distribution inside the FC and thus its performances. A bipolar plate of a FC stack, exposed in Fig.1, consists of a central active part (i.e., electrochemical active cell) and a peripherical inactive part (i.e., seal). Both invasive and non-invasive methods were developed to diagnose a FC. Magneto-tomography consists of measuring the magnetic field distribution around a FC. This interesting non-invasive method allows achieving an efficient study of FC health state. Hauer *et al.* (2005) [1] were the first to use this method for the FC diagnosis. To estimate the FC life state using magneto-tomography, the Biot-Savart's law [1]-[5], varying-network magnetic circuit [5] or the heuristic search method [6]-[7] are used. Recently, Plait *et al.* (2020) [8] developed a novel analyzer device of the magnetic field to increase the diagnostic performance.

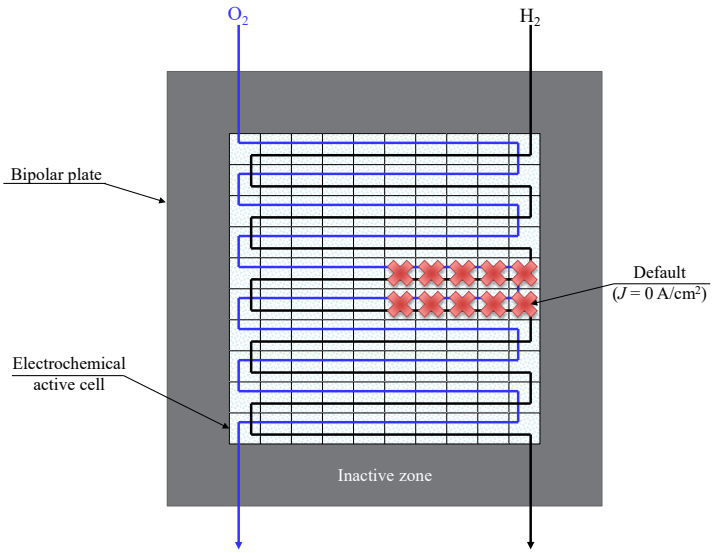

Fig. 1. Scheme of a FC bipolar plate

In this paper, an innovative magnetostatic model for the FC diagnosis is developed and validated by experimental measurements. The used experimental emulator, consisting of 100 aluminum bars and different switches, reproduces the behaviour of a FC that will have different types/locations of failure and reflects the current density distribution. Around the FC, the generated magnetic field is measured for a healthy FC and a FC failure with the default as indicated by the red cross in Fig. 1.

ANALYTICAL PREDICTIONS

The 2-D magnetic field distribution of the FC bipolar plate was studied from multi-layer model by solving magnetostatic Maxwell's equations in Cartesian coordinates (x,y). Knowing the current density distribution inside the FC, it's possible to accurately estimate the magnetic field distribution generated around the FC, or vice versa (by solving an inverse problem). The bipolar plate modeling is decomposed into 3 regions, viz., (R1) and (R3) similar to vacuum and (R2) the electrochemical active cell, as shown in Fig. 2.

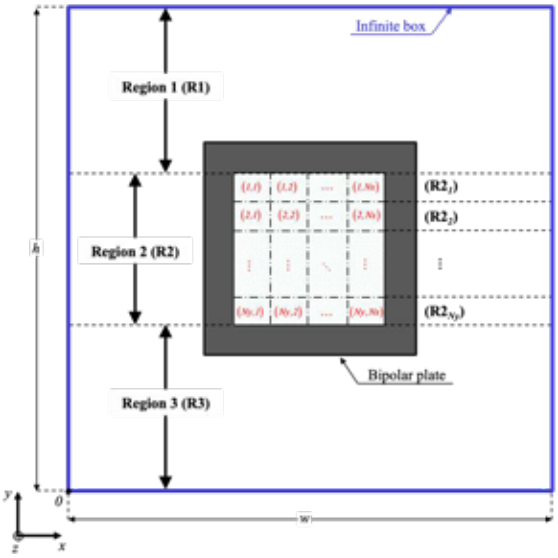

Fig. 2. FC bipolar plate modeling with 3 regions

The partial differential equations of magnetostatic in terms of magnetic vector potential ***A*** are defined by the Laplace's equation in (R1) & (R3) and the Poisson's equation in ($R2_i$) whose the electromagnetic source is the (in)homogeneous distribution of current density inside the FC stack. By using the separation of variables, the 2-D general formal solution of A in each region is defined by Fourier's series. The integration constants of series are determined analytically from a linear matrix system satisfying the classic boundary conditions [9].

EXPERIMENTAL FUEL CELL EMULATOR

To evaluate the capacity and efficiency of the developed 2-D multi-layer model, an experimental bench that reproduces the current density in operating condition is developed. The active part of this FC bipolar plate is emulated by multiple aluminum conductor bars supplied by DC current (white grid in Fig.1). A picture of the developed experimental bench is shown in Fig. 3. The emulator is surrounded by a non-magnetic support (3-D printed in white PLA in Fig.3), necessary for the installation of micro-Hall effect sensors. Both components of the magnetic field (viz., H_x and H_y) are measured at regular intervals around the FC emulator. A DC current of 100 A is distributed in the total surface of 100 cm^2.

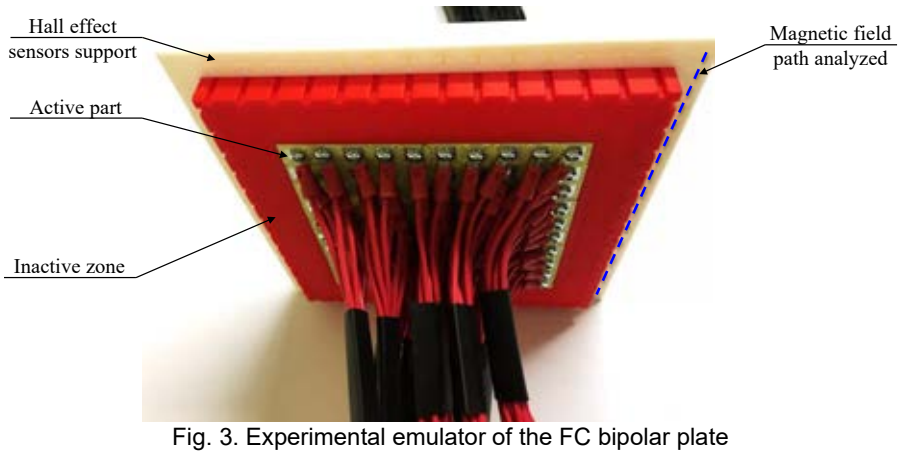

Fig. 3. Experimental emulator of the FC bipolar plate

RESULTS AND DISCUSSION

In this section, the analytical predictions are compared to experimental measurements. The focus is on the magnetic field waveform of the path shown in Fig. 3. The comparison is realized for a healthy FC (homogenous

current density of 1 A/cm^2) in Fig.4(a). Concerning an inhomogeneous distribution: a failure of 10% of the total active part as presented in Fig. 1 is considered. In case of failure the current density of the damaged part is zero and for the rest of the FC is equal to 1.11 A/cm^2. The analytical results and experimental measurements are shown in Fig. 4(b).

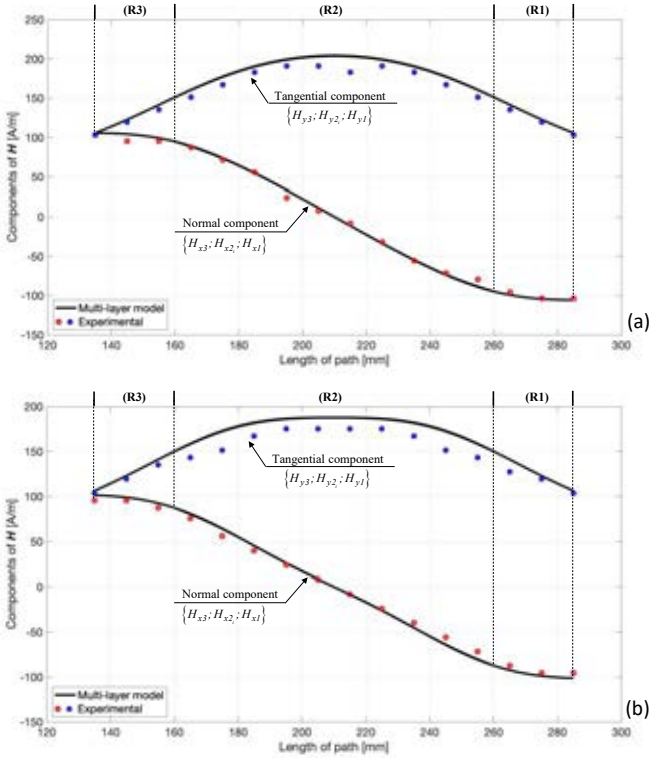

Fig. 4. Results comparison for (a) a healthy FC and (b) a FC failure

A current density fault (failure of 10%) results in a decrease of the magnetic field near the damaged zone and an increase away from it. A good accuracy between analytical results and experimental measurements allows the validation of the 2-D analytical model for both normal and abnormal FC operations.

CONCLUSIONS

In this paper, the analytical model is presented and the experimental setup is detailed. The analytical results and the experimental measurements are compared in order to validate the 2-D multi-layer model based on the Maxwell-Fourier methods. The validation is confirmed as the average difference is about 7%. The development of a fast and efficient multi-layer model is the first step. An inverse model is under development for the determination of the current density distribution in the FC from the measured magnetic field distribution.

NUMERICAL ANALYSIS OF LIQUID WATER PERMEATION PROCESS THROUGH THE DEFORMED GAS DIFFUSION LAYER OF PEM FUEL CELL

[1*] *Yingxu Liu,* [1] *Yinming Du,* [1] *Maximilian Wick,* [1] *Stefan Pischinger*
[1]Chair of Thermodynamics of Mobile Energy Conversion Systems,
RWTH Aachen University, Forckenbeckstrasse 4, Aachen, Germany

ABSTRACT

This research studies the impact of the gas diffusion layer (GDL) deformation on liquid water diffusion. A GDL model of a solid microstructure with randomly dispersed fibers is built parametrically. The Finite Element Method (FEM) is used to simulate the fiber deformation and porosity change at the rib's border area under different stresses. Finally, the deformed GDL's liquid water diffusion and dispersion are examined with the help of the Lattice Boltzmann Method. According to the findings of this study, the assembly pressure and radius of the rib corner has a crucial role in the liquid water penetration process.

Keywords: PEM Fuel Cell, Liquid Water, Gas Diffusion Layer, Lattice Boltzmann Method, Rib Corner

INTRODUCTION

Proton Exchange Membrane Fuel Cells (PEMFC) are considered a promising alternative to internal combustion engines, as they do not cause harmful emissions and have high efficiency [1]. The gas diffusion layer (GDL) is one of its key components, being a porous substance composed of many layers of carbon fibers. The primary function of GDL is to deliver hydrogen and oxygen to the electrical extremities where an electrochemical reaction occurs. At the same time, to transport water out of the fuel cell [2]. Assembly pressure on the contact surfaces between GDL and bipolar plates (BPP) directly determines the shape of GDL, and thus the liquid water permeation behavior, which further influences its performance [3]. Therefore, it is necessary to study the effect of GDL deformation on the flow process of liquid water within GDL. Under this background, in this paper, a GDL model consisting of randomly distributed carbon fibers was firstly generated. The deformation of the GDL model was then simulated for different pressures and BPP rib corner radii. The compressed GDL model is used to analyze the liquid water permeation process with the Lattice Boltzmann method (LBM). At last, the effect of compression and rib corner radii is evaluated.

METHODS

3-D parametric GDL model

With the help of ANSYS APDL, a 3-D parametric GDL model is firstly created, as shown in Fig.1.

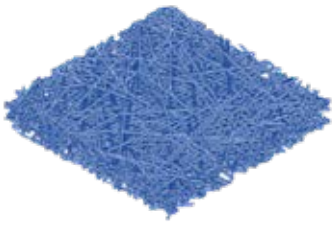

Fig 1. GDL produced with parametric modeling

The carbon fibers are the essential element to form this model. The geometric parameters utilized in the configuration of the GDL model are listed in Tab. 1.

Table 1. Geometric parameters of the 3-D parametric GDL model

Symbol	Quantity	Value
d_{f}	Fiber diameter	0.01 mm [4]
l_{f}	Fiber length	0.6 mm [4]
$\varepsilon_{\mathrm{GDL}}$	Porosity	0.78 [5]
H_{GDL}	Thickness	0.14 mm [5]

In this study, ideal hexagonal prisms are used to represent carbon fibers. This is based on three main reasons: firstly, using hexagonal prisms for the simulation saves computational resources compared with using cylinders; secondly, hexagonal prisms are promised with a better meshing process, which makes the model more suitable for finite element

analysis; thirdly, the contact area between a cylindrical body and a flat face is infinitely small, which can lead to an infinitely large pressure in the static stimulation.

GDL deformation

In the simulation, the pressure is loaded normally to the top surface of the bipolar plate. Due to the symmetrical and repetitive structure of the fuel cell cross-section, half of the ribs and half of the gas channels are presented in the geometric model.

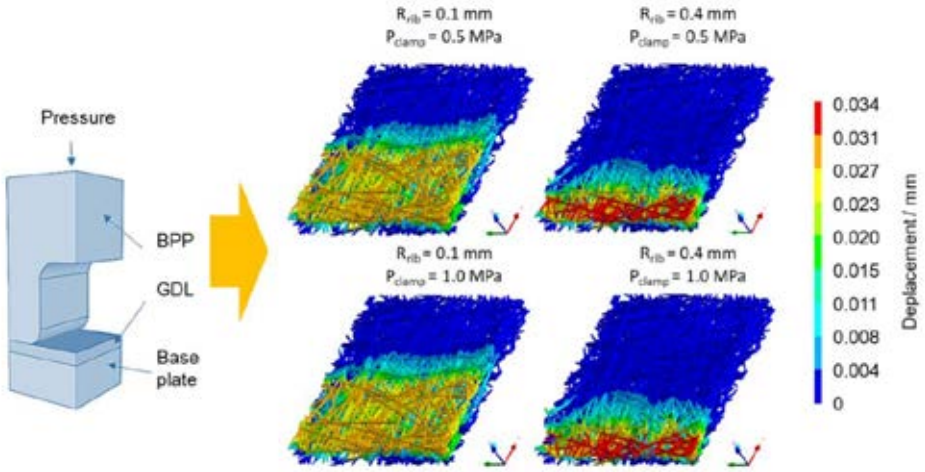

Fig 2. GDL deformation under compression of BPP rib

In the direction of the z-axis, the deformation of carbon fibers in the upper layer is more significant than in the lower layer. The maximal deformation is always found in the top layer. Besides, overlapped fiber nodes can transmit pressure and cause deformation to the fibers in lower layers. As a result of the rib intrusion into the fiber layer, the deformation of carbon fibers in the region under the rib is more significant compared with the region under the gas channel.

Liquid water permeation process

The water permeation process through compressed GDL is simulated via commercial LBM software X-Flow. The boundary conditions are presented in Tab. 2. It is worth noting that the simulation is based on the isothermal assumption, so temperature variations, as well as phase changes, are not considered.

Table 2. Geometric parameters of the 3-D parametric GDL model

Symbol	Quantity	Value
ρ_w	Water density	983.20 kg/m^3
ρ_a	Air density	0.98 kg/m^3
μ_w	Dynamic viscosity of water	0.466 mPa·s
μ_a	Dynamic viscosity of air	0.0184 mPa·s
v_w	Water inlet velocity	0.1 m/s

Simulation results are displayed in Fig. 3. As a result of GDL compression, the water in the cases with more considerable pressure will first break through GDL and contact the bipolar plate. After the water has flowed into the gas channel, the water flow is more random as fewer obstacles in the gas channel can constrain the flow.

Fig.3 also reveals that various rib corner radii significantly impact GDL water distribution. The water beneath the rib with a 0.4 mm corner radius comes into touch with the rib earlier than in other circumstances. This phenomenon is caused by the GDL thickness compressed under GDL, resulting in a significantly shorter distance for water to diffuse.

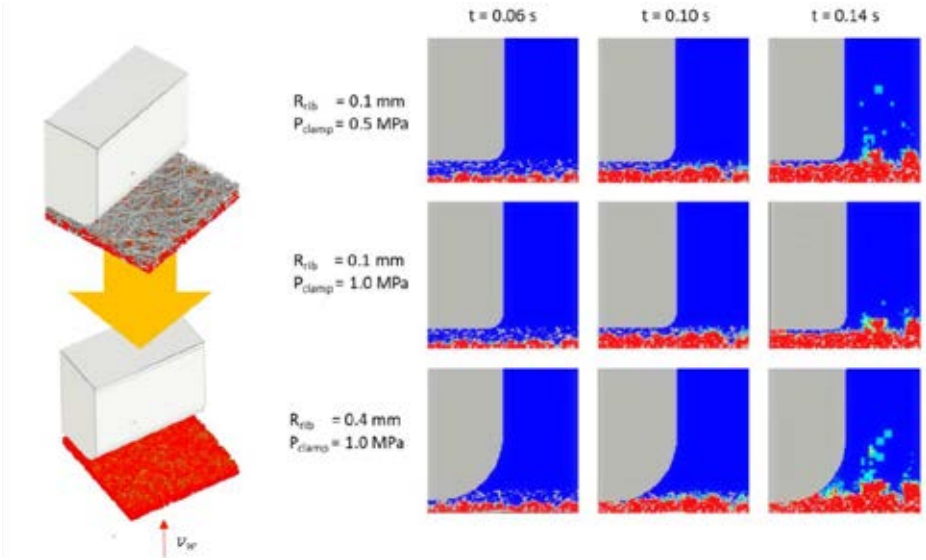

Fig 3. Water permeation process

The simulation also showed that in the event of a larger rib corner radius, the obstructed air bubbles might be released more quickly. This is because, compared to the case with a lower rib corner radius, the flat bottle surface takes up a more tremendous amount of the bottle, which is not favorable for the ejection of blocked air bubbles.

CONCLUSIONS

The microstructure GDL model is utilized in this thesis to simulate GDL deformation and examine the influence of deformation on liquid water diffusion. A parametrically generated solid microstructure GDL model with randomly distributed fibers was created. Fiber deformation at the rib's border region and the porosity change under various stresses were simulated using the Finite Element Method (FEM). Finally, the Lattice Boltzmann technique investigated the liquid water diffusion rate and distribution.

The simulation findings indicate that the radius of the rib corner plays a critical role in the liquid water penetration process inside the GDL. The distortion of the carbon fiber in GDL is more prominent when the rib corner radius is significant. Meanwhile, a big rib corner radius aids in water permeability. It is feasible to expect an ideal rib corner radius that balances the displacement of GDL and the rate of water penetration.

Further study on a series of chosen rib corner radii may be beneficial. Carbon fibers are modeled in this simulation as continuous entities bent but not broken. Carbon fiber's irreversible deformation may be explored in future studies. Additionally, the computational domain can be sufficiently enlarged to model the actual process.

THE IMPACT OF AMBIENT TEMPERATURE ON HIGH-TEMPERATURE PEM FUEL CELL

[1] *Phil-Jacques Alphonse,* [1] *Mert Taş,* [1,2*] *Gülşah Elden*
[1] Erciyes University, Engineering Faculty, Energy Systems Engineering Department, 38039, Kayseri, Turkey

ABSTRACT

The temperature management and temperature distribution in the fuel cell are important issues in terms of improving reaction kinetics. To examine the impacts of the different ambient temperatures on the heat transfer occurring inside a high-temperature PEM fuel cell, two dimensional and steady-state model is developed by using Comsol 5.5 Multiphysics. While the operating temperature is kept constant at 150 °C, the different ambient temperatures (10 °C, 20 °C, 30 °C and 40 °C) are applied to the model. The obtained results show that the fuel cell performance is improved with lower ambient temperatures. Moreover, the highest cell temperature is found in the $T_{ambient}$= 40°C case, which is around 425 K.

Keywords: HTPEM Fuel Cell, Modeling, Temperature Distribution, Reaction Kinetics

INTRODUCTION

High-temperature polymer electrolyte fuel cell (HT-PEMFC) systems have attracted a lot of attention in recent years with their features such as energy efficiency and power density. It is used in fixed systems such as portable and charging stations such as land, air, and sea vehicles, and uninterrupted power systems. Unlike polymer electrolyte membrane fuel cells (PEMFCs) operating at low temperatures (50°C-80°C), HT-PEMFCs can operate in the range of 120°C-180°C. This is possible by using polybenzimidazole (PBI) instead of Nafion as a membrane. Since the water is in the vapor phase at operation temperature, the water management problem is eliminated. However, cell temperature management and temperature distribution are much more important in terms of improving reaction kinetics and maintaining the single phase in HT-PEMFC.

A 3D physical model is used to investigate several ways of investigating heat management of an HT-PEMFC. It is observed that for the combined gas channel and reaction heating, the cell temperature can exceed the highest temperature limit [1]. Similarly, the effect of the ultrathin vapor chamber (UVC) on the output performance of a conventional PEMFC stack is studied [2]. Experimentation and simulation are used to investigate thermal management and operating stability. It is found that the UVC can significantly increase output voltage and thermal management under high current density. The heat, mass, and charge transport processes of fuel cells are analyzed at different stoichiometric ratios (1, 2, and 3). For the case with a stoichiometric ratio of 1, the temperature decreases along the flow direction [3]. The rib design of a HT-PEMFC is investigated by Xia et al [4]. They revealed that the temperature of the MEA is higher than the temperature of bipolar plates and gas channels due to entropy change and overpotential losses. The aim of this study is to examine the effects of the change in ambient temperatures on the thermal behaviour of the high-temperature PEM fuel cell.

MODELING

The 2D HT-PEMFC model is developed with Comsol 5.5 Multiphysics. The model geometry is illustrated in Figure 1.a. As is shown in this figure, the numerical model consists of two gas diffusion layers and membrane. The catalyst layers are reactive boundaries. While the cell operating temperature is kept constant at 150 °C, the ambient temperature is varied from 10°C to 40 °C (stepping by 10°C). The following assumptions are considered to simplify and minimize the complexity of the model. Also, the model parameters are listed in Table 1.

1. The process is in a steady state.
2. The gas flows in the flow channels are compressible and laminar.
3. All gas mixtures are considered to be ideal gases, including the fuel, oxidant, and generated water.
4. The porous structure of the GDLs and membrane ensures that they are isotropic and homogeneous in all directions.
5. Thermal conductivities of all materials are assumed not to change with temperature.

$$\nabla.(\vec{u}) = 0 \quad (1)$$

$$\frac{\mu}{K}\vec{u} = -\nabla P \quad (2)$$

$$\nabla(\vec{u}c_i)\text{-}\nabla(D_i^{eff}\nabla c_i)=S_i \quad (3)$$

RESULTS AND DISCUSSION

The change in the temperature difference between the ambient and the cell affects the temperature distributions within the cell. As is shown in Fig. 1.b, the model results are compatible with the experimental data [6]. Fig. 1.c. presents the polarization curves for four different ambient temperatures. It is shown that the performance of the fuel cell is improved with lower ambient temperatures. Fig.1.d demonstrate the maximum cell temperature change according to ambient temperatures. It is found that the cell temperature increased with the increase of ambient temperature.

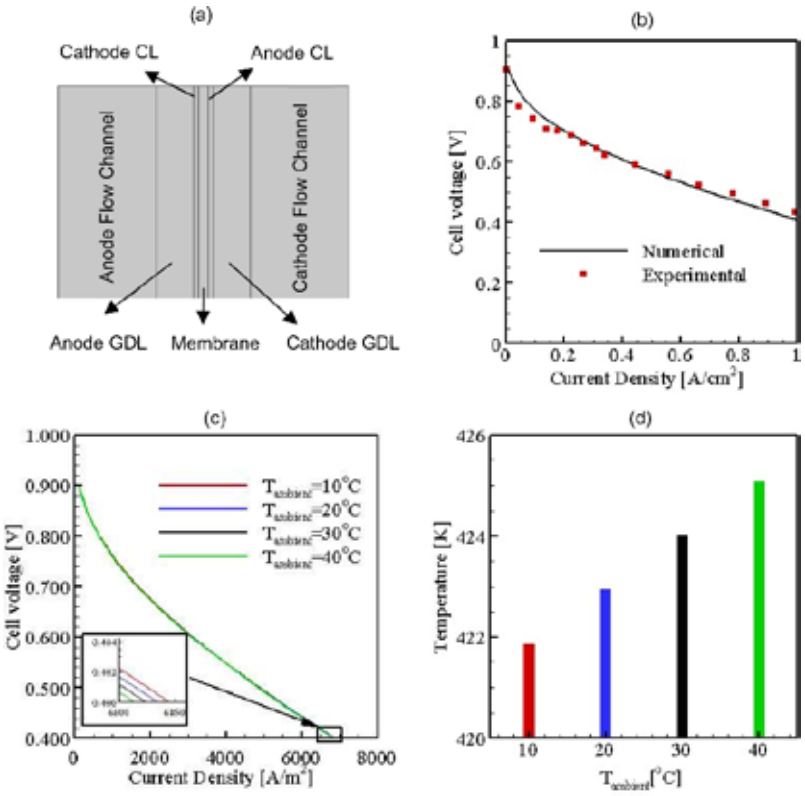

Fig. 1. (a) Model geometry, (b) Comparison of model results with experimental data [5], (c) The variation of polarization curves depending on ambient temperature, (d) Maximum cell temperature distribution for four different ambient temperatures at cell voltage of 0.4V.

CONCLUSIONS

The effects of ambient temperature on the performance and temperature distribution of HT-PEMFC are numerically analyzed. As a result of the analysis, it is revealed that the performance and temperature distribution of HT-PEMFC are affected by the change in ambient temperature.

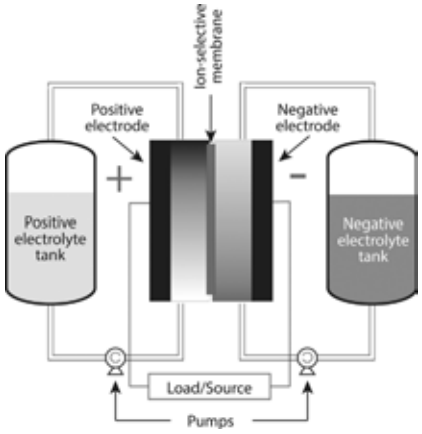
ABSTRACT



A single-channel H_2/Br_2 redox flow battery is modeled in this study. Within the scope of the modeling, the use of the redox flow battery only in the discharge mode has been studied. In this context, Nafion 115 was used as the membrane and SGL 34BC was used as the diffusion layer. The highest power density obtained in this context was reached at 0.8 V, and this value was obtained as 0.62 W/cm^2.

Keywords: Hydrogen, Bromide, Redox Flow Battery

INTRODUCTION

The issue of energy storage has gained importance, especially with the increase in the use of renewable energy sources. Unstable sources, predictably due to the nature of wind and sunlight, are a challenging problem for modern power distribution networks that draw power. By far the most efficient storage method is systems based on mechanical principles. Two of the best are pumped storage hydropower and compressed air [1]. However, to achieve high efficiency, these systems require large-scale deployment and thus significant initial investment. Not every location is suitable for the construction of these systems, and it is not always feasible or even desirable to build a large-scale system. Therefore, storing the excess energy produced in electrochemical cells (batteries) is a necessary choice and perhaps even the most practical method. The challenge, however, is to find batteries that are reliable, widely available, effective, and cost-effective [1]. Due to various problems with lithium-based batteries, which are frequently used today, studies on redox flow batteries have increased.

Flow redox cells differ from more common electrochemical cells in that the reactive material is not part of the structure but is supplied from external storage tanks in the form of a liquid phase during cycle transitions from the storage vessels. The total energy capacity of the system is then proportional to the amount of electrolyte in the external containers while the output power depends on the electrode arrangement (the electrode area of the system). The schematic diagram of the flow cell system is given in Figure 1 [2].

Şekil 1. Schematic diagram of the Redox battery.

It is thought that hydrogen will be in our lives in the future. For this reason, it will be possible to produce in high quantities and access it at low prices. However, bromine is a very cheap mineral and can be obtained at approximately 6 times more cost-effective than vanadium. Commercialization of H_2/Br_2 redox flow batteries has started quite recently and has not reached its full capacity. The main reason for this is the limited research on it. Some of the studies in the literature are summarized below.

Oh et al. [3] developed a three-dimensional model for H_2/Br_2 redox flow batteries, meticulously taking into account the species and charge transfer that occurs via redox reactions of hydrogen and bromine species and various cell

components. First, the H_2/Br_2 redox flow batteries model was validated experimentally against the measured discharge and charge voltage curves over a wide range of current densities up to 1.4 A/cm^2. Overall, the model predictions compare well with the experimental data. Particular emphasis was placed on analyzing the cross-membrane crossover of bromine species at detailed levels where the model calculates electro-osmotic and diffusive fluxes through the membrane; The relative sizes were compared at various charging and discharging stages. Additionally, a parametric study was performed to examine the effects of two important design variables on cell performance and migration behavior, namely the thickness of the membrane and bromine porous media. This fully 3D model of H_2/Br_2 redox flow batteries can be applied to realistic large-scale cell geometry for grid-scale energy storage applications and can be directly used to determine the optimum design and operating conditions for H_2/Br_2 redox flow batteries.

Chinannai et al. [4] developed a kinetic model of the chemical reaction by comprehensively taking into account the detailed reaction steps and incorporating a three-dimensional, time-dependent H_2/Br_2 flow battery model. First, the H_2/Br_2 flow cell model containing BrO^{-3} was validated according to experimental data in which cell voltage recovery was observed until the BrO^{-3} was completely consumed. The model successfully reproduced the voltage evolution data measured during discharge, thus accurately obtaining the transient behavior of an H_2/Br_2 cell affected by the bromate-bromide chemical reaction. In addition, H_2/Br_2 cells were simulated with and without BrO^{-3}, and model predictions revealed that the reversible voltage, ohmic overpotential at the membrane, and activation overpotential of the Br_2 reduction reaction was improved due to the use of BrO^{-3} in the catholyte. The current model for the H_2-Br_2-BrO^{-3} system has provided a quantitative analysis of the beneficial effects of using the redox-mediated bromate anion, thus making it a useful tool for the design and optimization of the H_2/Br_2 cell with BrO^{-3}.

In his master's thesis, Haile [5] aimed to perform a system architecture, dynamic behavior analysis, component selection, and experimental work to develop the control system of a commercial company Elestor's hydrogen bromine flow battery. To achieve this goal, different aspects of system architecture design have been proposed. In addition, components such as a current sensor and an electrolyte pump were selected and tested for the Elestor H_2/Br_2 flow battery. In addition, the first experimental study was conducted on the performance of the first Elestor H_2/Br_2 flow battery at different hydrogen pressure and electrolyte pump speed. In the theoretical analysis, the transfer function for both open and closed-loop electrolyte subsystems is investigated from dynamic mass balance, and step responses are also preplanned. From the theoretical analysis, it is found that the open-loop step response of the electrolyte subsystem behaves as a pure capacitive operation. The result of the analysis also showed that the closed-loop step response of the electrolyte subsystem behaves as a first-order system.

This limitation arises from the fact that experimental studies are not sufficient to ensure optimum reactions in all electrochemical energy conversion systems. For a better understanding of the system, H_2/Br_2 redox flow batteries are modeled in a computer environment and the performance of the cell's behavior in discharge mode is examined.

MODELING

H2/Br2 redox flow batteries are a promising system today. The reactants of this system are gaseous hydrogen on the negative side, and aqueous bromine and HBr solution on the positive side. During discharging, if the cell electrode loses the electrode and the proton passes through a proton-conducting membrane to the other solution, the gaseous hydrogen on the surface reacts with bromine to produce positive electrode HBr [6].Bu sistem için yarı reaksiyonlar aşağıda gösterilmiştir:

Positive electrode $2Br^-(aq) \leftrightarrow Br_2(aq) + 2e^-$ (2.1)

Negative electron $2H^+(aq) + 2e^- \leftrightarrow H_2(g)$ (2.2)

Total reaction $Br_2(aq) + H_2(g) \rightarrow 2Br^-(aq) + 2H^+(aq)$ (2.3)

The general standard potential for this system is E_0 = 1.09 V.

In the studies, heat transfer equations were excluded from the modeling scope and an isothermal model was developed. The model was prepared using diffusion equations, flow equations in a porous material (Briggmann equations), and electrochemical equations.

For the electrochemical reactions in the system, firstly the Nernst equation was used to determine the output voltage, and the modified Butler-Volmer equation was used for the modeling of the electrochemical reactions.

RESULTS AND DISCUSSION

The polarization curve of the modeling study is given in Figure 2. As can be seen from the polarization curve, the highest cell performance was obtained at 0.8 V. The power density produced at this point was obtained as 0.62 W/cm^2.

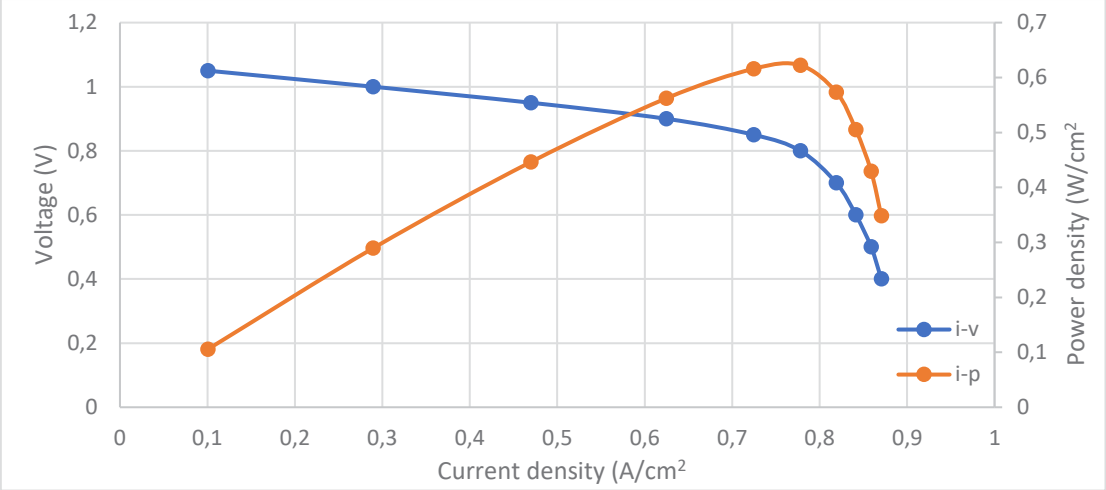


Figure 2. Polarisation curve

In Figure 3, the hydrogen concentration distribution on the anode side, and the bromide concentration distribution in Figure 4 are given.

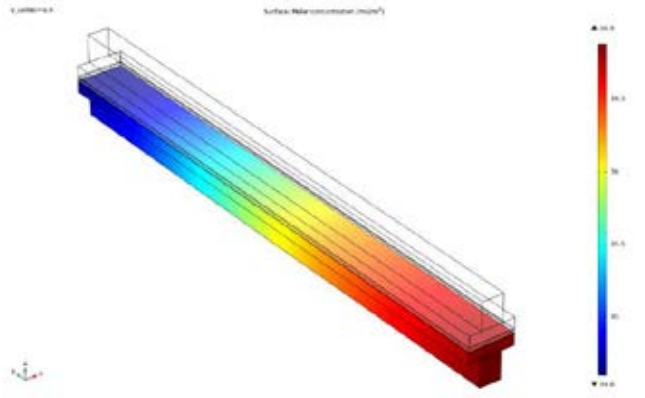

Fig. 3. Hydrogen concentration distribution

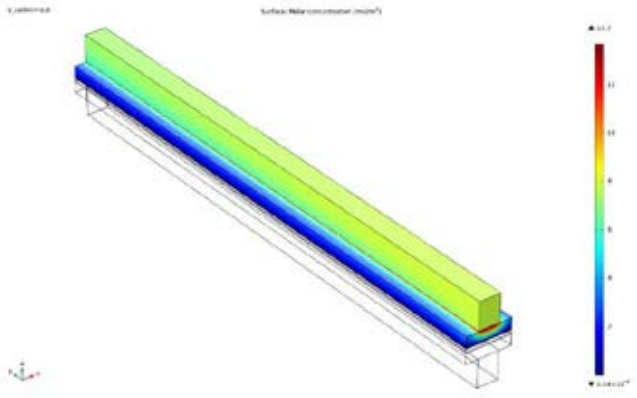

Fig. 4. Bromide concentration distribution

CONCLUSIONS

In this study, an isothermal model of a single-channel h2/br2 redox flow battery was studied. Within the scope of the modeling study, the polarization curve was created and it was determined that the maximum power density of 0.8V was reached. In this context, it is seen that all of the hydrogens are used, but the bromide concentration does not decrease too much. In this case, it is seen that the cell included in the scope of the study can also achieve higher performances.

ABSTRACT

The scope of the project is a research and development of a hydrogen range extender by implementing a hydrogen fuel cell, high pressure cylinders and other supporting components in a commercial battery-based multipurpose vehicle. In the final phase, the long term real-operation testing of the prototype vehicle will be carried out. The documentation for a small serial production will be prepared after a final optimisation of the whole electric power train system.

Keywords: Hydrogen, Fuel Cell, Multipurpose Vehicle, Range Extender

INTRODUCTION

The aim of the project is to develop a hybrid powertrain for a commercial multipurpose vehicle that will enable emission-free operation with comparable performance to conventional internal combustion engine vehicles. At present, the development of clean mobility mainly focuses on electric vehicles using battery energy. The range of electric vehicles is limited by the size and the battery capacity, which is limited due to weight and size, resulting in a shorter range. This problem is not so obvious for conventional cars, since analysis of traffic statistics shows that most journeys are made within a distance between 30 - 80 kilometres. Commercial vehicles, unlike passenger cars, are used in shifts that typically last 8 hours and it is therefore preferred that the vehicle does not have to be recharged for a longer period during the shift. Due to the higher investment costs of commercial vehicles, there is a desire to use them as much as possible. The research and development of a hydrogen range extender for commercial multipurpose vehicles allows the benefits of emission-free operation to be combined with the required operating time and comparable refuelling times to existing internal combustion engine vehicles.

Fig. 1. Preliminary tests of protype vehicle with hydrogen range extender

EXPERIMENTAL WORK

The use of hybrid powertrains in passenger cars faces space challenges. Commercial vehicles using an electric motor, on the other hand, have more space for battery storage, but weight is still a limiting factor. Hybridising the vehicle with hydrogen can ensure sufficient range.

The research and development of hybrid propulsion system is divided into three stages:

- Stage 1 - Technical design of the hydrogen fuel cell system integration
- Stage 2 - Implementation of hydrogen range extender into the prototype multipurpose vehicle
- Stage 3 - Optimization and testing of the prototype multipurpose vehicle

Technical design

Mathematical modeling for energy balance was carried out with goal to double a range of a battery electric vehicle. This modeling with a market research led to a design of fuel cell range extender present on Figure 2.

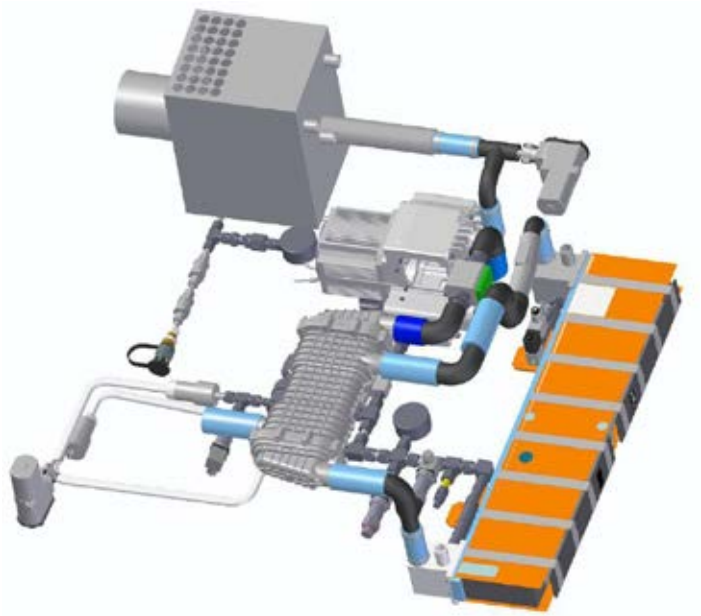

Fig. 2. 3D model of fuel cell range extender (excluding high-pressure cylinders)

Implementation of hydrogen range extender into the vehicle

In the second year of project, the all component including fuel cell, DC/DC converter, pressure cylinders etc. were implemented in a complex system and embedded on the vehicle platform. The own control system was developed and install and help to modify operating conditions of main component as well as safe operational data for later evaluation and optimisation. The complete prototype of vehicle with the implemented range extender is shown on Figure 3.

Fig. 3. The prototype of vehicle with fuel cell range extender via testing

CONCLUSIONS

In the first two years of project, the research team focused on the modeling, design and development of fuel cell range extender for multipurpose vehicle. Also, an analysis of the individual risks associated with the hydrogen range extender was prepared and the severity of their consequences and the level of risk were evaluated. Furthermore, the control philosophy of the vehicle as well as the design of the actual control electronics was completed.

The research team has mainly focused on the assembly of the hydrogen technology, verification of its complex functionality, installation of the technology into a prototype vehicle, development of the control unit and implementation of safety measures. First preliminary operational tests are underway with focus on efficient energy usage and control of heat distribution in colling system. A possible partial design modification resulting from the continuously evaluated test operation will be implemented in the following months.

ACKNOWLEDGEMENT

The development and research work is supported by Czech Ministry of Industry and Trade within the TRIO programme under project number FV40096.

ABSTRACT

Understanding about water transport in gas diffusion layer (GDL) is important for the water management of proton exchange membrane fuel cells (PEMFC). In this study, the in-plane water transport in a commercial GDL was visualized to investigate the transient characteristics using an optical imaging system providing a high spatial resolution. Previously proposed non-dimensional scaling model and specific interfacial area were obtained from measured wetted area, perimeter, and percolation pressure. In addition, the wetted area with time is graphically presented by spatiotemporal maps. It is newly found that the transition of flow characteristics including flow pattern and transport mechanism occurs. Results indicate that at higher compressions, the transition occurs earlier under lower saturation, and water invades along a more complex path through pores that are altered by compression.

Keywords: In-Plane Water Transport, Proton Exchange Membrane Fuel Cells, Gas Diffusion Layer

INTRODUCTION

The water management for the correct water content ranges is required for reliable proton exchange membrane fuel cells (PEMFC) operation because the proton conductivity of the polymeric membrane is directly related to the humidification levels [1]. Water produced by the electrochemical reactions is invaded into pores in the gas diffusion layer (GDL), and the occlusion of the GDL pores by water can lead to worse cell performance [2]. Although it is known that water transport through the GDL pores is mainly caused by the capillary effects [3], the mechanism of water transport through GDL pores is not fully understood.

To better understand water transport in the porous structure of the GDL, many studies focused on visualizing water percolation in this layer. The direct optical visualization technique, which is an affordable and easy-to-implement technique, is commonly employed to investigate water flows through GDL pores [4-6]. Most studies with an optical visualization method focused on the transports across the thickness of the GDL (in through-plane direction). While the through-plane transport is a realistic scenario of transport phenomena in an actual PEM fuel cell, both time and length are limited to observe fingering patterns due to the thin thickness of the GDL.

Several studies employed the optical method to visualize in-plane water transports through GDL pores to overcome the limitations of the through-plane observation [7, 8]. Compared to the through-plane transport, the in-plane percolation occurs over a longer time, increasing the experimental precision and providing more opportunity to identify flow patterns. The visualization of in-plane percolations with an optical method was employed to validate the drainage phase diagram [7] and an analytical scaling model [9]. In those studies, fluid evolutions through GDLs were observed only under the steady-state condition in a relatively larger displacement than the pore-scale due to the limitation of a spatial resolution. In the present study, the transient characteristics of the ex-situ in-plane water transport in GDL pores were observed by obtaining the pore-scale spatiotemporal variations of wetted regions with a measurement of percolation pressure.

EXPERIMENTAL APPARATUS

The schematic of the experimental set-up for the visualization of in-plane water transport is shown in Fig. 1. In order to obtain high-resolution images, a digital single-lens reflex (DSLR) camera (EOS REBEL T4i, Canon) was attached to a stereo-microscope (SMZ645, Nikon). This imaging system provided the corresponding field of view was 1.5 mm × 1.0 mm (5184 × 3456 pixels), and the equivalent spatial resolution was 0.289 μm/pixel. GDL sample was cut into 1.5 cm wide (W) square and placed between two transparent polycarbonate plates, and liquid water was injected from the bottom plate through a 250 μm diameter stainless steel capillary (U-111, Upchurch) with a syringe pump (NE-300, New Era Pump Systems Inc) at a flow rate (Q) of 100 μL/hour (inlet velocity v = 0.566 mm/s). The variations of the percolation pressure were monitored simultaneously using a pressure transducer (PX163-120D5V, Omega Engineering).

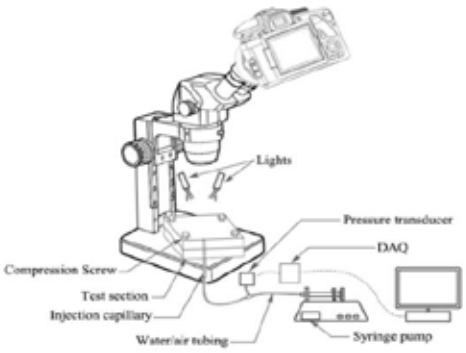

Fig. 1. Schematics of (left) the experimental set-up for visualization of in-plane water transport

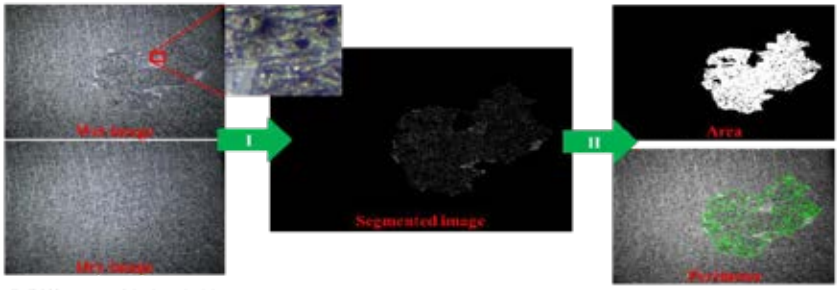

Fig. 2. Procedure of image processing. Wetted regions are segmented by subtracting wet and dry images with a threshold value. Area and perimeter of wetted regions are obtained after applying connected component analysis with methods of noise reduction and filling small holes

The digital image processing technique with an in-house-developed MATLAB code was applied, and the procedure of the image processing is shown in Fig. 2. As shown in the inset of Fig. 2, the spatial resolution of the employed imaging system is high enough to classify wet and dried regions on a pore scale. Wetted regions were segmented from difference images between wet and dry images with a threshold. Information on the wetted area and perimeter was obtained by applying connected component analysis after noise reduction and filling small holes.

RESULTS AND DISCUSSION

GDLs are generally compressed in practical applications, and different degree of compression leads to changes in flow inside the porous structure [8]. The effect of GDL compression with commercial GDL (Sigracet 29 BA having a thickness of 190 μm) on the water transport was investigated. The degree of compression was controlled with stainless steel shims having different thicknesses (δ). Temporal variations in wetted area normalized with the GDL sample width ($A^*=A/W^2$) during water transport are shown in Fig. 3(a). A* in all cases continuously increases, and the lowest compression (δ of 150 μm) had the largest A*.

A Non-dimensional scaling model for percolations in porous media was proposed by combining the time evolutions of pressure and the wetted area [9]. In the model, energy ratio ($Ce=p\delta^3A/Q\mu W^2$) and non-dimensional time ($t^*=t\sigma\delta^2/\mu W^3$) were defined where p is the pressure, μ is the dynamic viscosity, t is time, and σ is the surface tension. It was found that the Ce and t* have a linear relationship. Ce is plotted against t* in Fig. 3(b). Different from the previous observation of Ce-t* having a linear relationship with a single slope during the entire percolation process, Ce had two slopes where Ce linearly increased with a lower slope at a steady state after the rapid increase at initial states. Ce indicates the degree of energy dissipation or pressure-wetted area state. Both the time and Ce for the transition to the steady-state were decreased as the compression becomes higher. Therefore, the decreases of t* and Ce with the increase of compression represent that the transition occurs earlier under lower saturation.

The specific interfacial area defined as a ratio of the wetted perimeter and area (P/A) is commonly employed to investigate the fingering flow pattern, and normalized specific interfacial areas (P*/A*) are shown in Fig. 3(c). P*/A* rapidly decreased until at a specific time, thereafter it kept almost constant. P*/A* curve shifts to the upper left as the compression increases. Higher P*/A* indicates that more fingers or branches occur. Therefore, it is confirmed that the flow pattern is changed over time and water transport occurs along a more complicated path through pores split by compression.

The Ce variation for δ of 50 μm is compared to the variation of P*/A* in Fig. 3(d). It is known that P*/A* is strongly related to Ce, and the water transport pattern is changed when the phase of water transport changes to the steady-state. In order to compare wetted patterns with time, the distributions of the wetted area as time evolution are represented with spatiotemporal maps in Fig. 3(e). At the initial state, most of water comes from regions separated from previously wetted locations. In contrast, water mostly emerges from neighboring spots connected to already wetted regions.

Two typical mechanisms of transport were proposed by Nam and Kaviany [10] and Litster et al [5]. In the first mechanism, the flow is distributed like tree branches where both micro- and macro-transports simultaneously occur. In the second mechanism, the water transport is dominated by fingering and channeling which caused the formation of dead ends and breakthrough locations. Figs. 3(d) and (e) indicate that two different transport mechanisms are dominated in each state. Water transport is dominated by fingering and channeling at the initial state or lower saturation. In contrast, macro transport occurs along a preferential path at the steady-state or higher saturation.

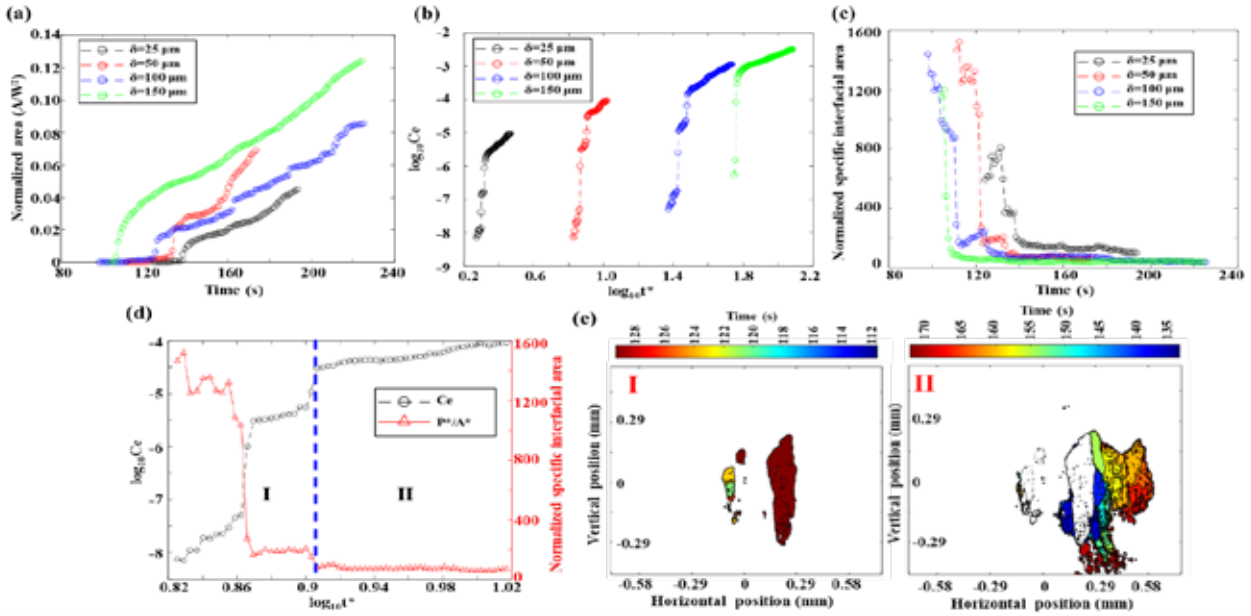

Fig. 3. Comparisons of (a) normalized wetted area (b) Ce, and (c) normalized perimeter with various compressions (16.7, 33.3, 52.6, and 78.9 % for shim thicknesses of 25, 50, 100, and 150 μm, respectively). (d) Time variations of Ce and P*/A* and (e) spatiotemporal maps at initial (left) and steady (right) states for shim thickness of 50 μm.

CONCLUSIONS

In the present study, the transient characteristics were investigated by visualizing the in-plane water transport in GDL. Ce-t* and P*/A* were analyzed, and the wetted area with time is graphically observed by spatiotemporal maps. It is confirmed that the transition of flow characteristics including flow pattern and transport mechanism occurs. As the compression becomes higher, the earlier transition with lower saturation level occurs, and water moves through pores broken by compression.

ABSTRACT

Performance reduction of polymer electrolyte membrane fuel cell caused by the degradation of gas diffusion layer (GDL) is hydrodynamically analyzed by comparing visualized two-phase flows in flow channels. GDL was chemically degraded using hydrogen peroxide, and the degree of GDL degradation was controlled by changing soaking time. The I-V curves for fresh and aged GDLs were compared using a commercial single cell, and the behavior of water in the cathode flow channel was visualized using a specially designed single cell having a transparent window. Two-phase flow characteristics were quantitatively compared after applying image processing technique to captured images. As a result of the experiment, it was confirmed that the hydrophobicity of GDL decreases as it degrades, absorbing the water generated inside, and reducing the efficiency by blocking the supply of reactants.

Keywords: Proton Exchange Membrane Fuel Cell, Gas Diffusion Layer Degradation, Flow Visualization, Reduced Hydrophobicity, Mass Transport Loss

INTRODUCTION

Hydrogen is regarded as an eco-friendly alternative energy source that can replace fossil fuels, and polymer electrolyte membrane fuel cell (PEMFC), which convert hydrogen to electric power has been widely studied in various fields because of its high energy efficiency. PEMFC has a fatal disadvantage in its long-term durability. Water management is critical to the suitable water content for the reliable operation of PEMFC, and poor water management causes reducing durability and performance by aging internal components [1]. GDL (Gas Diffusion Layer) plays a role in the fuel diffusion and electric and heat transfers, and it also effectively manages the water inside the PEMFC. It is known that GDL is degraded due to hydrogen peroxide and electrochemical oxidation during the practical operation of PEMFCs, and the GDL degradation leads to the increase of mass transport losses resulting in the performance reduction of PEMFCs.

The accumulation of liquid water accumulation causes performance degradation such as voltage instability, and many researchers have studied water distributions inside PEMFCs. Donggun Ko et al. investigated water accumulation inside PEMFC using X-ray imaging technique [2]. Juliane Kätzel et al. studied the relationship between the degrading time and droplet size distribution of GDL through neutron radiographs [3]. Although several studies have been conducted to quantify the liquid water in the cathode flow channel, the effect of flow patterns inside the flow channel on mass transfer is still not clear and systematic studies about the GDL degradation effect on flows are still lacking.

In this study, cell performances for pristine and aged GDLs were measured, and corresponding two-phase flow in the cathode flow channel was visualized using optical high-speed imaging. The relationship between flow pattern and cell performance was analyzed.

MATERIALS AND METHODS

To degrade GDL (SGL 39BB), it was immersed in a 35 wt% hydrogen peroxide solution at 90 °C. Three degradation GDLs with different degradation degrees were prepared by changing the immersion time to 4, 12, and 24 hours. Degraded samples were soaked in DI water for 24 hours to remove residual hydrogen peroxide and then dried in an oven. For the performance test, hydrogen and oxygen were supplied to the cell. The temperature of the cell was set higher than the supply pipe to prevent the condensation of the fully humidified gas. The polarization curves for fresh and aged GDLs were measured using a commercial unit cell with a 25 cm2 active area. For accurate performance comparison, the degraded GDLs were placed only at the cathode side, and fresh GDLs were used in the anode side. To investigate the direct effect of the GDL degradation on the mass transport loss PEMFC, two-phase flows inside the cathode flow channel were visualized using a specially manufactured single cell. End plate was changed with a transparent plate mead of quartz. Images of flows were captured for 8 seconds using a high-speed camera at a current of 1.0 A/cm2 where mass transport losses significantly occur.

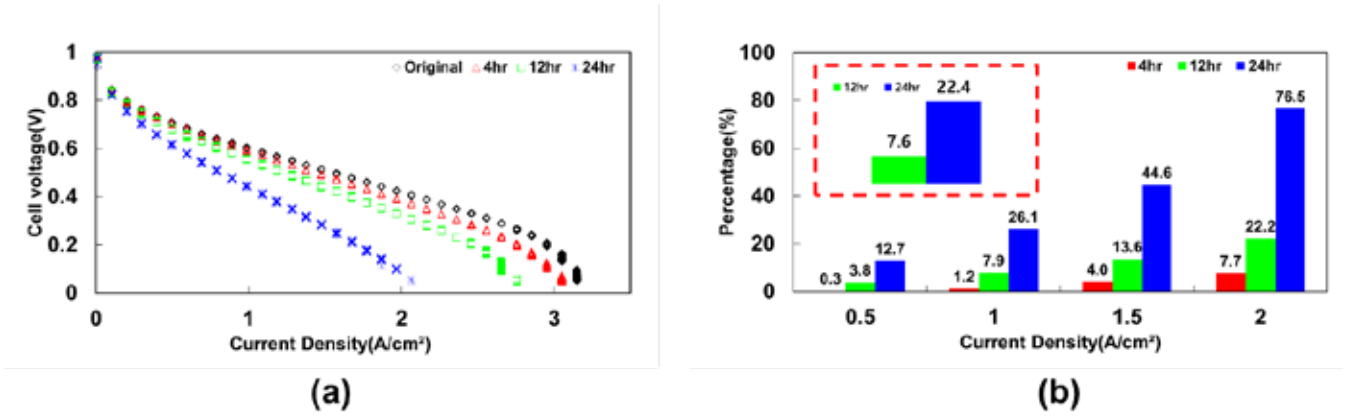

Figure. 1. (a) Comparison of the I-V curves and (b) The voltage decay ratio for degradation GDLs compared to the pristine GDL at various current densities (voltage decay ratio at 1.0A/cm^2 with the visualization cell is represented in red dashed box).

RESULTS AND DISCUSSION

Fig. 1(a) compares the I-V curves with various degradation GDLs. The voltages in all GDLs gradually decreased as the current density increased, and decreased rate of voltages with the increase of current became higher as the degradation time increased. Compared to voltages in the fresh GDL, the voltage reduction ratios in each GDL at various current densities are quantitatively calculated in Fig. 1(b). The voltage reduction rapidly increased as the degrading time was longer. The 4 hr degraded GDL had a small voltage reduction rate, and the maximum reduction was 7.7 %. Whereas, the performance reductions significantly occurred for the 12 and 24 hr GDLs, and the reductions reached to 22.2 % and 76.5 % at a current density of 2.0 A/cm^2, respectively. This means that the degradation of GDL strongly affects the performance of the cell, and it is important to understand the relationship between water transport and cell performance because the degradation of GDL mainly leads to the change of mass transport.

In order to confirm the similarity of operations in the visualization cell, the voltage reduction at 1.0 A/cm^2 was also calculated in Fig. 1(b). The voltage reduction was almost identical to that of the commercial cell. Therefore, the operations in the visualization cell are similar to those in the commercial cell. In addition to the operating condition, material properties (particularly the wettability of flow channels) strongly affect flows inside flow channels. Contact angles on Teflon film on the transparent plate side in contact with the gas channel in the visualization cell were measured, and both surfaces had similar contact angles. Fig. 2(a) shows the procedure of image processing with Matlab and Image J software to obtain information of two-phase flows. Flat field correction was firstly applied to captured images based on a background image obtained before operations, Thereafter, liquid water and gas were finally distinguished after performing threshold correction and noise reduction. Void fractions were calculated using areas of liquid and gas from 1000 images and compared in Fig. 2(b). Liquid water covered 5.9 % channel area in the fresh GDL. The degradation GDLs represented higher void fractions, and GDLs with the degradation time of 12 and 24 hours had 14.1 % and 21.2 %, respectively. This indicates that as the degradation time of the GDL increases, the liquid water remains in the gas channel longer.

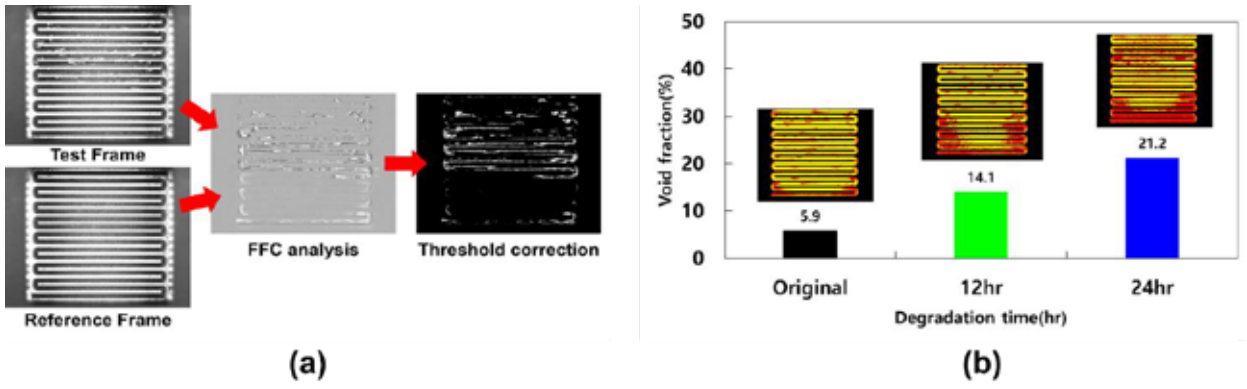

Figure. 2. (a) Procedure of image processing and (b) comparison of void fractions in the flow channel

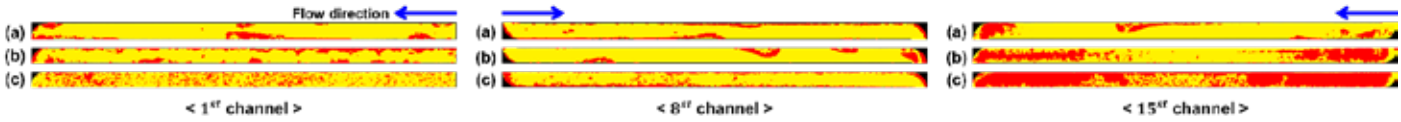

Figure. 3. Typical flows in channels near inlet, middle, and outlet for (a) pristine, (b) 12 hr, and (c) 24 hr degradation GDLs.

To compare flows more clearly, typical liquid and gas distributions are represented in Fig. 3. Yellow and red regions represents the gas and liquid phases, respectively. From inlet to outlet, the amount of liquid water increased and gas flow velocity decreased because gas supplied to MEA through GDL and produced water by a chemical reaction uniformly discharged from GDL and coalescence of droplets occurred. Therefore, flow characteristics vary according to channel locations, and images in three channels at different locations near inlet, midstream, and outlet are represented in Fig. 3. Slug flows where dropwise liquid water moved were observed near the inlet. Almost liquid water removed for the pristine GDL when droplet passed. Whereas, water remained on surfaces for degradation GDLs because the hydrophobicity of GDL surface decreased with GDL degradation, and the amount of remaining water was increased with the increases of the degradation time. As liquid water flows further, continuous liquid columns are formed due to droplet merging. Near the midstream, stratified-wavy flows with long liquid columns were observed, and the width of liquid columns increased as the degree of GDL degradation was higher. When liquid columns have a large width comparable to the channel width, severe channel flooding having liquid films completely covering GDL surfaces and moistures on the transparent plate occurs. When the severe flooding occurs, it is difficult to distinguish liquid and gas phases from optical images of liquid flows. Therefore, liquid continuously flows although no liquid region is distinguished in processed images. Near the outlet where severe flooding occurred, distributions of only remained water were mainly observed from image processing as shown in Fig 3, and liquid water accumulated at curved locations. The number of channels having a high accumulation of liquid water at bended location indicates the number of flooding channels, and the flooding channels increased with the increase of degradation time. These results show that more surface areas of GDL were blocked by liquid water which caused the reduction of supplying gas to chemical reaction sites resulting in the voltage drop.

CONCLUSIONS

In this study, the deterioration of PEMFC performance cause by GDL degradation was analyzed in terms of mass transport loss by visualizing two-phase flows in cathode flow channels. The reduction of hydrophobicity in degradation GDLs leads to the increase of water fractions because water was not completely removed from GDL surfaces when droplets passed. As liquid water flows further, continuous liquid columns are formed, and the width of those liquid columns gradually increased. Liquid column having large width caused the severe channel flooding, and the flooding region increased with the increase of the degradation time. More flooding channels with the GDL degradation leaded the increase of mass transport losses resulting in the decrease of PEMFC performance.

ABSTRACT

To further improve the overall marketability of fuel cell vehicles, improves are necessary in particular on the durability of the employed proton exchange membrane fuel cells. A key factor in durability is the distribution of mechanical stresses within the cells, which can be reduced by optimization of the bipolar plate rib structure. However, this optimization should not be performed without taking into account further physical quantities such as porosity and electric resistivity, as these have a direct impact on the cell performance. Therefore, this study presents a multiphysical simulation model based on a new analytical approach, which, in addition to the stress and strain distribution can also compute a variety of relevant physical quantities. The model's capability is demonstrated on an exemplary fuel cell layout. Compared to FEM models, the computation time can be reduced by a factor of up to 1000. Thus, extensive simulation studies with multi-criterial optimization can be implemented with reasonable computational effort.

Keywords: PEM Fuel Cell, Analytical Model, Gas Diffusion Layer, Mechanical Stresses, Physical Properties

INTRODUCTION

PEM fuel cell stacks consist of two main components, the solid bipolar plates (BPP) and the soft membrane electrode assemblies (MEA), which are alternately stacked and clamped. BPPs conduct the electric current between the cells, dissipate the waste heat from the stack, and distribute the reaction gases over the cell surface via the integrated gas channels. MEAs in turn consist of a proton exchange membrane (PEM) in the center, which is enclosed by a catalyst layer (CL) and a gas diffusion layer (GDL) on each side. The GDLs, which may account for up to 95 % of the MEA's overall thickness, are composed of carbon fiber fabrics [1]. Because of its physical structure, GDLs exhibit highly anisotropic mechanical properties. The carbon fibers conduct electricity and heat and provide mechanical support for the fragile membrane. Through the pores, gas and liquid water are transported.

One of the main reasons for early-stage failure of fuel cells is mechanical damage [2]. This risk can be reduced by optimizing the BPP rib structure with respect to the mechanical stress distribution. But changing the flow field may affect other relevant physical properties including the GDL's porosity and electrical resistance, both of which have a direct impact on cell performance. However, multicriterial optimization of the BPP structure is rare in the literature. The aim of this study is to address this research gap.

In this study, a novel analytical model (AM) is utilized. In contrast to the traditional finite element method (FEM), the equations are not solved interactively for defined grid nodes. Instead, explicit analytical formulations are established for each quantity. The computational speed is thus increased by a factor of up to 1000, with an average inaccuracy of less than 5 % [3]. Thus, instead of small segments, entire flow fields can be optimized with reasonable computational effort.

MODELING

Firstly, the general modelling approach of the AM is explained. Then the geometrical build-up and solving algorithm for the mechanical properties are introduced, followed by an extension of the model for other significant physical properties.

Analytical Modelling Approach

The modeling approach has been described in detail in our previous work Liu et Al. [3]. Therefore, only the basic assumptions and equations will be presented here: 1) The MEA is approximated as 100 % GDL; 2) The GDL is significantly stiffer in in-plane direction than in through-plane direction, thus, the in-plane strain can be neglected; 3) the BPP is assumed to be rigid; 4) only forces in the principal stress direction (y) are considered.

For an infinitesimal element, the force balance is as follows:

$$\frac{\partial \sigma_y(x,y)}{\partial y} = -\frac{\partial \tau_{xy}(x,y)}{\partial x} \quad (1)$$

The shear stress τ_{xy} on the GDL surfaces is directly related to the 2nd derivative of the GDL surface curve $h(x)$. With the shear modulus G_{xy} and the Timoshenko coefficient k, it holds:

$$\tau_{xy,surf}(x) = kG_{xy}\,\frac{\partial^2 h(x)}{\partial x^2} \tag{2}$$

For the sub-surface shear stress distribution, the following relationship is proposed:

$$\tau_{xy}(x,y) = \tau^{Top}_{xy,surf}(x)\left(0.5+\frac{y}{H_{GDL}}\right)^{n^{Top}} + \tau^{Bot}_{xy,surf}(x)\left(0.5-\frac{y}{H_{GLD}}\right)^{n^{Bot}} \tag{3}$$

n^{Top} and n^{Bot} are parameters fitted against FEM simulations and dependant on the rib radius R_{rib} and the initial GDL thickness H_{GDL}. The relation between GDL deformation and normal stress is governed by Hook's law:

$$\frac{h^{Top}(x)-h^{Bot}(x)}{H_{GDL}} = \frac{1}{E_y}\int_{y=-\frac{H_{GDL}}{2}}^{\frac{H_{GDL}}{2}} \sigma_y(x,y)dy \tag{4}$$

From these basic equations, by applying the specific boundary conditions, analytical equations for normal and shear stress as well as displacement and deformed height can be derived.

Model build-up and solving algorithm

Starting from pre-designed anode and cathode flow fields, one (or more) characteristic cross-sections are placed across a single fuel cell (Fig. 1a). Then, based on symmetry, recurring segments are identified (Fig 1b), which are subsequently divided into distinct regimes depending on the clamping state (Fig. 1c). In each regime, the top and bottom surfaces are each subjected to either the flat BPP bottom, the BPP edge, or are free under the channel. Some of the regime boundaries are geometrically determined and thus fixed, whereas others depend on the GDL deformation and are thus movable. The specific boundary conditions that apply in each regime simplify the set of analytical equations and ultimately the coupling conditions of the regimes allow the system to be solved. The moving boundaries are determined iteratively by setting the adjacent shear stresses equal.

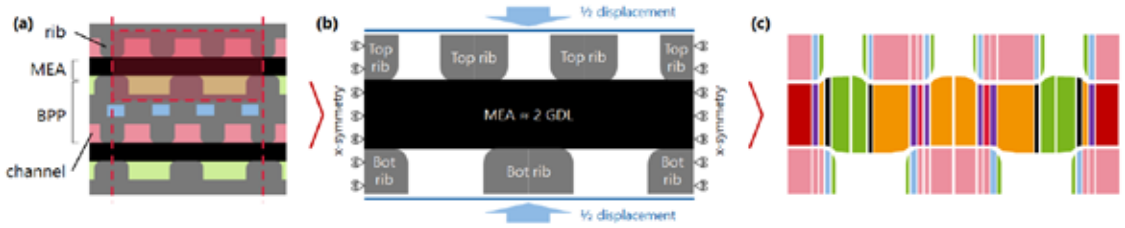

Fig. 1. Model build-up (a) cross-section through single cell (b) recurring segment (c) subdivision in regimes

The obtained simulation results are continuous and differentiable on the surfaces, but not in the interior of the GDL. This is because the model does not take into account the y-direction Therefore, the model employs a smoothing algorithm, that preserves the GDL surface curve and the y-force balance. Thus, continuous normal and shear stress distribution maps are obtained for the whole fuel cell cross section. This also enables further relevant physical quantities to be derived.

Muliphysical extension

The strain ε of a perfectly-elastic material can be determined from the normal stress by Hook's law. From the strain, distribution, the porosity ϵ (fraction of pore volume V_{pore} in total GDL volume V_{tot}) can be calculated:

$$\epsilon = \frac{V_{pore}}{V_{tot}} = 1-\frac{1-\epsilon_0}{1+\varepsilon} \tag{5}$$

From the porosity, further quantities are derived, e.g. the diffusivities of the individual gases and liquid water. Another quantity is the volumetric resistivity ρ , which can be determined from the effective conductivity κ_{eff} using the Bruggemann approximation, where κ_s is the bulk conductivity and m is the Bruggemann coefficient:

$$\rho_V = \frac{1}{\kappa_{eff}} = \frac{1}{\kappa_S\,(1-\epsilon)^m} \tag{6}$$

The contact resistance is mainly dependant on the pair of materials, the surface textures, and the contact pressure. It is usually measured experimentally. The overall material resistance results from the combination of volumetric resistivity and surface resistance.

MODEL DEMONSTRATION

To demonstrate the model's capability, an exemplary GDL is investigated multiphysically. The geometrical and physical input parameters are listed in Table 1 and reflect typical values for automotive fuel cells.

Table 1. Simulation Parameters

	Para	Description	Value / Unit			Para	Description	Value / Unit	
Geometrical	d_{rib}	Rib width (anode / cathode)	1000 / 600	µm	Physical	E_y	Young's Modulus of GDL	8.79	MPa
	d_{ch}	Channel width (anode / cathode)	500 / 400	µm		G_{xy}	Shear Modulus of GDL	8.55	MPa
	R_{rib}	Rib edge radius (anode / cath.)	150 / 200	µm		ϵ_0	Bulk porosity of GDL	0.5	-
	H_{gdl}	Thickness of gas diffusion layer	400	µm		κ_s	Bulk conductivity of GDL	1000	S/m

The geometrical conditions result in a recurrent segment of 3000 µm width with 2 channels on the top side and 3 on the bottom side. The simulation results for normal y-stress, porosity and volumetric resistivity are depicted in Fig. 2a-c. With the resistivity and the contact resistance interpolated from experimental data by Zamel et Al [4] and an assumed voltage of 1 V between the BPPs, an electrical potential field is (Fig. 2d).

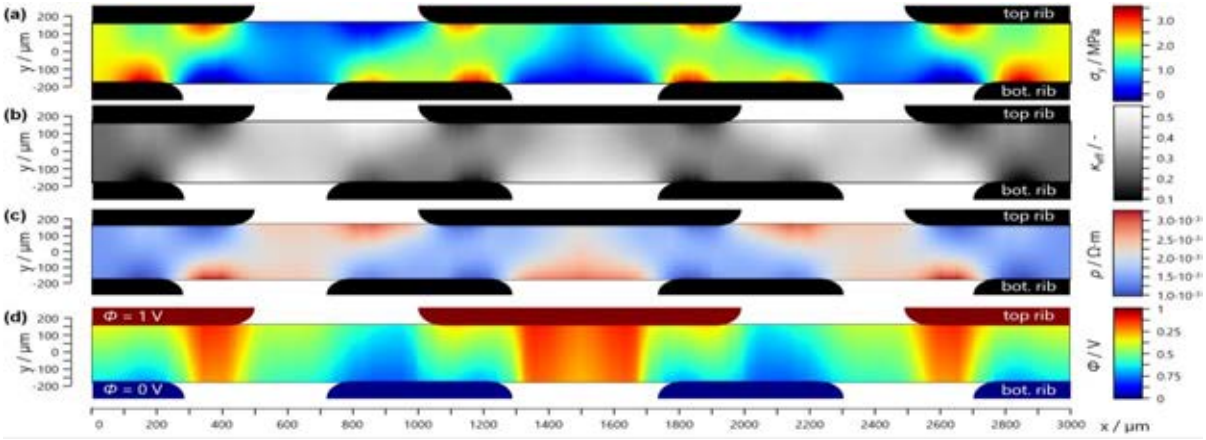

Fig. 1. Multiphysical analysis of a 400 µm thick GDL between 2 nonequal BPPs
(a) through-plane stress, (b) porosity, (c) volumetric resistivity, (d) electric potential.

CONCLUSIONS

In this study, a scalable simulation tool based on a novel analytical method for multiphysical analysis of PEM fuel cells is presented. Due to the high computational speed compared to FEM, extensive simulation studies of entire flow fields can be performed. In addition to shear and normal stresses, other relevant physical quantities, such as porosity and electrical resistance can also be calculated. Hence, the model is highly suited for multicriterial optimization tasks of BPP structures.

STUDY OF CATALYST LOADING AND GDL POROSITY GRADIENT VARIATION EFFECT TO PEMFCs PERFORMANCE THROUGH RECURRENT NEURAL NETWORK (RNN) DATA-DRIVEN ASSISTED MODELLING

Hanhui Lei
Northumbria University, UK

*Corresponding author e-mail: hanhui.lei@northumbria.ac.uk

The required electrochemical activities and mass transport rates of polymer electrolyte membrane fuel cell (PEMFCs) is different owing to the inhomogeneous distributions of reactants and products within the membrane electrode assemblies (MEAs). The graded distributions of Pt loading in the catalyst layer (CL) and porosity of gas diffusion layer (GDL) along the in-plane and through-plane directions significantly affect the spatial distributions of electrochemical reaction and mass transport rates, thus influence the cell performance, i.e., the limiting current density. Herein, we developed a two-dimensional (2D), multi-physics, two-phase flow model to investigate the gradients of linear change of two design parameters, i.e., platinum loading and GDL porosity at the cathode. Both the profiles of platinum loading and GDL porosity obey an elliptic function, leading to the linear variations of these two design parameters along the in-plane and through-plane directions (see Fig. 1a and 1b). Six parameters were selected, and their interaction was numerically studied by the recurrent neural network **(**RNN) model, including the 1). platinum loading at the CL-GDL interface at the cathode inlet, 2). platinum loading gradient along the in-plane direction (from inlet to outlet), 3). Platinum loading gradient along the through-plane direction (from CL-GDL interface to PEM-CL interface), 4). GDL porosity at the CL-GDL interface at the cathode inlet, 5). GDL porosity gradient along the in-plane direction (from inlet to outlet), and 6). GDL porosity gradient along the through-plane direction (from CL-GDL interface to GDL-channel interface). The combination of these parameters will generate 5000 permutations at the accuracy of 0.1. To reduce the computational time and resources of solving the mechanistic model, a data-driven surrogate model is developed based on RNN algorithm, which is used to assist the identification of the relationship between the chosen parameters and the objective function (current density at 0.1V).

Initial data acquisition was conducted using COMSOL Multiphysics for training and testing the surrogate model. Then Latin hypercube sampling method is used to guarantee the uniformity of sampling data. Random nodes are selected to train the RNN algorithm to accelerate the acquisition of simulation results. The RNN model achieved > 97% prediction accuracy (Fig. 1d).

The separate studies of platinum loading and GDL porosity indicated that the highest current density of 3.627 A cm^{-2} was achieved when 0.2 mg cm-2 platinum loading was implemented at the membrane-CL interface at the cathode inlet (point A in Fig. 1c) and at the CL-GDL interface at the cathode inlet (point B in Fig. 1c), while the platinum loading at the membrane-CL interface at the cathode outlet (point F in Fig. 1c) was 0.3 mg cm-2 and the GDL porosity was uniformly maintained at 0.7. On the contrary, the impact of GDL porosity on current density is monotonous - the current density increases with the increase of GDL porosity. When the inhomogeneous distribution of GDL porosity is simultaneously considered, the maximum current density of 3.820 A cm-2 was obtained when the platinum loading was 0.1, 0.2, and 0.8 at A, B and F in Fig. 1c, and the GDL porosity is 0.8, 0.8, and 0.8 at B, C and E, respectively. It also showed that machine learning algorithm could effectively assist the optimal design of PEMFCs.

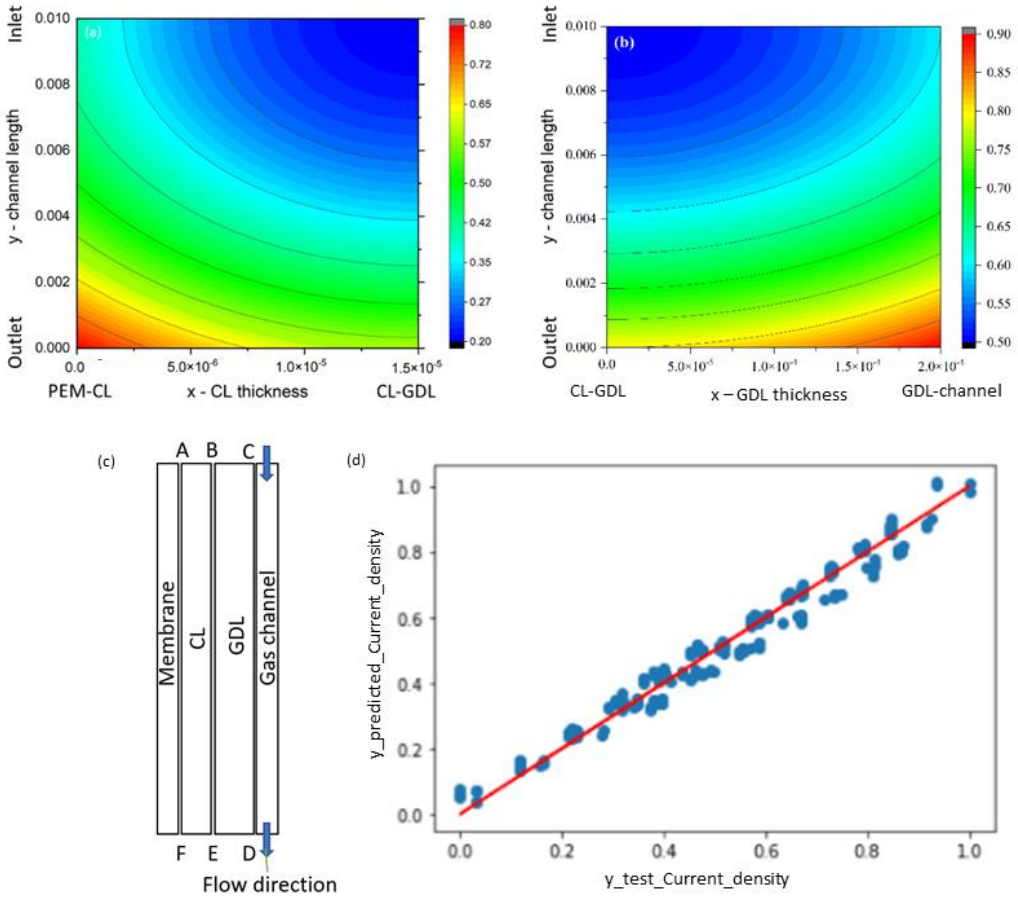

Fig. 1 Profiles of platinum loading (a) and GDL porosity (b) with $m_{Pt,0}$ = 0.2 mg cm^{-2}, $m_{Pt,1}$ = 0.4 mg cm^{-2}, $m_{Pt,2}$ = 0.6 mg cm^{-2}; and $\varepsilon_{GDL,0}$ = 0.5, $\varepsilon_{GDL,1}$ = 0.6, $\varepsilon_{GDL,2}$ = 0.8. Structure of device (c), AD edge is inlet, CB edge is outlet. Comparison of fitting results between prediction set and test set (d)

ABSTRACT

In this study, dual electrospinning were employed to fabricate proton conducting membranes comporising sulfonated silica, Nafion® and PVDF or P(VDF-TrFE) as the carrier polymers. Firstly, dual electrospinning was carried out to obtain dual fiber-based mats and converted into compact membranes via hot-pressing. After obtaining compact membranes, effect of various amounts of Nafion and type of carrier polymers were investigated. FTIR, ionic conductivity, ion exchange capacity (IEC), water uptake measurments and mechanical test were conducted for these membranes. Finally Membrane-electrode-assemblies (MEAs) were prepared via composite electrospun membranes and sprayed electrodes and fuel cell performance tests were performed. The fuel cell test showed that presence of sulfonated silica in the composite membranes improved the performance at lower humidity conditions. The P(VDF-TrFE)-Nafion®/S-SiO_2 membranes with 60/30 wt% Nafion®/S-SiO_2 compositon showed the best ionic conductivity and fuel cell performance.

Keywords: Dual Electrospinning, Sulfonated Silica, Sol-Gel, Membranes, PEM Fuel Cells

INTRODUCTION

Growing demand for clean energy, global warming issues and depletion of fossil fuel resources are highligheted the urgent need for developing alternative energy conversion systems in recent years. Among various clean energy technologies polymer electrolyte (PEMFC) fuel cells have received a lot of interest due to thier exceptional merits such as compact set-up, rapid start-up, and high efficiency [1]. However, significant design and component innovations are required to address the drawbacks and high cost of existing systems. In PEM fuel cells hydrogen and oxygen or air are fed into to anode and cathode side respectively as fuel to generate electricity, heat and water are being the only by products of this electrochemical reaction. The central part of a PEMFC is a proton conducting membrane, which is responsible for proton conduction from the anode to cathode as well as preventing of water and oxygen to diffuse back into anode side [2]. Perfluorosulfonic acid-based membranes (Dupont's Nafion®) are the most common membrane material for PEM fuel cell applications; but their proton conductivity is limited to fully humidified conditions, and they are expensive. As a result, research into finding a cost effective membrane material that can match the fundamental features of high proton conductivity, chemical stability and mechanical property under harsh cell operating conditions and efficient system performance is a hot issue [3].

Due to the this fact sulfonated silica-based composite proton exchange membranes for PEMFC applications were prepared via dual electrospinning method. Incorporation of hydrophilic sulfonated silica network to reduce the Nafion® amount results in minimizing excess water swelling problems of Nafion® membranes while maintaining ionic conductivity at low humidity levels, mechanical properties and fuel cell performance.

MATERIALS AND METHODS

Sulfonated silica was prepared via sol gel method using tetraethyl orthosilicate (TEOS) as silica precursor. PVDF and P(VDF-TrFE) were used as carrier polymers mixed with Nafion® solution. The prepared solutions were loaded in two different syringes. Sulfonated silica solution was electrospun from one side and PVDF-Nafion® or P(VDF-TrFE)-Nafion® from opposite side on to the rotating drum. The obtained mats were hot-pressed and annealed to convert dual fiber mats to the compact membranes. Figure 1 shows schematic of electrospinning set up and dual fiber-based membrane preparation steps.

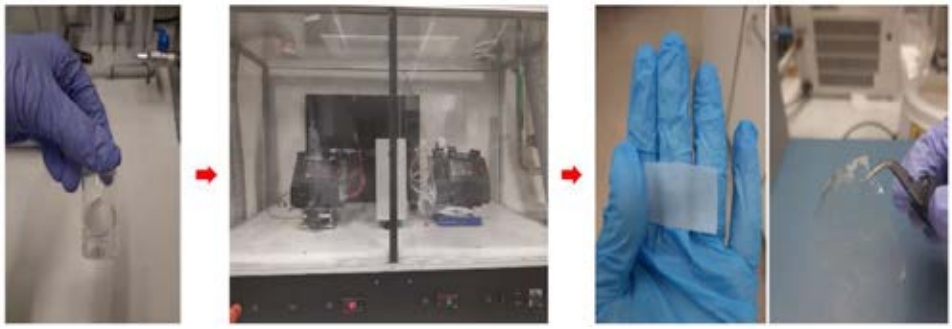

Figure 1. Schematic of dual-electrospuning setup and preparation steps of the membrane

Scanning Electron Microscopy (SEM) were conducted to investigate the morphology of resultant electrospun mats before and after hot pressing. Tensile tests were performed to analyzed mechanical properties such as Young's modulus and maximum elongation. Ion exchange capacity (IEC), water up-take (%) at room temperature were conducted prior to conductivity test. The conductivity tests at room temperature and 80°C were performed. The composite membranes with promising characteristics were selected for fuel cell test.

RESULTS AND DISCUSSION

Figure 2 shows the SEM images of resultant electrospun membrane prior to hot-pressing as well as hot-pressed compact membrane that reveals a homogenous fibrous morphology for resultant mats and uniform dense membrane without pores and cracks after further manipulations.

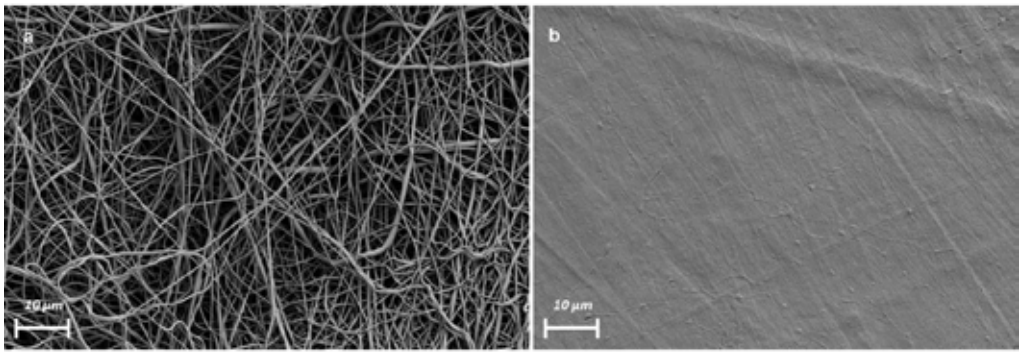

Figure 2. SEM images of P(VDF-TrFE)-Nafion/S-SiO_2 electrospun mat a) before hot-pressing and b) after hot-pressing

CONCLUSIONS

In this work, dual electrospinning method were used to synthesize sulfonated silica Nafion®-based composite membranes. P(VDF-TrFE) as the reinforcing polymer was used for the first time for this purpose in the literature. The obtained proton exchange membranes were characterized to find out the promising membrane for PEM fuel cell application at low relative humidity condition. The water-uptake and ionic conductivity of the membranes is reduced with decreasing the amount of Nafion in membrane composition for either using PVDF or P(VDF-TrFE) as carrier polymers. The highest ionic conductivity of 132 mS/cm was achieved for P(VDF-TrFE)- Nafion®/S-SiO_2 membranes with 60/30 wt% Nafion®/S-SiO2 at 80°C and 100% relative humidity. Furthermore, unlike to prinstine Nafion membranes, these membranes showed no significant reduction in ionic conductivity or fuel cell performance when relative humidity was reduced up to 60%. Therefore, we can conclude that these membranes can be considered as promising candidate for low humidity PEM fuel cell applications.

ABSTRACT

Clay (kaolin, bentonite) doped Nafion composite membranes are considered as an alternative material for proton exchange membrane fuel cell (PEMFC). In this study, 10% clay (wt./wt.) doped Nafion membranes were prepared by solution casting method and characterized by water uptake capacity, ion exchange capacity (IEC), X-Ray diffractometry (XRD) and Fourier transform infrared spectrometry (FT-IR). The results showed that kaolin and bentonite doped Nafion membranes can be evaluated for PEM fuel cells.

Keywords: Nafion, Kaolin, Bentonite, Membrane, Fuel Cell

INTRODUCTION

The membrane is considered the key component for the operation of Proton exchange membrane (PEM) fuel cells [1]. The main function of PEM is to transfer protons from the anode to the cathode and to prevent mixing of reactants (H_2 and O_2). Therefore, an ideal PEM should have high proton conductivity, low permeability to fuel, excellent mechanical and chemical stability, and high durability [2]. Nafion is the most widely used electrolyte in PEM fuel cells due to its chemical and electrochemical stability and high proton conductivity [1,3]. However, the proton conductivity of Nafion above 80 °C is significantly reduced as it depends on the hydration level of the membrane [3]. In order to improve the thermal stability and water uptake properties of the membrane, hygroscopic particles such as SiO_2, ZrO_2, TiO_2, ZrP and clays with high SiO_2 content are included in the structure of the membrane [4]. Composite membranes are of interest because most of the additives used can operate at much higher temperatures than pure polymers. The main roles of fillers in composite membranes are to retain water within the membrane to improve proton conductivity and ion exchange capacity while maintaining good mechanical and thermal stability [5]. Although there are studies in the literature with sepiolite, laponite and zeolite doped composite membranes, no studies have been found with kaolin and bentonite. In this study, composite membranes containing kaolin and bentonite added to Nafion were prepared by solution casting method and characterized by water uptake capacity, IEC, XRD and FTIR.

MATERIALS AND METHODS

Materials: In membrane synthesis, Nafion solution (Ion Power, D2021, 20% polymer content) was used as a polymer and N-N Dimethylformamide (DMF, 99%, Sigma Aldrich) was used as a solvent. Sulfuric acid (H_2SO_4, 95%, Merck), hydrogen peroxide (H_2O_2, 30%, Merck), sodium chloride (NaCl) and sodium hydroxide (NaOH, 85%, VWR Chemicals) was used without further purification. The bentonite and kaolin were supplied from a commercial company in Turkey.

Membrane preparation: Nafion/clay composite membranes were prepared by the solution casting method. The solution is prepared with a 1:2.5 ratio of Nafion solution:DMF is mixed for 30 minutes. The specified amount of clay is added to the mixture and homogenized for 1 hour by ultrasonic. The solution is poured into a glass petri dish and dried at 80 °C for 20 hours, then at 100 °C for 4 hours, then membrane was removed using deionized water. Composite membranes containing 10% kaolin and bentonite were labeled as Nafion-K10 and Nafion-B10 respectively. For comparison, recast Nafion and commercial Nafion-212 were used. Recast Nafion was prepared from a 20 wt.% Nafion solution by the same steps without the addition of any clay and labeled as Nafion. Then, as a protonation process, all membranes were treated with hydrogen peroxide, deionized water, sulfuric acid and deionized water at 80 °C for 1 hour. Each membrane was stored in deionized water.

Characterization techniques: The water uptake of the membrane was calculated from the weight difference between the dry and wet weight of the membrane. The membrane was dried at 105 °C until it reached a constant weight. The dried membrane was kept in deionized water at room temperature for 24 hours. Eq. 1 was used to calculate the water uptake capacity of the membranes. Where W_u, W_w and W_d are the water uptake capacity, wet and dry weight of the membrane, respectively.

$$W_u = \frac{W_w - W_d}{W_d} \times 100 \quad (1)$$

IEC of the membranes were measured by the acid-base titration method. Membrane samples (0.05 g) were kept in 10 mL of 3 M NaCl solution for 24 hours to exchange H^+ with Na^+ ions. NaCl solution containing H^+ ions were titrated using 0.01 M NaOH by adding phenolphthalein indicator. The IEC of the membrane samples was calculated using Eq. 2.

$$IEC = \frac{Volume\ of\ NaOH\ Consumed\ x\ Molarity\ of\ NaOH}{Weight\ of\ dry\ membrane} \quad (2)$$

The crystal properties of the membranes were investigated with the Rigaku Rint 2200 brand XRD device operating with 40 kV voltage and 30 mA current. Cu-Kα radiation was used as the X-ray source. XRD analyzes were performed at a scanning angle of 0.02° and a scanning speed of 2°/min and a Bragg angle of 2-70°.
Thermo Science Nicolet IS10 FT-IR device was used to detect the chemical functional groups of the membranes at 64 scan rates and 4 cm^{-1} resolutions and 525-4000 cm^{-1} scanning range.

RESULTS AND DISCUSSION

The proton conductivity of the membrane is highly dependent on the water uptake of the membrane. Clays are an extremely hygroscopic material, and these properties affect the water uptake. The water uptake capacity of the membranes at room temperature was calculated according to Eq. 1 and is presented in Fig. 1. When the results are examined, the water uptake of the Nafion membranes is clearly higher than that of the recast Nafion. With the addition of kaolin and bentonite, the water uptake capacity increased 2.7 and 2.4 times. This increase may be related to the water affinity between the additive and the polymer. Another reason is that the high water content facilitates the conduction of protons across the membrane [6].
The IEC values of the membranes were calculated by Eq. 2. Looking at Fig. 2, the IEC value of recast Nafion and Nafion-212 is higher than composite membranes. Compared with Nafion, the decrease in IEC in the composite membrane can be attributed to the interaction of the clay nanoparticles with the sulfonic groups of the polymer matrix. Despite the reduction of available sulfonic sites after the addition of additives, the conductivity values of such membranes may not be affected. This is due to the fact that the incorporation of clays into the Nafion matrix increases water uptake and thus proton conductivity in composite membranes [9].

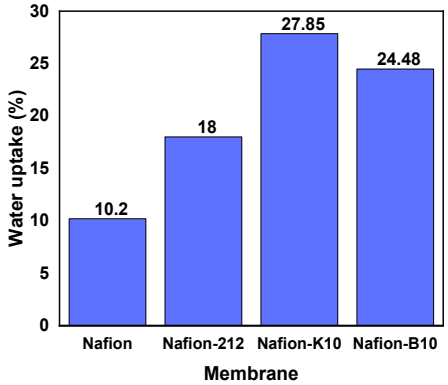

Fig. 1. The water uptake of the membranes

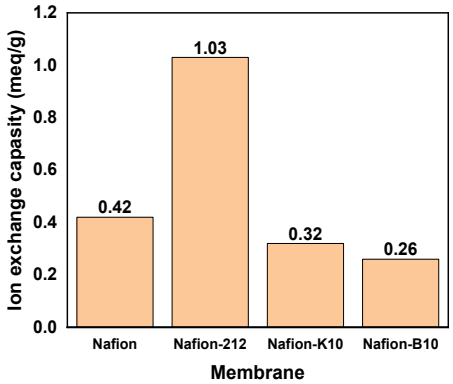

Fig. 2. Ion exchange capacities of membranes

Recast, commercial and composite Nafion membranes were characterized by FTIR to confirm changes in Nafion groups. Fig. 3 shows the spectra of Nafion 212 membrane and recast Nafion and composite membranes in the 525–4000 cm^{-1} range. In the FTIR spectrums, symmetrical O–S–O bending at 512 cm^{-1}, stretching of C-S groups at 632 cm^{-1}, C–O–C stretching at 976 cm^{-1}, symmetrical S–O stretching at 1060 cm^{-1}, symmetrical C–F stress bands at 1145 cm^{-1} and C–F stretch bands at 1201 cm^{-1} are seen. It also shows O–H stretching vibration at 3456 cm^{-1}, which corresponds to physically adsorbed water, and at 1630 cm^{-1}, which is attributed to the O-H bending vibration of free water molecules. It is seen that the Nafion-B10 membrane is more prominent than the other membranes. This may be due to clay doping, which increases the water content in composite membranes [7]. Due to the tensile bands of S=O and the tensile bands of the C-F bonds, it showed very strong and wide absorption bands characteristic of Nafion around 1200 and 1145 cm^{-1}. These bands were observed in the same IR region of the main and intense bands of the phosphonate compounds, and hence the Nafion bands overlap with the characteristic phosphonic acid bands [1]. The spectra of the composite membranes show all characteristic bands attributed to Nafion without shifts or modifications. The absence of characteristic bands of additives occurs due to the low concentration of clays in the polymeric matrix [3].
XRD analyzes were performed to determine the crystal phases of the membranes (Fig. 4). It was also used to confirm whether the clay particles were indeed incorporated into the membrane by the casting process. Nafion has a semi-

crystalline structure and shows two peaks, one at 19-20° (large crystalline) and 39-40° (small amorphous peak) [2]. Two main peaks observed at 17.6° and 38.8° appear in all membranes and are attributed to the characteristic peaks of Nafion [2,4,5,7]. It was observed that the positions of these diffraction peaks changed slightly, and the intensity decreased with the clay.

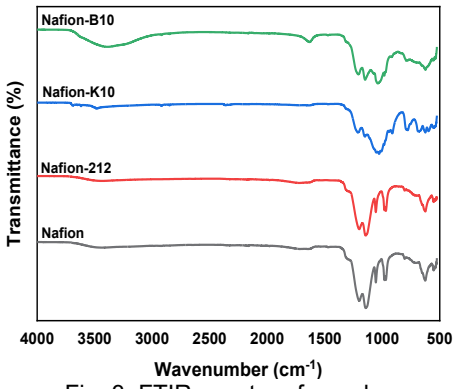

Fig. 3. FTIR spectra of membranes

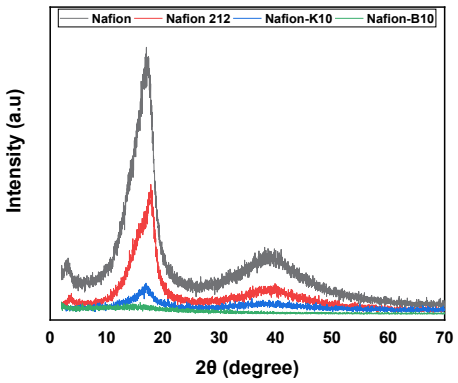

Fig. 4. XRD pattern of membranes

CONCLUSIONS

Kaolin and bentonite doped composite membranes were prepared by solution casting method and characterized by water uptake capacity, ion exchange capacity, FTIR, and XRD. Depending on the found results, it was determined that the clays were successfully added to the membrane structure. The results of XRD and FTIR show that clays be added to the structure. Although the ion exchange capacity (0.26-0.32 meq/g) values of composite membranes are not in the expected results range, the water uptake capacity (24.48%-28.85%) results are compatible with the literature. Since the proton conductivity in the membranes is provided by two different mechanisms, it is planned to make a comparison by making proton conductivity and cell performance characterizations in the future study for a more accurate result.

ACKNOWLEDGEMENT

This study was supported by Eskişehir Technical University Scientific Research Projects Commission (Project no. 21DRP138) and the Council of Higher Education (YÖK) 100/2000 Doctoral Scholarship Program.

ABSTRACT

The structural morphology of high surface area carbon (HSC) on which both the platinum catalyst and ionomer are dispersed is very complex and critical for understanding the transport of oxygen (O_2). This study aims to develop a model to simulate O_2 transport in the cathode catalyst layer of proton exchange membrane fuel cells fabricated using HSCs. A stochastic two-dimensional multiscale domain, including micro and mesopores, and connecting throats is constructed. Steady state coupled transport and electrochemical reaction models are then implemented into using transport properties estimated using in-house atomistic level calculations. This study provides a multi-scale approach by relating the pore-scale approach with the atomistic level model, allowing to represent a large modeling domain at higher detail. Oxygen concentration in HSC surfaces is predicted for dry and flooded cases. Results show an effective diffusivity of $8.752 \cdot 10^{-8}$ m^2/s and $4.851 \cdot 10^{-8}$ m^2/s for the flooded case and non-flooded case, respectively. Oxygen concentration drops significantly when micropores are flooded, consequently Pt utilization decreases.

Keywords: Pore-scale modeling, PEMFC, catalyst layer, transport phenomena, multiscale modeling, high surface carbon area

INTRODUCTION

Proton exchange membrane fuel cells (PEMFCs) are a competitive power technology because of their benefits such as low-temperature operation, low-carbon emission, and rapid start-up. However, the wide commercialization of this technology still depends on cost and lifetime, which must become competitive with traditional power technology (e.g., internal combustion engine) [1]. Here, the critical component is the Pt group metal (PGM) catalyst that contributes to a significant portion of the cost of fuel cells. The development of the PGM catalyst layer has progressed towards enhancing Pt utilization. High surface area (HSA) carbon support is a promising material to enhance the reaction area due to its high porosity (i.e., three times greater than typical carbon support [2]). HSA carbon consists of the hierarchical microstructure of the carbon support upon which the Pt-alloy particles are dispersed, as shown in Figs. 1a and 1b. This HSA carbon support is bounded by an ion-conducting polymer (ionomer). Microtomography studies reported that up to 85% of Pt particles can be inside the micropores of the carbon particles, which are in the range of 2-10 nm [3]. Oxygen typically needs to pass first through the ionomer film and transport through these micropores to reach the catalyst inside of the HSA. In a typical HSA carbon support, the carbon particles have macropore regions of dimension ~20 nm in diameter that could be only accessible by means of the micropore openings of dimensions ~2 nm on its surface.

Cetinbas et al. [4] investigated the effects of carbon microstructure and relative humidity (RH) on the local oxygen transport resistance. Porous carbon agglomerate was reconstructed using a hybrid approach that combines a nano-CT image with statistical information from TEM images and porosimetry techniques. Direct simulation was then performed on the reconstructed geometry to determine local oxygen transport resistance (R_{O2}) for different structures. When the primary pores are filled with condensed water at various levels of RH, the agglomerate size and shape become significant factors determining R_{O2}. If primary pores are on the other hand dry, ionomer resistance becomes more dominant on R_{O2}. Ramaswamy et al. [2] studied the effect of carbon structure on the high current density transport losses in PEMFC cathode under various relative humidities. They compared Ketjen Black® - a high surface area carbon - and Vulcan - a medium surface area (MSA) carbon. Measured H_2/O_2 polarization curve showed that HSA (Ketjen Black®) is superior in terms of kinetic activity of the catalyst even though micropores lead to the additional resistance.
Pore network model (PNM) is an effective method for describing transport phenomena inside porous media due to its capability to resolve even nanopores in the simulation [5]. We utilize PNM approach here to investigate O_2

transport in the HSA carbon microstructure considering transport through the ionomer and micropores for flooded and non-flooded cases.

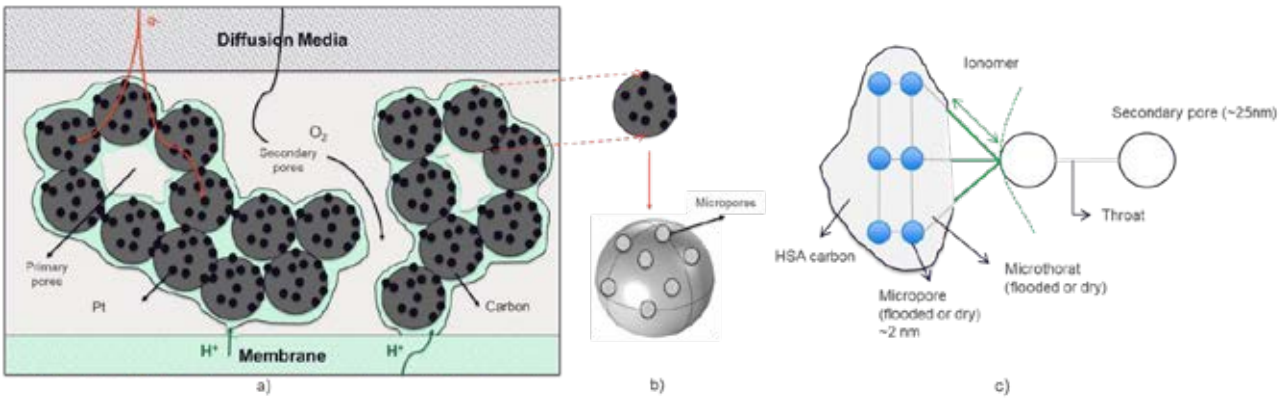

Fig. 1. a) Schematic description of a typical PGM electrode b) HSA carbon support c) PNM representation considered in this study

MODELING APPROACH

PNM is an alternative modeling approach to the volume-averaged approach (e.g., CFD model) to model porous media. In PNM, the porous domain is idealized as interconnected pores and throats. Therefore, the transport is modeled as a resistor network. Capillary transport in porous media can also be described similarly using the percolation theory concept to investigate multiphase transport [6,7]. This approach can be used for complex transport phenomena in many engineering applications (e.g., fuel cells, batteries, CO_2 storage, electrolyzers).

In this study, the PNM approach is used for the understanding of O_2 transport in a multiscale porous cathode structure including secondary pores, primary pores, micropores, and ionomers. To obtain a multiscale structure, first the secondary pores are constructed based on statistical distributions. Then some secondary pores are replaced by micro domains, which include micro-pores and throats. Here, the micropores and throats represent narrow porous region inside carbon, where Pt particles are embedded, as displayed in Fig. 1c. The O_2 transports from the secondary pore region passing through the ionomer and reaches the micropores. Therefore, the ionomer resistance is implemented between micro- and secondary pores. The steady-state reactive transport model is implemented into this domain considering transport properties estimated using in-house atomistic DFT level calculations. For this purpose, the diffusion coefficient due to binary and Knudsen is calculated for secondary pores, while atomistic level calculations are used for estimation of the diffusion coefficient in micropores (as shown in Fig 2). Therefore, the conductance which is a function of geometry and diffusion coefficient for each pore-throat-pore assembly is calculated. The kinetic is modeled using the form of Butler-Volmer equations for cathode reactions. Here, one of the important assumptions is that the reaction terms are assigned for only micropores.

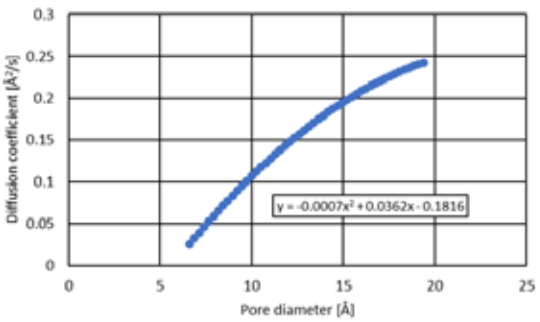

Figure 2 Diffusion coefficient in flooded micropores based on atomistic DFT level calculations

RESULTS AND DISCUSSION

The O_2 transport simulation is performed for a 4x4 μm^2 multiscale electrode domain, as illustrated in Fig 3a (dark black regions → micro domain with 10x10 micropores). The arbitrary pore and throat size distribution for secondary pore domain ~20 nm) micro domain (~2 nm) is assigned. In the geometry considered in this study, outlet of the geometry is bound to membrane, while inlet is bound with the gas diffusion layer.

The effective diffusivity is calculated as $8.752 \cdot 10^{-8} m^2/s$ and $4.851 \cdot 10^{-8}$ m^2/s for flooded and non-flooded case, respectively, that are three order magnitude smaller than binary diffusion coefficient of O_2 in N_2. The reason can be explained with geometry effect (Knudsen effect due to micropores) and additional phase resistant (e.g., ionomer, water). The structural characterization shows that the micropore volume fraction (which is the ratio of the volume of micro domain to bulk domain) is 1 %. Micro domain area is found as $1.21 \cdot 10^{-13}$ m^2 in an electrode volume of $1.6 \cdot 10^{-18}$ m^3. The concentration distribution is shown in Figs. 3b and 3c for non-flooded and flooded micropores, respectively. As expected, the O_2 concentration is consumed dramatically under the flooded case that is subjected to the reaction in micropores and drops to almost 0. These results also shows that utilization of interior Pt decreases significantly after ~ 1 μm distance from the membrane because the O_2 concentration is not satisfied for the non-flooded micropore case. On the other hand, 2 μm distance from the membrane is an ineffective in terms of Pt utilization for the flooded micropore case even though effective diffusivity increases for in this case. It is because of that the reaction sink term specified for microdomain consumes O_2 concentration significantly in this case.

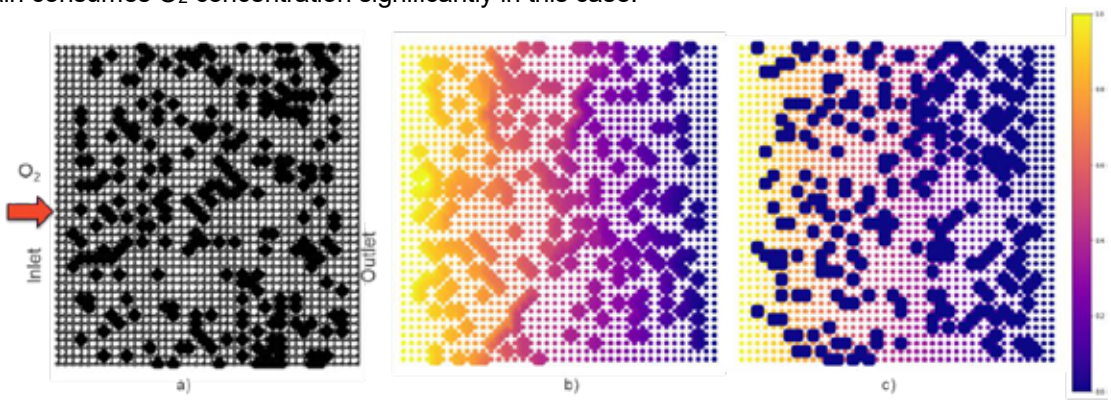

Figure 3 a) the multiscale structure considered in this simulation, b) O_2 concentration distribution for non-flooded case, c) O_2 concentration for flooded case

CONCLUSIONS

PNM is used to describe O_2 transport in a multiscale catalyst layer constructed stochastically. The model is incorporated with atomistic level calculations. The effective diffusion coefficient is found as $8.752 \cdot 10^{-8}$ m^2/s and $4.851 \cdot 10^{-8} m^2/s$ for flooded and non-flooded cases, respectively. The simulation is performed for dry and flooded scenarios. The oxygen concentration drops significantly when micro domain is flooded as the reaction is specified for micropores even though effective diffusivity in flooded case is greater than non-flooded case, and thus the Pt utilization decreases.

ABSTRACT

Here, we report on characterization routines for carbon blacks both in terms of their intrinsic properties resulting from their synthesis history and process-related quality parameters. We establish characterization methods based on analytical centrifugation which work fast, reliable and at low cost and were developed in-house. We apply them to analyze CB particle properties (particle size distribution, morphology, surface properties) and link them with ink properties. First results indicate that small deviations in feed quality can be determined by our stability trajectories. By the same methods, we found out that mixing parameters in the course of ink preparation greatly influence stability parameters which are important in the subsequent process chain of electrode production.

Keywords: Carbon Black, PEMFC, Stability Trajectories, Analytical Centrifugation, Hansen Solubility Parameters

INTRODUCTION

In recent years, technical carbon blacks (CB) increasingly become a valuable and attractive material in the context of various energy related applications. Due to their low cost, abundance, favorable intrinsic properties (e.g. conductivity, specific surface area) and flexibility regarding mentioned intrinsic properties, they are heavily used as conductive additives in battery electrodes or as conductive support for electrocatalysts in fuel cells [1]. Usually, they are produced via incomplete combustion of carbon sources (oil or gas) and possible post-processing steps (e.g. surface functionalization). The flexibility in their properties is a direct result of the variety in production and post-processing steps that are applied by the numerous manufacturers. Although initially seen as an advantage, the broad range in material properties can at the same time raise problems for users in the subsequent value chain who focus on large-scale production of proton exchange membrane fuel cells (PEMFC) or lithium-ion batteries (LIB). Possibly facing fluctuations in product quality, they seek fast, reliable and standardized measures for CB characterization in order to keep control over their processes which eventually define final electrode properties.

So far, characterization of commercial CB involves several techniques including N_2 physisorption and determination of sulfur content. For an additional characterization, specialized techniques for distinct questions play a role. For example, thermogravimetric analysis or Boehm titration can be used to identify surface functional groups [2]. These methods have in common that they are quite time-consuming and costly. Additionally, they are not optimized for the targeted electrochemical application fields. To this end, we report on standardized characterization routines for CB materials designed for fuel cell and battery application. By mainly applying analytical centrifugation (AC), we identify parameters like particle size, morphology and surface properties that are influential for the overall value chain in electrode manufacturing. This helps to minimize the effects of material inherent property fluctuations as well as process related fluctuations on final electrochemical performance.

MATERIALS AND METHODS

The primary use of analytical centrifugation has the advantage that CB powder properties can be assessed in liquid / dispersed state. Since formulation investigations play a major part in the mentioned electrochemical applications, AC measurements enable investigations under real process conditions with technically relevant solid concentrations [3,4]. For a first assessment, we investigated the dispersibility of CB in 14 probe liquids at diluted solid concentrations in order to deduce Hansen solubility / dispersibility parameters (HSP, Table 1) [5].

We derived stability trajectories and S scores (Fig. 1a & 1b) [3,4] based on the sedimentation behavior of CB in the listed PL measured via AC. In subsequent considerations, we used S scores for ranking the PL, calculated HSP based on this ranking and compared this HSP derivation with the standard method by Süß et al. [6].

Table 1: Overview on selected probe liquids (PL) for dispersibility tests of CB.

No.	Probe liquid	Abbreviation
1	2-propanol	IPA
2	methanol	MeOH
3	acetonitrile	ACN
4	ethyl acetate	EA
5	acetone	Ace
6	dimethyl sulfoxide	DMSO
7	dimethylformamide	DMF
8	tetrahydrofuran	THF
9	1-methyl-2-pyrrolidone	NMP
10	1,4 dioxane	Diox
11	2-(butoxyethyl)-acetate	BAc
12	triethylamine	TEA
13	p-xylene	Xyl
14	n-hexane	Hex

Furthermore, our investigations were expanded towards full inks. We determined the effects of mixing intensity variation during ink preparation by applying stability trajectories as well as rheological characterization. The initial investigations predominantly consisted of lab-scale mixing techniques using simple magnetic and / or sonication methods. Other methods are planned for future studies.

RESULTS AND DISCUSSION

Since we aim at developing robust and reliable routines for CB characterization, our first investigations entailed reproducibility tests. Not only repeated measurements at the AC for the same batch of a selected CB were conducted but different batches of the same material were measured under identical conditions. Fig. 1a & 1b illustrate the results in this context. A very good reproducibility of dispersion stability analysis for two Vulcan XC72 batches in selected PL is displayed. With minor deviations in the stability trajectories, it can be stated that with this method changes in material properties can be detected in a fast way.
For full fuel cell inks, it is apparent that the type of mixing technique as well as the mixing intensity have a large influence on the stability of the obtained inks (Fig 1c & 1d). Simple magnetic stirring produces the least stable inks. Stability increases with the use of sonication methods, but probe sonication at high intensities seems to be disadvantageous for FC ink preparation in terms of stability. Rheological data confirm these findings by showing a comparable, yet not identical trend with the applied mixing techniques. From MS (magnetic stirring) → UB (ultrasonic bath) → UB+S20 (ultrasonic bath + 20% probe sonication intensity) → UB+S70 (ultrasonic bath + 70% probe sonication intensity), a general decrease in dynamic viscosity within a small range is observed for the mainly Newtonian inks. The effect on particle size by the applied mixing method is one factor that can describe the trend in viscosity where breakage of aggregates/agglomerates possibly enhances flow properties. Similarly, possible effects on the chemical stability of other additives like the ionomer can be used as explanation. A degradation and shorter chain length of the polymeric ionomer due to critical intensity applied by sonication might change the overall flow properties as well.

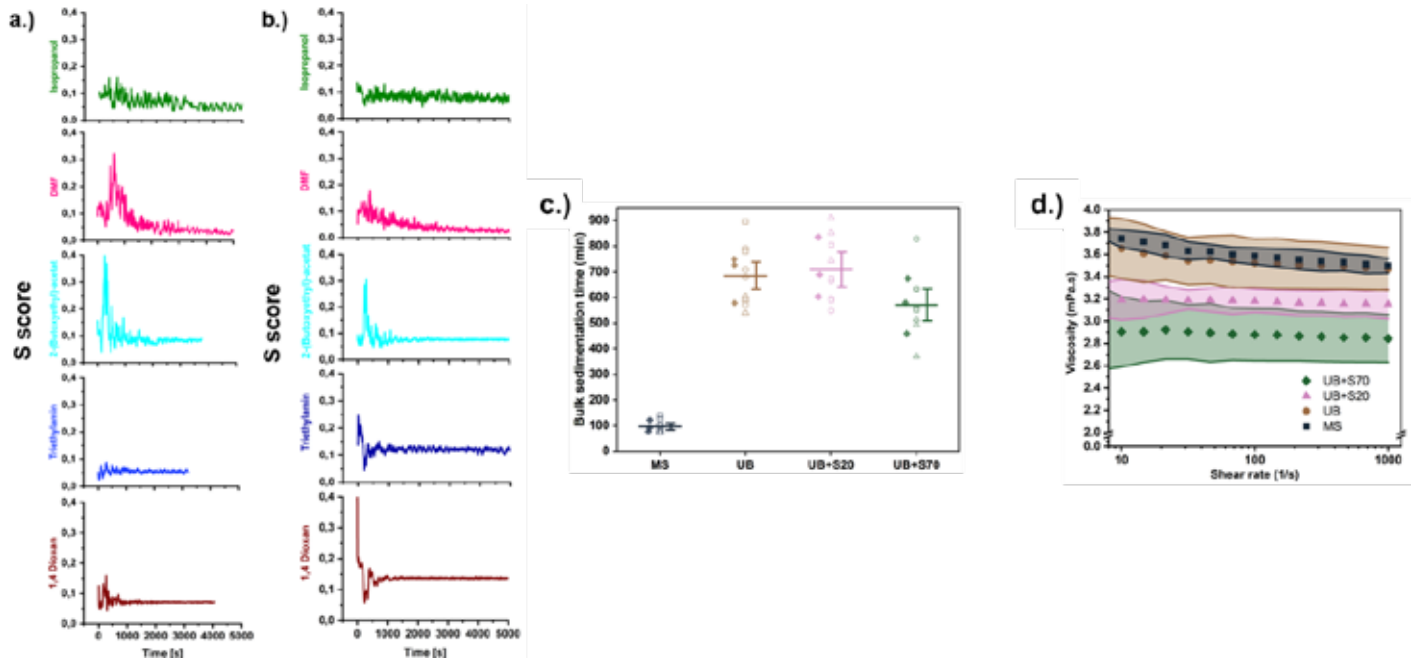

Fig. 1: Stability trajectories for two different batches of Vulcan XC72 in five selected probe liquids (a.) and b.)); bulk sedimentation times for full inks as function of applied mixing techniques (MS: magnetic stirring; UB: ultrasonic bath; S20: probe sonication at 20% intensity; S70: probe sonication at 70% intensity) and intensity derived from stability trajectories (c.)) and dynamic viscosities of same inks as function of the same applied mixing conditions and shear rate (d.)).

CONCLUSIONS

In conclusion, we were able to identify differences in CB materials by applying AC-based characterization. Those differences play a huge part in the overall process chain of electrode production as they are decisive in formulation considerations mainly, but also in the subsequent processing steps. We were able to link both intrinsic material properties and processing parameters to formulation properties. In future, we will focus on closing the process chain and try to apply our characterization routines for an efficient identification of decisive process parameters at every stage of production. Additionally, we want to transfer gained knowledge from lab-scale techniques (e.g. sonication methods) to industrially relevant mixing procedures. By this, we want to give electrode manufacturers tools at hand for a fast characterization of the feed materials to save costly and lengthy adjustment of processes due to quality fluctuations. An accelerated implementation of green energy solutions is sought by this approach.

ABSTRACT

Solid oxide fuel cells (SOFCs) are highly efficient, low emission and fuel flexible (H_2, CH_4, and CO) future energy device that can also operate in reverse as co-electrolysis cell, converting the CO_2 and H_2O into useful fuel (H_2). However, among numerous sources of electrochemical degradation, the inter-diffusion between electrolyte and cathode has been identified as pre-dominant factor in long run operation, facile method for manufacturing GDC buffer layer should be accomplished for long-term stability and cost effectiveness. Herein, established a highly reliable durable buffer layer that exclusively suppresses the detrimental elemental diffusion at high temperature. This buffer layer is manufactured via tape casting film approach, in which both electrolyte and buffer layer films are laminated by warm iso-static press (WIP) to control the interfacial and bulk properties. The simple approach for electrolyte and buffer layer enables to manufacture a desired thin film structure. Subsequently, the formation of harming insulating phases and decomposition of cathode are effectually prevented, resulting in a remarkably enhancement in electrochemical performance and long-term stability. The scalability and feasibility of mass production are confirmed via the fabrication of large area cells.

Keywords: Solid oxide fuel cell, Thin film SOFC, WIP (Warm iso-static pressing), Buffer layer, Interfacial

INTRODUCTION

Solid oxide fuel cell (SOFC) technology is capable and adaptable energy next-generation design. SOFC is widely used in variety of applications to offer compensations of fuel flexibility, high-energy conversion efficiency and environmentally friendliness. It has much higher conversion efficiencies than the conventional combustion method. However, the major challenges in SOFCs have been associated with elevated temperature and its impact on long-term reliability. High temperature degradation is a crucial factor in SOFC commercialization because it leads to performance deterioration. Cathode and electrolyte are reacted at high temperature, resulting in La and Sr diffusions from state of art perovskite cathode (LSCF and LSC) to form a detrimental secondary phase such as $La_2Zr_2O_7$ and $SrZrO_3$ [1, 2]. The conductivity of these secondary phases is very lower than electrolyte. The universal approach to address this challenge is to insert the buffer layer between the cathode and electrolyte.

To overcome the above challenge, a facile method for fabrication of GDC buffer layer is developed and the very thin, dense and adherent interfacial properties are achieved. The GDC films are engineered to complete densification for control of interfacial properties and to suppress elemental diffusion from cathode using tape casting approach.

EXPERIMETATION

Commercial powders of NiO (Nickelous oxide green, kojundu, Japan), coarse YSZ (TZ-8Y, TOSOH, Japan), Scandia stabilized zirconia ScCeSZ (Fuel cell material, USA and gadolinium-doped ceria GDC (Fuel cell material, USA were used as raw materials for anode NiO-YSZ, Anode functional layer NiO-ScCeSZ, ScCeSZ electrolyte and GDC buffer layer. The raw materials were first mixed and ball-milled for 24hr to form a homogenous slurry. Tape-casting was performed using a tape casting machine (Hansung system, Korea), by which slurry was coated on a Si- coated polyethylene (PET) carrier film at a rate of 1 cm s − 1 at 50 ◦C. The film thicknesses of the green tapes produced were 40 μm for the anode (Figure1), 15-10 μm for the AFL, 6-5μm for the electrolyte and 2-3μm for buffer layer (GDC) respectively. The anode-supported electrolytes were laminated with several anode sheet, AFL sheet, electrolyte sheet and GDC buffer film. The specimens were laminated using WIP by means of a non-directional method. The GDC film-laminated green cell put into the furnace for burning organic substances and co sintering were carried out by heat treatment at 25°C to 1400 ◦C for 60 hr

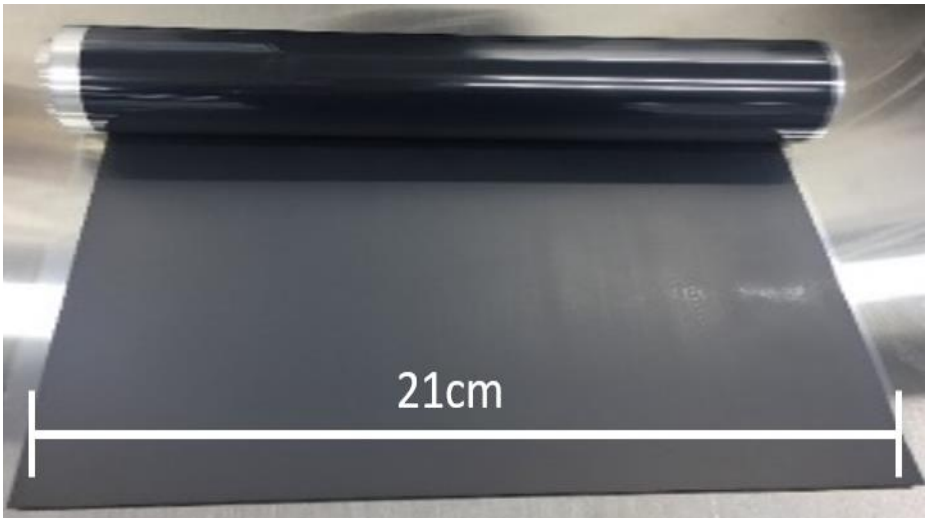

Figure 1. Fabrication of anode support film by tape casting

RESULTS AND DISCUSSION

To examine the effects of buffer layer on electrochemical performance and long-term stability, a large area anode supported planar type cell was fabricated by multi-layer structure (Figure 2). Dense and Defects free buffer layer successfully was fabricated via tape casting approach. Electrolyte and buffer layer have incredibly interfacial adhesion bonding state, which can be clearly recognised. Although few small pores are observed, and all of them are isolated and not connected so that they do not contribute to elemental diffusion and migration from cathode to electrolyte. The advantages of this GDC fabrication method are its scale up capability. To demonstrate the feasibility and scalability of this method for real applications, it was applied on the 12cm×12cm large area anode supported planar cell. The large cell was successfully fabricated. Also the long-term test of the cell was carried out, and there were no delamination between cathode and GDC buffer layer during long-term test. Stability of their interface is confirmed by elemental diffusion and microstructure analysis.

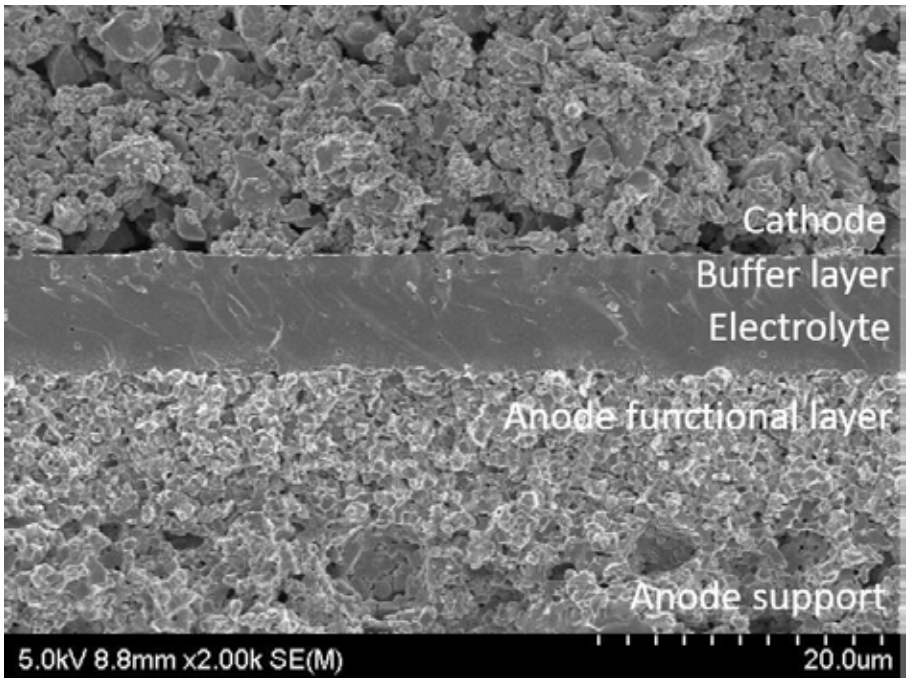

Figure 2. Cross sectional SEM morphology of multi-layer film structure (NiO-YSZ/NiO-ScCeSZ/ScCeSZ/GDC) of large area anode supported planar type SOFC.

CONCLUSIONS

Thin film structure GDC buffer layer are successfully fabricated by tape casting and multi-layer lamination approach. The highly reliable buffer layer suppressed efficiently the secondary phases between cathode and electrolyte, and prevented the performance losses during long-term operation.

ABSTRACT

The long-term stability of Solid Oxide Cells (SOCs) is seen as one of the key obstacles hindering commercialization. The effects of morphological changes in fuel electrodes account for a large part of the cell performance degradation during long-term operation. The morphological changes refer to the migration processes of the Ni phase in Ni-based composite electrode at high operating temperature (600-1000 ℃). The initial smaller Ni particles will agglomerate to reduce the surface energy and form larger particles, and this is the Ni coarsening process which will occur in both fuel cell and electrolysis mode. The Ni coarsening will reduce the density of three-phase boundaries (TPBs) and increase the cell overpotential. Another Ni migration process may be quite destructive, which refers to the redistribution of the Ni phase from one location to another. The redistribution of the Ni phase usually occurs in the electrolysis mode. A series of experimental studies have revealed that the Ni phase will migrate away from the most active functional layer close to the dense electrolyte, which greatly aggravates the performance degradation process. In this study, we conduct a numerical investigation on the Ni migration process in SOCs using an integrated model. First, a phase field model is established to track the morphology evolution of Ni-based electrodes. After experimental validation, the phase field model provides a good characterization of the Ni migration process. Then a lattice Boltzmann model is used to evaluate the electrochemical performance of the fuel electrode at different operating times. The results show that severe Ni depletion can cause an increase of the total overpotential by 0.081 V at high operating current density. Besides, the effects of initial microstructure and operating conditions are also investigated.

ABSTRACT

In this work we explore an in-house made carbon metal fabric (CMF) electrodes for enhanced performances in regenerative hydrogen/vanadium fuel (or flow) cells. CMF is manufactured via a sophisticated electrospinning method followed by carbonization that leads to the development of carbon nanotubes and trichome-like structures with iron nanoparticles that improve the vanadium electrolyte utilization in the RHVFC significantly. The long-term storage costs of the RHVFC are reduced when CMF is used as electrodes, and this leads to a successful systems integration for water desalination and/or solar energy storage plants.

Keywords: Hydrogen, Regenerative fuel cell, Electrospinning, Levelized cost, System integration

INTRODUCTION

Hydrogen as a zero-emission fuel has shown significant promise, as it possesses the highest gravimetric energy density in comparison to any other known substances [1]. It has mainly been applied as direct fuel and its application in fuel cell technology is well documented [2-4]. Both VRFBs (all-vanadium redox flow batteries) and PEMFCs are well known technologies in their own rights but have drawbacks that limit their complete acceptance by end users [5,6]. On their own, both technologies seem to suffer from incompatible material platforms. Therefore, researchers have looked at developing a strong materials-based platform by combining both of these technologies that has the potential to affect a major step change in the stationary energy storage market [7]. This involves the simple replacement of the OER/ORR reaction with the VO^{2+}/VO_2^+ couple that not only lowers cost but also promises a system, known as the regenerative hydrogen vanadium fuel cell (RHVFC), that can almost eliminate capacity fade issues related with the VRFB [8].

In this investigation, we have compared the performance of the RHVFC using several positive electrodes for enhancing the vanadium half-cell reactions. The initial study involved comparing several commercially sourced electrodes to determine the best one as a platform for depositing or modifying with carbonaceous catalysts. Electrophoretic deposition was then used to deposit reduced graphene oxide (rGO) and nitrogen doped graphene (N-G) to compare with a specially synthesized carbon paper catalyst that was fabricated by means of a combination of electrospinning and carbonisation. The RHVFC operation is briefly illustrated in Fig. 1, which also displays the electrochemical reactions occurring in the system.

MATERIALS AND METHODS

Vanadium (IV) oxide sulfate (hydrated) was purchased from Sigma-Aldrich (purity > 99%). Sulfuric acid (5 M) was obtained from Fluka. Electrode modification via electrophoretic deposition is given in detail in our earlier publications [10]. Electrospinning followed by carbonisation was employed to prepare carbon metal fabric electrodes as detailed elsewhere [11]. Vanadium sulfate electrolyte solutions were prepared at a concentration of 0.8 M dissolved in 5 M sulfuric acid based on previously utilized electrolytes for VRFBs, some of which provided high power densities (in excess of 1 W cm^{-2}) [12]. The volume of electrolyte used was 60 ml. A peristaltic pump (Cole Parmer Masterflex Model 77200-50) was used to circulate the vanadium electrolyte between the cell and the reservoir at a constant flow rate of 50 ml min^{-1}. The humidified hydrogen (was passed through the anodic side at a constant flow rate of 100 ml min^{-1} for polarization experiments or 30 ml min^{-1} for charge and discharge, while a glass reservoir was connected to the hydrogen outlet to collect any vanadium electrolyte cross-over [13]. The galvanostatic tests were performed using a Bio-Logic

potentiostat (VSP-300). For all tests, the RHVFC system was allowed to reach an upper cut-off voltage of 1.4 V and a lower cut-off voltage of 0.4 V.

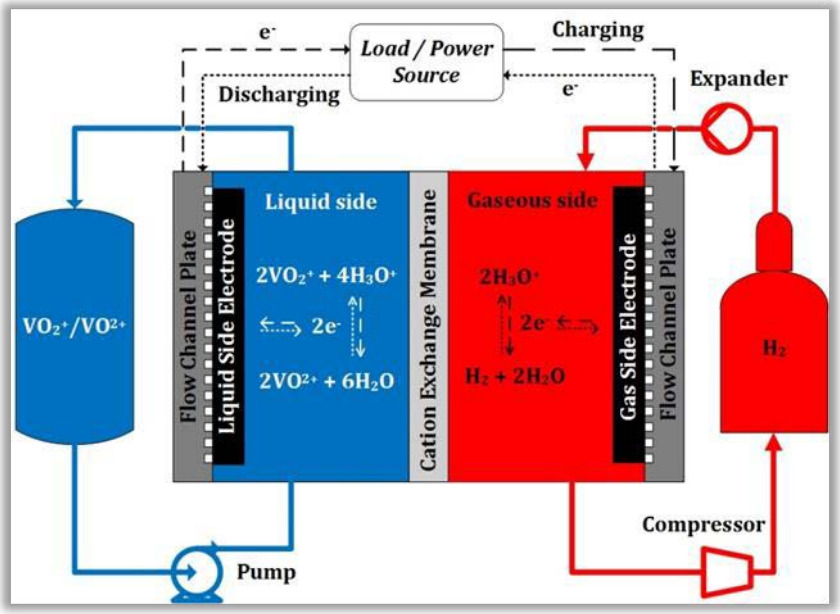

Fig. 1. RHVFC operation showing the key electrochemical reactions occurring in each half-cell. Electrode modification was performed on the liquid side. Reproduced with permission from ACS [9]

RESULTS AND DISCUSSION

Three commercially sourced electrodes - SGL (hydrophobic gas diffusion layer carbon paper), Freudenberg (hydrophilic flexible carbon paper) and ELAT (hydrophilic carbon cloth), all sourced from Fuel Cell Stores Ltd. - were modified with rGO and their power densities were compared in the RHVFC (Fig. 2a). The ELAT cloth gave best performance (even better than the nitrogen doped graphene SGL or N-G_SGL) and was used along with a single layer of CMF as the positive electrode (labelled CMF_ELAT) in an RHVFC. The power density noted was exceptional for a non-optimised system as reported elsewhere [10]. A comparison of the fifth cycle electrolyte capacity utilisation displayed much better performance for CMF_ELAT when compared to pristine ELAT (Fig. 2b).

A cost analysis of the RHVFC (for 8 h of storage) has been performed to rationalize the use of the carbon fabric electrode as catalyst layer (along with carbon cloth) for potentially scaling-up this system in comparison to the standard VRFB [16]. Although the levelized cost of VRFB and RHVFC appears similar at the same continuous discharge power density, RHVFC becomes cheaper with increased current density (hence power density) and this cost can be further reduced in comparison to VRFB if the system is operated at higher power densities (see Fig. 3).

CONCLUSIONS

The positive electrode for a regenerative hydrogen/vanadium fuel cell was modified with reduced graphene oxide and carbon metallic fabrics (CMFs) to enhance the vanadium-based liquid electrochemistry of the system. This not only resulted in higher power densities, but also higher capacities were generated, especially when using CMF as electrodes. Levelized cost of storage was lower when applying CMF.

ABSTRACT

This study focuses on the synthesis, characterization, and processing of LSF based composite cathode for solid oxide fuel cells. The cathode comprises three oxides; LSF, rp-LSF and ScSZ which are synthesized by co-sputtering using combinatorial approach. The electrolyte was Scandia doped Zirconia (ScSZ), as it has attractive ionic conductivity at lower temperatures. Having chosen the electrolyte ScSZ as electrolyte. After detailed analysis regarding conductivity and thermal expansion for each oxide, the compositions selected were $La_{0.8}Sr_{0.2}FeO_{3-\delta}$, $LaSr_3Fe_3O_{10-\delta}$, and $Sc_{0.15}Zr_{0.85}O_{2-\delta}$ LSF, rp-LSF, ScSZ respectively. A total of 21 composite cathodes were deposited on electrolytes, each with a different composition. The performance of cathodes was characterized via EIS measurements on symmetric cells. A temperature ranges from 600 ^{0}C up to 800 ^{0}C was covered at 50 ^{0}C interval. LSF-rpLSF-ScSZ ternary diagram was mapped in terms of area specific resistance (ASR). The ASR values at 600 ^{0}C varied from 2.159 to 34.68 ohm.cm^2. At 800 ^{0}C the values were significantly better which ranged from 0.1649 to 0.85 ohm.cm^2.

Keywords: SOFC cathodes, Electrochemical impedance spectroscopy, Magnetron sputtering

INTRODUCTION

SOFC is a fuel cell technology that operates at high temperatures. They are useful in large, high-power applications such as industrial stations and large-scale power plants. The electrolyte in a SOFC system is typically solid ceramic, and the system run at high temperatures (600-1000 ^{0}C). This high working temperature facilitates quick electro-catalytic reactions with non-precious materials and generates heat as byproduct for cogeneration. The efficiency of this type of fuel cell can be as high as 70%.

Because of its relatively large activation energy for the oxygen reduction process, the cathode electrode is the primary contributor to the overall resistance of a SOFC, especially at intermediate and low operating temperatures. One of the most significant methods for improving cell performance in SOFCs is to reduce the polarization resistance of the cathode electrode. As a result, substantial research has been conducted on the modification and improvement of SOFC cathodes to lower oxygen reduction reaction (ORR) activation energy and resistance of the electrode. For the cathode in SOFC, LSF is an often-used oxide in composite cathodes. LSF has a perovskite type structure, and because it has good oxygen ion conductivity and does not react with a zirconia-based electrolyte, it has been employed as the cathode electrode for SOFCs by numerous studies. Furthermore, because of its oxygen nonstoichiometry at high temperatures, Ruddlesden-Popper type layered perovskite, $LaSr_3Fe_3O_{10}$, has been described as a viable cathode material for solid oxide fuel cells. $LaSr_3Fe_3O_{10}$ has been found to have nearly no overpotential at the air electrode when used as an electrocatalyst for rechargeable metal-air batteries.

EXPERIMENTAL PROCEDURE

For the synthesis of active powders, Pechini method was followed. Precursors used for the synthesis of active powders were nitrates of La, Sr, Fe, Mn, Sc and Zr elements. Nitrates were mixed with deionized water in a large beaker at the intended stoichiometry with the aid of a magnetic stirrer. After the cations were dissolved in water, three times the total number of moles of cations, citric acid was added to the mixture and the solution was mixed for 20 minutes at 100 ^{0}C. Subsequently, four times the molar number of citric acid, ethylene glycol was added to the solution and the temperature was gradually increased to 150 ^{0}C and then to 200 ^{0}C. Mixing was continued at this temperature until foam formation occurred. The gel, which dries after the foam formation, is kept in a 250 ^{0}C oven for 12 hours to be purified from organic compounds. As the last process, the dry gel was calcined at the appropriate temperature.

The production of target discs was carried out by pressing followed by sintering. Deformable Teflon dies were used for this purpose. Initially, the powders were compacted to high density using a small die and subsequently sintered at different temperatures.

Thin film cathodes were sputter deposited on electrolytes. For this purpose, a prismatic chamber with dimensions of 500x500x500 mm was used which incorporates three peripheral sputter guns placed in a diameter of 350 mm, Fig. 1. In this study, the substrates are ¾ inch diameter electrolyte discs and there are total of 21 discs on the substrate holder on triangular distribution. What makes this system special is the ability to produce 21 different compositions at the same time.

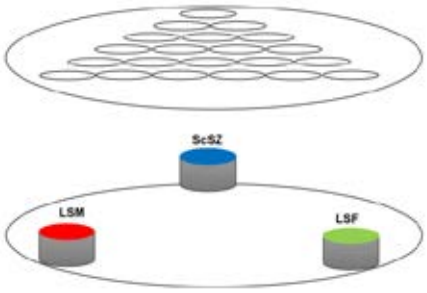

Figure 1. Drawing of samples in the substrate holder with guns in the gun holders

All the fabricated materials in this thesis were characterized by X-ray diffractometer (XRD). The D/MAX-2200 Rigaku X-ray Diffractometer with Cu-Kα radiation with 2^0/min scan rate was used. Rietveld analysis were applied to refine the X-ray patterns using Maud software. Fabricated samples were characterized using SEM. For this purpose, FEI Nova NanoSEM 430 were used. Where necessary, the use was also made of EDX attachment in SEM for elemental analysis of the synthesized powders.

Electrochemical characterization of cathodes produced with combinatorial approach was performed by symmetrical cell measurements. The symmetrical cell prepared for electrochemical characterization was place at the end of an alumina tube with an inner diameter of 14mm and an outer diameter of 24mm, and sealing was provided with AREMCO ceramic adhesive. The setup created is shown in Figure 3.6 as placed in a split oven. The produced symmetrical cells were subjected to EIS measurements at different temperatures.

RESULTS AND DISCUSSION

All the results obtained should be discussed in detail.
EIS measurements were conducted via Gamry ref. 3000 Potentiostat/Galvanostat. As perturbation voltage and frequency, 10mV and 0.1Hz-0.3Mhz were used respectively. Results were obtained between 400-800 ^{0}C with 50 ^{0}C intervals. Some examples of Nyquist plots obtained is given in Fig. 2. Nyquist plots were used to obtain the total cathode resistance.
Results are given as area specific resistance (ASR). This value is obtained from multiplying area of the cathode with the cathode resistance divided by 2 since there are cathodes on both sides of the cell. Obtained ASR results were mapped, Fig. 3.

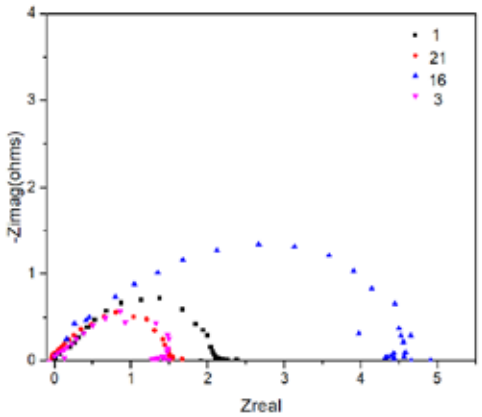

Figure 2. Nyquist plots of sample number 1,21,16 and 3 at 800 ^{0}C.

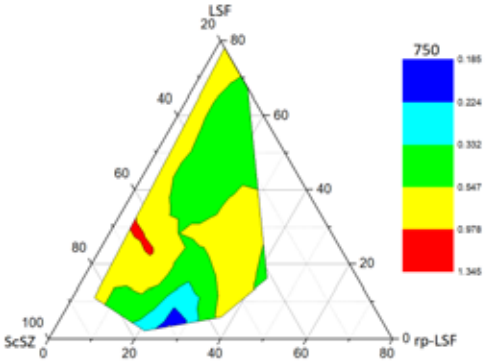

Figure 3. Contour mapping of ASR results of all 21 cells at 800 ^{0}C.

CONCLUSIONS

In this study, a combinatorial study was carried out to develop new cathode materials based on for LSF-rpLSF-ScSZ ternary system. A total of 21 cathode compositions were sputter deposited each with different compositions and were screened using symmetric cell via electrochemical impedance spectroscopy as a measure of their ORR performance. It can be determined from the study that; combinatorial approach is very useful for determining the optimum composition in the composite cathode system.

ABSTRACT

It is proposed that dual conductive electrolytes have the potential to improve the performance of Molten Carbonate Fuel Cells by using oxygen ion conductors as matrix material, creating what is termed composite electrolyte. This paper presents the results of testing of a composite electrolyte layer based on Yttria Stabilized Zirconia and Lithium/Potassium carbonates for its electrochemical performance as a matrix for MCFC. The voltage–current density curves were collected for a range of temperatures: 500–800°C. Without very accurate measurements it is not easy to determine the additional electric charge provided by oxygen ions ($O^{=}$). We tried to build a mathematical model which takes into account both conductivities and, based on the model, estimated the ratio of electric charge provided by oxygen ions and carbonate ions.

Keywords: MCFC, Composite electrolyte, Dual conducting; YSZ, Li/K

INTRODUCTION

The efficiency of energy production has a major impact on operation costs and pollution. Molten carbonate fuel cells (MCFCs) [1–4] are approaching commercialization, mostly as megawatt (MW) scale systems. MCFC can operate on biofuels and hydrocarbons with negligible pollution and high efficiency of fuel conversion due to the absence of Carnot cycle efficiency restraints. This obviates the need for hydrogen, which is quite difficult to generate and store. One way of boosting the performance of these fuel cells is to improve the ionic conductance of the electrolyte matrix, a component that is exclusive to cells with a liquid electrolyte and needed to withhold the carbonate melt in its fine open-porous structure. Therefore, alternative matrix materials that have additional oxygen ionic conductivity (like yttrium stabilized zirconia – YSZ) [5] at 500–800°C have been developed for use in MCFCs.

Recently, a paper was published [6] which is very critical about the interpretation of dual conductivity provided by Li [7]. It is interesting that the arguments Nafe gives are only supported by his own papers (8 of 11 papers in the references) and he ignores other investigations made in the field (as presented in this chapter). Additionally, Nafe suggests that Li misunderstood the experimental results on the conductivity of carbonate-based composites due to disregarding electrode polarization and making the purely speculative assumption that the nature of ions mobile in the conducting media is determined by the surrounding species. Finally, Nafe concludes that composites do not distinguish themselves by enhancing ionic conductivity, but they can enjoy better performance due to their ability to reduce the extent of electrode polarization. In fact, we too do not understand why Li et al. claim that there is double “protonic” and “oxide ionic” conductivities of the electrolyte made from SDC (oxygen ion conductor, two electrons charge) and Li/Na carbonates (carbonate ion conductors, two electrons charge as well).

We believe we could try to contribute to the discussion by trying to estimate the oxygen ion conductivity of composite electrolyte indirectly by introducing the additional conductance to a fuel cell model. A few years ago, the reduced order model was proposed for describing fuel cell voltage [8]. The model is based on a combination of electric laws, gas flow relationships, solid materials properties, and electrochemical correlations. An adequate equation for cell voltage estimation was derived and commented on. The model contains only physically explained parameters (with the minimum possible number of required factors) and considers all important thermal flow as well as architecture parameters. The model assumed that fuel cell electrolyte is a conductor of one type of ions ($CO_3^{=}$). This paper presents the upgraded model of the Molten Carbonate Fuel Cell which is used for estimating the additional conductivity caused by using YSZ as the matrix material.

The experimental database composed of about 3,000 experimental points was used to validate the model and to identify the oxygen ion conductivity of the electrolyte.

Table 1: The parameters obtained by using the model

	Li/K	YSZ
Electrolyte thickness, δ, mm	2.32	1.73
Pre-exponential factor, σ_0 , S/cm	14.6*	391*
Activation energy, E_{act} , J/kmol	18.1*	87.8*
Electric resistance, r_e, Ω·cm^2	154	13
*fixed parameters as per literature data		

The model was created in Excel®. The factors which were found are set out in Table 1. It was assumed that the structure of the composite electrolyte does not change the temperature characteristics of the individual materials (YSZ and Li/K), thus the area specific resistance values are provided (r_e, Ω·cm^2). Additionally, the temperature dependent conductivity of anode and cathode was also found by fitting to the experimental data, and is given by the following equation:

$$\sigma_{anode+cathode} = 29.5 \cdot \exp(-0.895/R/T)$$

The oxygen ion conductivity of the composite electrolyte was found by mathematical modeling. The conductivity is expressed by the equivalent thickness of the YSZ matrix at a value three times greater than the electrolyte layer itself. Surprisingly, the simulated path for carbonate ions is even longer, but finally the favorable temperature characteristics of the molten salts give lower specific resistance.

DISCUSSION OF THE OBTAINED RESULTS

Based on the mathematical modeling and experimental investigations, we tried to identify the oxygen ion conductivity of the composite electrolyte. To do so, the reduced order model of MCFC was modified to include additional conductivity of the oxygen ion by a matrix prepared from YSZ.

Path length of oxygen ions (δ_{YSZ}) was found at a value of 3.8 times greater than the physical thickness of the electrolyte. This indicates that there is visible oxygen ion conductivity through the composite electrolyte. If no oxygen conductivity is found, the length should be very high (infinite in theory). On the other hand, for pure solid electrolyte as used in SOFC, the oxygen ion path length is equal to the physical thickness of electrolyte.

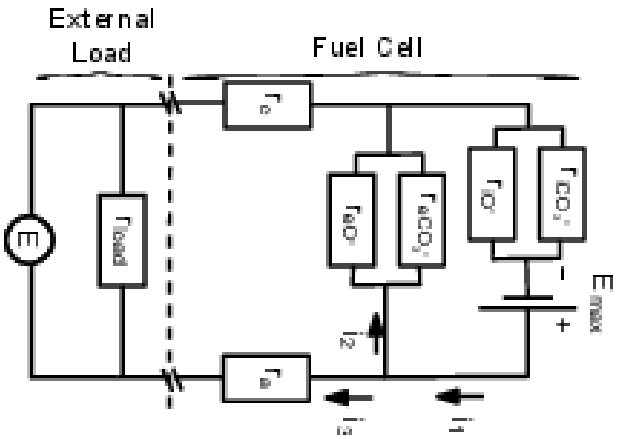

Figure 1: The equivalent electric circuit for dual conductivity MCFC

Surprisingly, the free path of carbonates ions is even longer than with oxygen ions: 5 times thicker than the electrolyte layer. This issue merits further studies and experiments. The free paths of the ions are not directly translated into the internal current which flows through composite electrolyte. The ionic conductivity of the material is strongly dependent on temperature. The average value of internal current density (i_1 in Figure 1) is the sum of oxygen and carbonate ions charges. Based on the results obtained, the average internal current caused by carbonates is 0.0936 against 0.000509 A/cm^2 made by oxygen ions, thus the oxygen ionic conductivity can be described as marginal (about 0.5% of the total internal current density). The value obtained is close to the measurement and modeling inaccuracies, thus cannot be seriously used as proof of oxygen ionic conductivity.

Presumably, if we raise the operating temperature, the part of total internal current caused by additional ionic conductance will play a larger role.

There were additional two fitting parameters: internal electric resistance of both materials used for constructing the composite electrolyte. In fact, here we do have an opposite effect: lower conductivity (higher resistivity) means better fuel cell performance. The internal electric resistance of molten salts is found to be 11.9 times higher than the solid material used. This can be explained by reference to the different mechanisms that apply to charge transfer in the two materials.

CONCLUSIONS

In this paper we provide insight into the oxygen ionic conductivity of composite electrolyte through using a mathematical model fitted to more than 3000 experimental points. The original impulse for this work came from a paper published by Nafe [6] which was very critical about work done by Li [7]. We modified the reduced order model to include hypothetical additional conductivity caused by solid material of the matrix manufactured from oxygen ion conductors (YSZ). Then the model was fitted to the experimental data, and we indicated that oxygen ion conductivity is not so evident. The obtained values of internal current density produced by oxygen ions are very small, approximating to the level of inaccuracies of experiments and modeling.

To resolve this issue, we intend to carry out – soon – an accurate analysis of cathode off gas during operation of a fuel cell that is based on composite electrolyte.

ABSTRACT

Grain boundaries are frequently responsible for a poor performance of gadolinium-doped ceria-based electrolytes, due to a low ionic conductivity, orders of magnitude smaller than the bulk conductivity. Silica, the dominant impurity in many low-grade ceramics, namely, in ceria-based materials, has a detrimental effect on grain boundaries conductivity. Several previous works had explored the silica-scavenging effect. In the present work, we exploit an alternative approach using the addition of 5% (w/w) of Y_2O_3, as silica scavenging agent, and sintering by hot pressing at low temperature to minimize bulk dissolution of yttrium in the CGO lattice. Gadolinium-doped ceria-based powders were co-fired with additions of 1% (w/w) of silica, and silica and yttrium oxide to test the silica scavenging role of yttrium. The samples were prepared by hot press at low temperature (1000ºC) and were characterized by impedance spectroscopy as a function of temperature in air, in order to de-convolute different microstructural contributions to the overall electrical behaviour. Combined information obtained from structural, microstructural, and electrical characterization allowed one to study the impact of new phases on the resulting ceria-based solid electrolytes.

Keywords: Ceria, Yttria, Scavenge effect, Heterogeneities, Hot press.

INTRODUCTION

The threat of global warming due to burning fossil fuels and clean-up challenges from using nuclear power have resulted in rise of environmental consciousness and tremendous efforts on seeking alternative power sources in the whole world. The fuel cell is one attractive alternative that can produce clean and efficient electricity to meet the environmental challenges and is a radically different way of making electrical power from a variety of fuels. The major requirement for current carrying devices like solid oxide fuel cell (SOFCs) is the fast ion conduction in solid electrolytes, which is the combined result of large concentrations of ionic defects and high ionic mobility. Materials with the fluorite-type structure are amongst the most effective oxygen-ion conductors. The fluorite structure shows comparatively high oxygen-ion mobility and accepts high levels of anionic disorder, which can be introduced to compensate for aliovalent metal doping [1,2]. One of the most used fluorite-type oxides is yttria stabilized zirconia (YSZ), which, due to the relatively low ionic conductivity, requires an operating temperature range reasonably high, and consequently the use of expensive complementary materials. Reducing the operating temperature allows the use of cheaper construction materials and more reliable seals. Thus, new materials have been investigated to lower the operating temperature to 500/700ºC, which includes new electrolyte materials [3] with higher ionic conductivity. The recommended use of low-grade ceramics, much cheaper than the high purity oxides, has silica as predominant constituent of the grain boundary region. Doped ceria is one of the most recognized electrolytes in the intermediate temperature range (IT-SOFCs), and shows much higher ionic conductivity than that of the well-established yttria-stabilized zirconia (YSZ) [4, 5]. However, the grain boundary behaviour usually dominates the total conductivity of ceria-based electrolytes in intermediate temperature range [4-6]. Due to the presence of thin siliceous films, the grain boundary has a blocking effect to the transport of oxygen ions across the electrolyte. In the well-established stabilized zirconia system, there have been many studies [7–13] aimed at improving grain-boundary conduction by engineering the grain-boundary phase. The principal approaches are the scavenging of the siliceous phase by the addition of Al_2O_3 [7–11], the gathering of a Si-containing phase into a discrete configuration [11,12] and the dewetting of the intergranular phase by crystallization [13]. However, alumina additions to CGO ceramics showed a detrimental effect attributed to the formation of another non-conductive phase, $GdAlO_3$ [14]. Another attempt with CGO ceramics involved additions of lanthanum oxide, as scavenging agent, which proved to be effective on removing the siliceous phases from the grain boundaries [15].

In the present work, we exploit an alternative approach to optimize the total conductivity of CGO electrolytes, using the addition of 5% (w/w) of Y_2O_3, as silica scavenging agent, and sintering by hot pressing at low temperature to minimize bulk dissolution of yttrium in the CGO lattice and hence promoting the formation of heterogeneous microstructures.

EXPERIMENTAL

Ceramic samples were prepared using commercially high purity powders as starting materials (Table 1). CGO5 was used as a reference material to compare with the prepared compositions. All samples were prepared using conventional ceramic solid state processing route. To obtain dense ceramics, the powders were sintered by hot press (HP) at 1000ºC for 2 h with 65 MPa. To study the temperature effect, a posterior thermal treatment was done at 1100ºC and 1400°C for 2h. The density was calculated using Archimedes method. The samples were analysed by x-ray diffraction (XRD) and SEM/EDS. The relative density (RD) was obtained using the density from Archimedes method and from XRD The bulk and grain boundary resistances were obtained by ac impedance spectroscopy in air, using HP Impedance Analyzer. The electrical measurements were performed in air between 1000ºC and 300ºC, in the frequency range of 20 -10^6 Hz. The same analyser was used to assess the oxygen partial pressure (pO_2) dependence of the total conductivity, during isothermal measurements carried out between 800 and 1000°C, with pO_2 changing from about 10^{-15} Pa to air, using a gas mixture of 5%H_2 and 95% of N_2.

RESULTS AND DISCUSSION

Structural characterization by XRD confirms a CGO single phase material with the fluorite type structure, without detection of silica and yttrium oxide. SEM/EDS analysis also show a homogeneous distribution of Si and Y over all the samples, suggestion an incorporation of this elements into the CGO lattice. Slight increase of the lattice parameter (Table 1) also suggests the formation of solid solution.

Table 1. Prepared samples notation, composition, thermal treatment, and obtained relative density (RD) and lattice parameter (a_0).

Sample	Composition	Thermal treatment	RD (%)	a_0 (Å)
CGO5	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$	HP	92.42	5.416535
CGO5 Si	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2	HP	77.56	5.4176936
CGO5 Si 1100	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2	HP + 1100ºC 2h	93.36	5.4157112
CGO5 Si 1400	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2	HP + 1400ºC 2h	95.97	5.4139509
CGO5 Si 5Y	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2+5% (w/w) Y_2O_3	HP	83.97	5.417249
CGO5 Si 5Y 1100	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2+5% (w/w) Y_2O_3	HP + 1100ºC 2h	85.44	5.41408
CGO5 Si 5Y 1400	$Ce_{0,95}Gd_{0,05}O_{2-\delta}$ +1%(w/w) SiO_2+5% (w/w) Y_2O_3	HP + 1400ºC 2h	93.44	5.412672

Silica addition significantly decrease the specific grain boundary conductivity, which suggests the presence of this impurity on the grain boundary (Fig.1A). Specific grain boundary conductivity partially recovers with the addition of yttria for all temperatures of thermal treatment. This effect on the specific grain boundary conductivity denotes that Si and Y have a preferential effect on grain boundaries.

The oxygen partial pressure dependence of the total conductivity shows the well-known behaviour of CGO based materials, with an ionic plateau for high oxygen partial pressures and an onset of n-type conductivity for low oxygen partial pressure. Silica as a negative effect on both types of conductivities, while yttria addition reveals some recover of the ionic conductivity and no significative effect on the n-type conductivity.

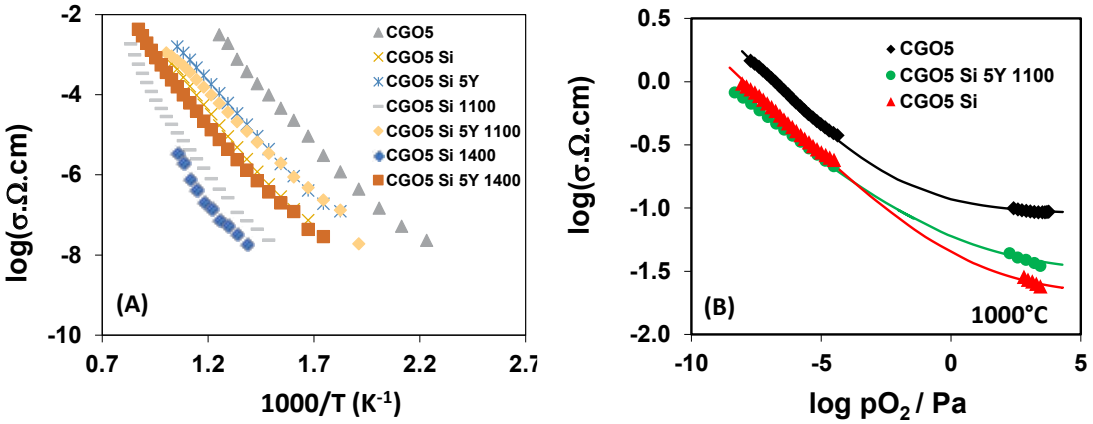

Fig. 1. Arrhenius plot of specific grain boundary conductivity (A) and oxygen partial pressure dependence of total conductivity (B).

CONCLUSIONS

Samples of gadolinium-doped ceria-based electrolytes were thermal treated at different temperatures (1100 and 1400ºC) after hot press at 1000ºC. High density (≥90%) was achieved with almost all the samples.
Addition of small amounts of impurity of silica reduces the total conductivity when compared with pure ceramic sample. However, addition of yttria increases total conductivity when compared with samples without yttria. This effect is related with the partial recover of specific grain boundary conductivity, suggesting a preferential location of Si and Y cations on grain boundaries.

ABSTRACT

Commercial ceria–gadolinia powders were used to prepare dense CGO (5 mol% Gd) samples, by hot press method at relatively low temperature (1000°C). To study the effect of post-sintering, further the as-sintered bodies were subjected into different thermal treatments 1100ºC-1400ºC. The sintered samples were characterized by impedance spectroscopy as a function of temperature in air, in order to identify each microstructural contribution to the overall electrical behaviour. Scanning electron microscopy shows that the increase in the temperature of thermal treatment leads to grain growth. Electrical properties were studied with different oxygen partial pressures and ion blocking methods. Y_2O_3 (5 wt%) additions were used to seek the grain boundaries heterogeneities effects in CGO material, prepared by hot press and subjected into post sintering thermal treatments. Electrical conductivities of CGO samples were analysed with and without Y_2O_3 additions.

Keywords: SOFC, Hot press, CGO, Electrical conductivity, Heterogeneities.

INTRODUCTION

The electrolyte is a crucial component of solid-state electrochemical systems, in which ions must diffuse between electrodes. Gadolinium doped cerium oxide (CGO) electrolytes have an extraordinary range of applications, which include solid oxide fuel cells (SOFC), electrolysers, oxygen sensors, oxygen permeation membrane systems, oxygen storage capacitors, pumps and photo catalysts, mostly, due to its unique properties, such as high electrical conductivity (high mobility of oxygen ions) and catalytic activity (large oxygen storage capacity) compared to those of conventional zirconia-based electrolytes. However, a high material cost or insufficient performance of CGO may prevent commercial success in some of these applications [1-3]. It is noted that the contribution of grain-boundary resistivity to the overall resistivity of CGO based materials are known to be 2-3 orders of magnitude higher than the grain-interior resistivity, due to the depletion of oxygen vacancies near the grain-boundary, due to the formation of a space charge layer. Though, promising properties of CGO can be obtained by selecting the proper concentration of oxygen vacancies in the crystal structure, as well as the fitting microstructure, since both have a direct and decisive effect on functional properties [4-5]. However, it is challenging to obtain homogeneous microstructures with full densification for ceria-based materials, since CGO has a poor sinterability due to its high refractoriness. It is also expected that ionic conductivity of ceria-based electrolytes might be optimized by engineering core–shell microstructures, with higher contents of trivalent additive at the shell [6].

In this work, we assess and correlate the sinterability, microstructural evolution, and electrical properties of CGO samples with and without addition of Y_2O_3, prepared by hot press method.

MATERIALS AND METHODS

Commercially available $Ce_{0,95}Gd_{0,05}O_{2-\delta}$ (Praxair) and Y_2O_3 (Alfa Aesar) high purity powders were used as starting materials. Doped Y_2O_3 (5 wt%) into $Ce_{0,95}Gd_{0,05}O_{2-\delta}$ powder was prepared using conventional solid-state reaction method. The $Ce_{0,95}Gd_{0,05}O_{2-\delta}$ powders with and without Y_2O_3, were sintered by hot-press method in an alumina die under 60 MPa at 1000ºC for 2h, 5˚C/min heating and 10ºC/min cooling rate were used. The sintered samples are labelled CGO5 and CGO5 5Y. In order to study the effect of post-sintering, further the as-sintered bodies were subjected into different thermal treatment at 1100˚C and 1400˚C for 2h. The samples were named CGO5-1100˚C, CGO5 5-1100˚C and so on. Scanning electron microscopy was used to characterize microstructure features of sintered ceramic samples. The total conductivity measurements were performed on dense pellets prepared by hot-press and post thermal treatment, using an AC impedance spectroscopy in air HP Impedance Analyzer. The pellets were painted on both sides with porous platinum electrodes and fired at 900ºC. All measurements were carried out from 1000 to 100°C with 25°C steps, in the frequency range of 20 -10^6 Hz. In order to obtain the n-type conductivity, a dense CGO based samples were painted with a Pt electrode and then sealed against a dense alumina disk with glass ceramic seal, to achieve gas tightness required for ion blocking measurements. This electrode was polarized cathodically, at different values of applied voltage and the corresponding current was measured.

RESULTS AND DISCUSSION

The morphology of CGO samples sintered at 1000˚C by hot press and with post thermal treatment at 1100˚C and 1400˚C are presented in Fig.1. The ceramics sintered at 1000˚C show relatively small grains and a further increase in temperature of thermal treatment leads to grain growth. Along with, CGO ceramic thermal treated at 1400ºC achieved large grains.

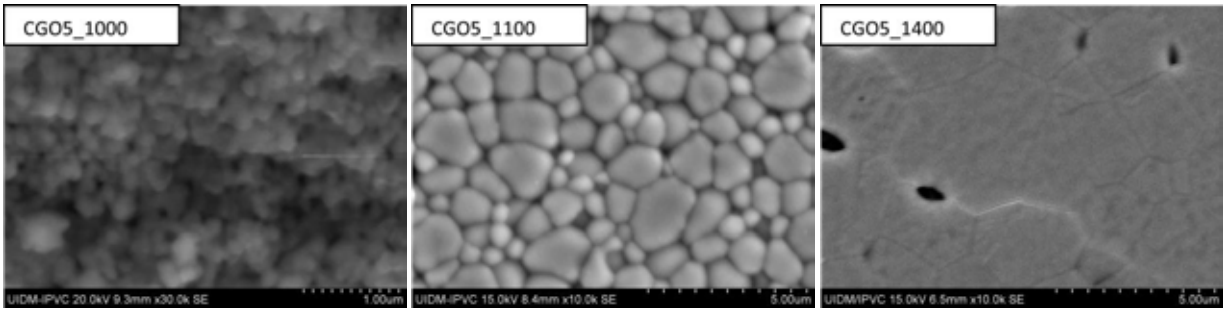

Fig. 1. SEM micrographs of CGO ceramics: sintered at 1000ºC, 1100ºC and 1400ºC.

Specific grain boundary conductivity of selected samples was determined and is showed in Fig. 2. In order to understand the effect of hot press approach, CGO sample prepared by conventional sintering at 1400˚C is also included. Sample prepared by hot press at 1000ºC with and without Y_2O_3 shows higher specific grain boundary conductivity than CGO from conventional sintering. Thermal treatments of the samples between 1100°C and 1400ºC have a negative effect on specific grain boundary conductivity, with the worst value observed at the temperature of 1400ºC, which suggest a degradation of properties of the grain boundary with the increase of the thermal treatment temperature. The thermal treatment temperature effect it is much evident for Y-doped samples than for the pure CGO, which suggest a dissolution of Y into the grain interior for higher temperatures.

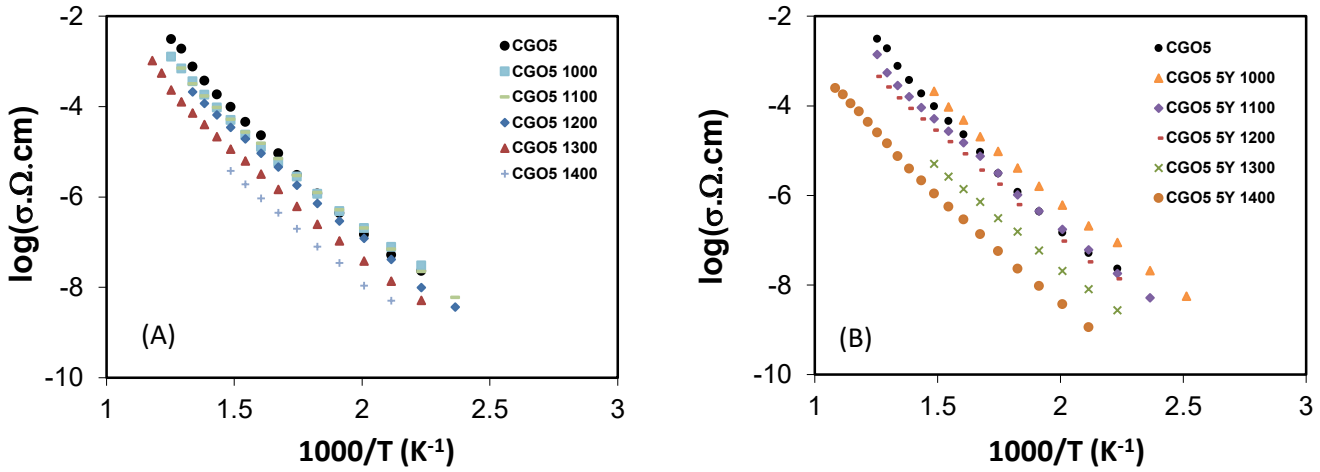

Fig. 2. Arrhenius plot of specific grain boundary conductivity of CGO (A) and CGO 5Y; (B) ceramics with post thermal treatment 1100ºC and 1400ºC.

The oxygen partial pressure dependence of the total conductivity and ion blocking measurements, shows the well-known behaviour of CGO based materials, with an ionic plateau for high oxygen partial pressures and an onset of n-type conductivity for low oxygen partial pressure (Fig.3).

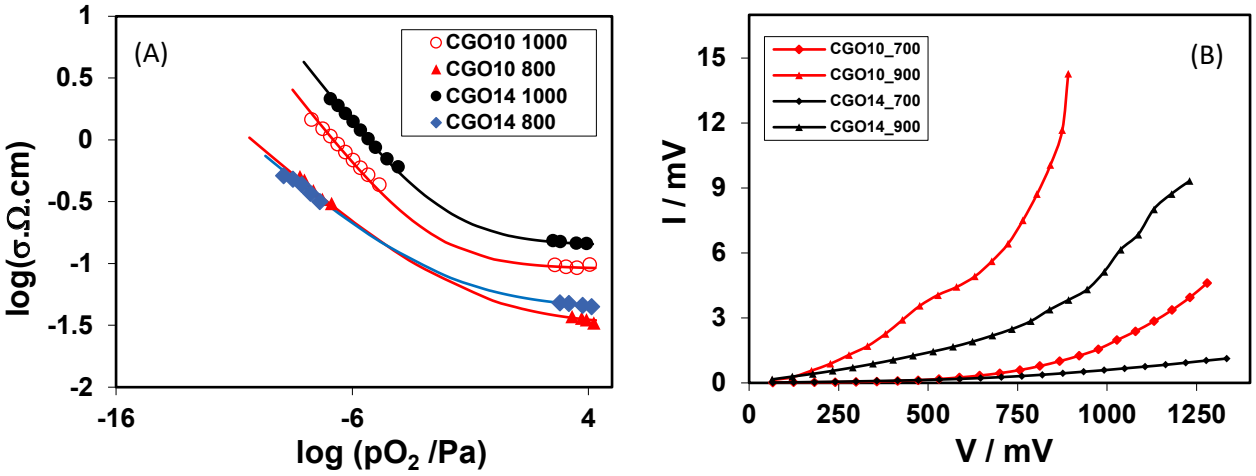

Fig. 3. Electrical conductivity as a function of the oxygen partial pressure(A) and ion blocking results (B) for of CGO based ceramics sintered at 1000˚C and 1400°C.

CONCLUSIONS

The present studies have shown that, using hot press sintering method, the widely used gadolinia doped ceria (CGO) electrolyte ceramics could be densified at relatively lower temperature 1000°C-1100°C with favourable performance, namely with higher electrical conductivities of the grain boundaries, when compared with traditional materials obtained at higher sintering temperature (≥1400˚C).

ABSTRACT

Zirconia-based materials are still the state of art electrolyte for high temperature electrochemical systems, and for non-electrochemical applications. Their purity is known to affect performance, thus requiring high-grade expensive precursors and additional concerns about contamination during high temperature processing and/or during long term applications at intermediate temperatures, as found for contamination by silica. Thus, the purpose of this work was to demonstrate the scavenging ability of praseodymium oxide to minimize or suppress the impact of contamination by silica.

In the present work, one used TZP precursor powders from Tosoh and Innovnano. Starting materials of both powders contained significant fractions of monoclinic phase, coexisting with tetragonal zirconia, and yielded highly dense samples after sintering at 1450°C/2h. Praseodymium oxide and/or silicon oxide additions did not affect significantly the sintering behaviour. Additions of Pr and Si yielded co-existing tetragonal and cubic phases, as revealed by XRD and Rietveld refinements, with an impact on lattice parameters of the cubic phase.

The electrical characterization showed the expected severe decrease in conductivity after the addition of silicon oxide addition and also showed that this negative impact is at least partially reverted by additions of praseodymium oxide.

Keywords: solid electrolyte, yttria-stabilized zirconia, praseodymium oxide, scavenging, silica impurity

INTRODUCTION

Growing environmental concerns force the search and development of alternative energy technologies. However, the buoyancy in renewable energy production and the mismatch between energy production and demand point to the need for energy storage systems. Therefore, the importance of the study and development of solid electrochemical systems is relevant in deepening the knowledge of solid oxide fuel cells (SOFC), solid oxide electrolysis cells (SOEC) and, more recently, solid oxide reversible cells (rSOC) [1]. The growing importance of the latter cells is related to the finding that the degradation that occurs at the oxygen electrolyte/electrode interface can be delayed with the cell operating in a reversible SOEC/SOFC regime and the degradation that occurs in the SOEC regime can be partially recovered when the cell works in SOFC mode, properly controlling cycle duration [2-4]. One possible approach might be to introduce active components into the reduction. To achieve greater chemical and thermomechanical compatibility, these components can be based on zirconia with the addition of yttria and additions of cations of varying valence such as manganese and praseodymium [5].

MATERIALS AND METHODS

Commercially available Tosoh and Innovnano tetragonal zirconia powder (3% molar percentage of Y_2O_3) (TZP), Pr_2O_3 and SiO_2 high purity powders were used as starting materials. Doped powders were prepared using the conventional solid-state reaction method. The powder mixtures were weighed and mixed through ball milling in ethanol medium using zirconia balls. The prepared slurry was dried in and grounded using agate mortar and pestle until a fine powder was obtained. To study the effect of SiO_2 as impurity and Pr_2O_3 as a scavenging solution, pellets of undoped and doped TZP were unidirectionally pressed at 125 MPa and then sintered at 1450°C for 2 hours with heating and cooling rates of 10°C/min. The densities of sintered samples at various temperatures were calculated by the Archimedes method. X-ray diffraction was used to characterize the phase composition of the as-prepared and thermally treated ceramics, also the lattice parameters were calculated after Rietveld refinements. Scanning electron microscopy and EDS were used to analyse microstructure characterization of sintered ceramic samples. The total conductivity measurements were performed on dense pellets, using an AC impedance spectroscopy in an air atmosphere by HP Impedance Analyzer. The variation of the total conductivity with oxygen partial pressure at a fixed temperature was also made.The pellets were painted on both sides with porous platinum electrodes and sintered at 900°C. All measurements were carried out in the direction of decreasing temperature, from 1000 to 200°C with at 25°C steps in the frequency range of 20 -10^6 Hz.

RESULTS AND DISCUSSION

The high densification of the samples of all compositions is achieved for the sintering conditions used, see Table 1. There are no remarkable differences in densification with the additions of silica or praseodymium oxide. The high densification is confirmed by SEM, Figure 1, where is also evident the small size of the grains. It is also clear some bimodal distribution of the grain sizes.

Table 1. Sample identification, density and relative density (RD) of the different compositions sintered at 1450°C for 2h.

SI	Innovnano	1	0	5.882	97.4
S3PI	Innovnano	1	3	5.546	91.8

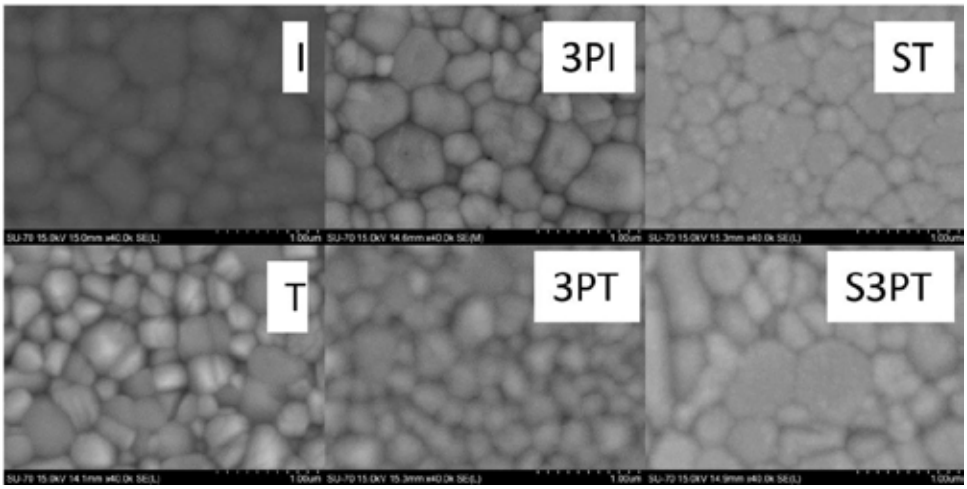

Fig. 1. SEM micrographs of the different studied compositions.

The overall conductivity of the samples is strongly affected by the presence of silica, but not so much with the additions of praseodymium oxide. It is also noticeable that the addition of praseodymium oxide to samples with silica benefits the samples, the conductivity decrease is not so relevant. By the analysis of the bulk and the grain boundary conductivities, it is clear that the more significant variations are seen on the grain boundary conductivity, as illustrated in Figure 2.

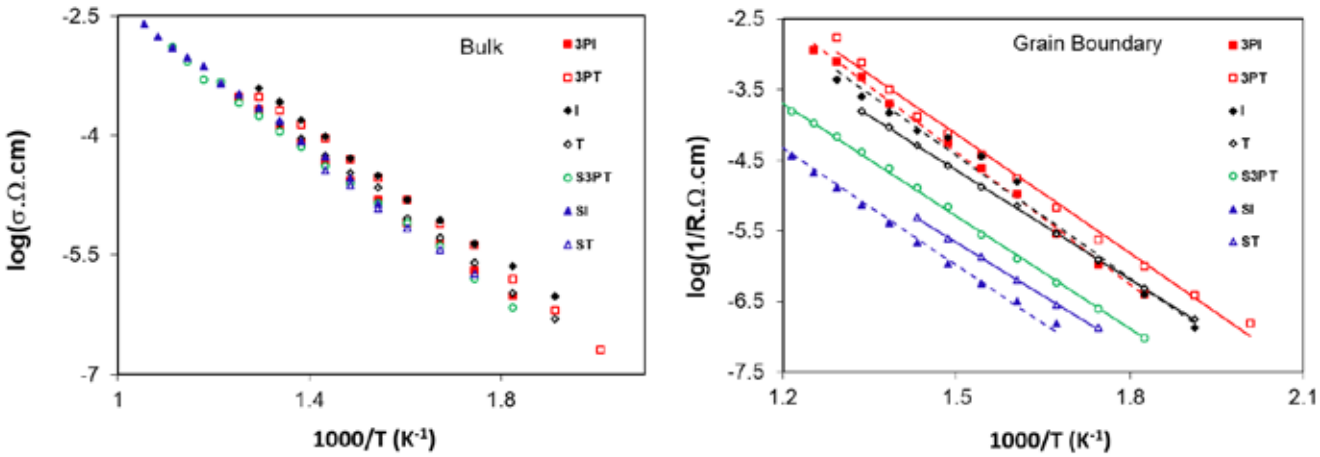

Fig. 2. Bulk and grain boundary conductivities as a function of temperature for the studied compositions.

CONCLUSIONS

The addition of praseodymium oxide to TZP to prevent or diminish the prejudicial results of the impurity silica is a viable hypothesis. The degradation in the conductivity is attenuated and further studies should be carried on to preview the right amount of praseodymium to be added to obtain the maximum effect to correct the deviations promoted by silica and not to alter the properties by itself.

ABSTRACT

Although Solid Oxide Fuel Cells (SOFC) are key for the energy transition, current lifetimes represent a critical barrier for deployment and a full understanding of the degradation mechanisms is yet to be reached. In this work an innovative testing approach has been implemented to evaluate an Accelerated Stress Test (AST) via chemical redox cycling as stressor for electrolyte supported SOFC Ni-CGO fuel electrodes. The fuel electrodes were aged with an *ex-situ* approach by exposing half-cells to alternating redox cycles (up to 12 cycles). Successively, fresh oxygen electrodes were screen-printed and the resulting full-cells with pre-aged anodes were electrochemically tested (comparing IV curves and EIS spectra with a virgin full-cell) and characterized with SEM post-test imaging. Preliminary results show that chemical redox cycling seems a viable AST pathway, showing a coherent performance degradation (both in terms of voltage and impedance) with increasing number of cycles. The accelerated degradation ascribed to the anode processes (both charge and mass transfer) by the impedance analyses is confirmed by SEM observations which show Ni particle agglomeration within the fuel electrode. However, full-cell stability with high number of redox cycles might represent a limiting factor in terms of AST replicability and testing performance, since recurrent cathode detachment is observed.

Keywords: Solid Oxide Fuel Cells, Accelerated Stress Tests, Redox Chemical Cycling, Electrochemical Testing, SEM

INTRODUCTION

Solid Oxide Fuel Cells (SOFC) are a key technology for the energy transition, due to high conversion efficiency and fuel flexibility, among other features, especially in the perspective of hydrogen as future energy vector. However, the high temperature operating conditions (500-800 °C) in relation to current material properties result in high degradation rates, leading to low lifetimes with respect to competing technologies, which represent a major criticality [1].
The determination of the degradation phenomena of a SOFC is extremely complex since multiple processes and reactions occur simultaneously in different components of the SOFC, which can be affected in several ways. Cell degradation occurs both in normal operating conditions over very long periods of operation time (several thousand hours) and in the occurrence of events (on-off cycles, thermal cycles, etc.) which can trigger soft or hard failures. The cell degradation trend is typically non-linear, and its direct observation is time-consuming since significant data is obtained only after long testing periods under several different operating conditions and occurrences [2].
The development of Accelerated Stress Tests (AST) is a prominent trend which aims to replicate the spontaneous degradation obtained in long periods of time by performing tests of shorter duration in which one or more operating parameters, named stressor (e.g. thermal, chemical, electrochemical, mechanical, etc.), are set to a harsher condition respect to standard operation. In this way the degradation mechanisms can be studied over shorter periods of time, providing meaningful information to understand the trend and evolution of each specific performance loss in order to ultimately develop suitable mitigation strategies (i.e. cell design or cell operation strategies) [2–4].
In this work an innovative combined *ex-situ* and *in-operando* testing approach has been implemented to evaluate chemical redox cycling as stressor, thus developing an AST protocol with particular focus on accelerating degradation phenomena occurring at SOFC fuel electrodes during both standard ageing and fuel-lacking events, in which Ni re-oxidation might occur such as on-off procedures, hot standby or fuel leakages/starvation.

MATERIALS AND METHODS - EXPERIMENTAL

The first step of this work is related to the *ex-situ* pre-ageing of the fuel electrodes via chemical redox cycling. Figure 1 illustrates the main features of the experimental setup.
Commercial Electrolyte Supported Cell (ESC) half cell samples have been provided by Sunfire for the study composed of State-of-Art materials. The cells present a square geometry with a YSZ supporting electrolyte layer (3x3

cm; ≈85 µm) and a single 3-layer Ni-CGO fuel electrode (1x1 cm; ≈25 µm in reduced phase). The other side of the electrolyte is bare.
The cells are mounted in a 10x10 cm single-cell metallic cell holder, in which a customized sealing geometry is designed to ensure single atmosphere at the target electrode for up to four housed samples. The gas distribution system is adapted to provide alternating reducing (H_2 and N_2) and oxidizing (air) atmospheres to all samples by two three-way non-return valves fitted on the inlet/outlet pipes. The samples are placed in a temperature-controlled furnace which is operated at fixed temperature (850°C, nominal ESC temperature) with ≈50 kg applied spring load.
After the initial heat-up procedure, the chemical redox cycles are composed of: *i)* reduction step [3 h; 400 ml/min; 25/75% H_2/N_2]; *ii)* purge phase [1 h; 400 ml/min; N_2]; *iii)* oxidation step [1 h; 400 ml/min; Air]. The duration, flow rates and compositions of each step have been selected to ensure full reduction or oxidation of the Ni particles [5,6]. When the n redox cycles are completed a final reduction step is performed before cooling down the cell under reducing conditions to fix structural variations induced by the redox cycling in typical operating conditions (reduced fuel electrode).

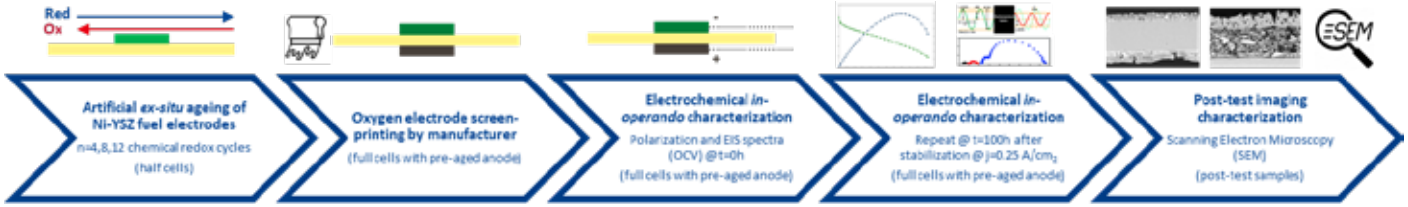
(a) **(b)** **(c)** **(d)**

Fig. 1. Experimental setup for *ex-situ* artificial pre-ageing of fuel electrodes via redox cycling. **(a)** Custom gas sealing; **(b)** Cell holder configuration; **(c)** Test rig configuration; **(d)** Redox cycling procedure scheme

Once the *ex-situ* artificial pre-ageing of the fuel electrode is completed, a fresh LSCF cathode layer (1x1 cm; 30-35 µm) was applied by screen-printing & sintering on the bare side of YSZ electrolyte, resulting in full cells with pre-aged anode. In this way any performance loss is ascribed to the degradation of the fuel electrode since the oxygen electrode did not undergo the pre-ageing chemical treatment (it is assumed that the YSZ electrolyte is chemically stable).
The second step of this work is related to the *in-operando* characterization of the full cells with pre-aged fuel electrode. Figure 2 illustrates the complete experimental workflow procedure which was followed.
The electrochemical characterization is carried out in a standard ceramic button-cell test setup [7]. The cells are tested at 850°C with stationary fuel and oxidant feeds of [100 ml/min; 60/40% H_2/N_2] and [200 ml/min; air], respectively. The electrochemical characterization is performed in OCV both at t=0 h and at t=100 h after a stabilization under a current load of 0.25 A/cm^2 to ensure stationary conditions of the performed following measurements:

- Polarization curves (galvanostatic mode, stepwise current sweep from OCV up to 0.5 A/cm^2) from which the average Area Specific Resistance (ASR) parameter is obtained from the average slope of the IV curve;
- Electrochemical Impedance Spectroscopy (EIS) spectra [OCV; ΔV_{AC} 10 mV; f=2x10^{-3}-10^5 Hz; 12 points/decade].
    - The deconvolution of the EIS data is elaborated via Distribution of Relaxation Times (DRT) technique. The trend of each process contribution is assessed by analysing the shifts in the DRT spectra with respect to the physico-chemical process mapping previously obtained by EIS testing of the virgin cell and from literature review [8].

Finally, the samples are characterized with post-test imaging via Scanning Electron Microscopy (SEM) to detect morphological and structural modifications.



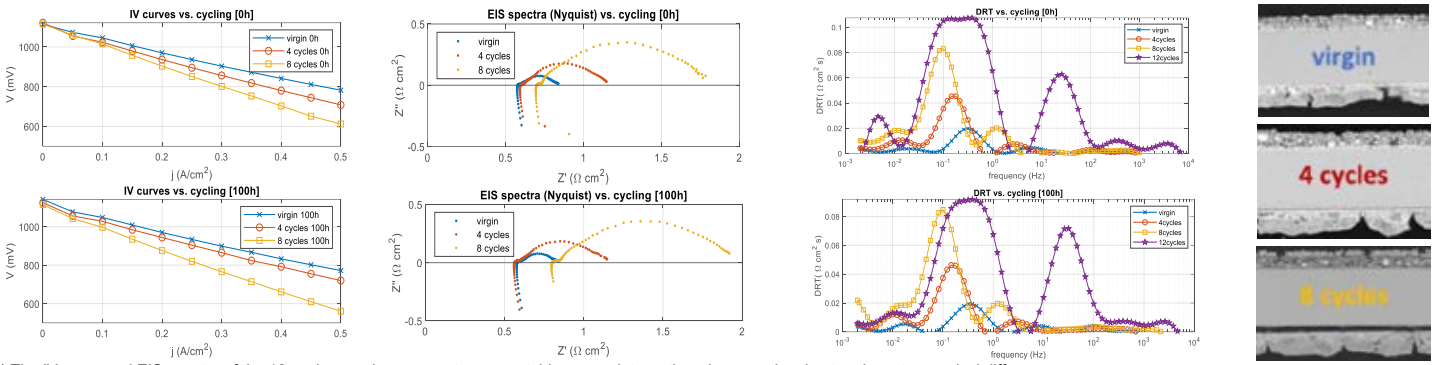


Fig. 2. Integrated experimental workflow

RESULTS AND DISCUSSION

In the following section the preliminary cell characterization results are presented for samples which have performed 4, 8 and 12 redox chemical cycles. The results – illustrated in Figure 3 – are compared with a

benchmark full cell (virgin), manufactured with the same 2-step approach starting from a half cell which has not undergone the pre-ageing procedure. The full benchmark characterization and process mapping via DRT analysis of the virgin cell are not here reported for sake of brevity.

* The IV curve and EIS spectra of the 12-cycle samples were not representable same plots as the other samples due to relevant numerical differences.

(a) **(b)** **(c)** **(d)**

Fig. 3. Summary of preliminary results vs. cycling: **(a)** IV polarization curves; **(b)** EIS spectra; **(c)** DRT spectra; **(d)** SEM images

From the IV curve the ASR is gradually increasing with increasing n (0.72 Ωcm², 0.83 Ωcm² and 1.01 Ωcm² for the virgin, 4- and 8-cycle samples respectively). Despite several repetitions the 12-cycle samples did not reach acceptable performances, suggesting a stability issue for high n (also slightly observed for the 8-cycle sample).
In terms of EIS parameters, R_0 is unaffected for the 4-cycle sample, only slightly increased for 8-cycle sample and dramatically increased for the 12-cycle samples. On the other hand, R_{pol} seems to follow a gradual increasing trend with increasing n. The DRT analysis confirms that the most impacted processes are the anode ones (both charge and mass transfer, which are convoluted between 0.01-10 Hz due to the Ni-CGO properties [8]). The result is consistent with structural variations in the cermet network caused by the alternating Ni-NiO phase transitions ($\Delta V/V \approx 40\%$ [6]), as seen in [5,6,9]. Thermal cycling during the various procedures could also have an impact [3]. In addition, an increase of the cathode charge transfer impedance (1-10 and 30-100 Hz [8]) is observed for the 8- and 12-cycle sample.
The post-test SEM images show a progressive Ni particle agglomeration with increasing n, which matches with worsened anodic performance (both mass and charge transfer). The coalescence of Ni particles seems to induce μ-cracks in the Ni-CGO substrate, modifying its porosity and particle distribution [6]. Delamination of the external layer is observed with regions where the anode bulk thickness is sensibly reduced due to lost material. Furthermore, the 8- and 12-cycle samples show an important cathode detachment, which - together with loss of electronic continuity of the external Ni contact layer - is responsible for the dramatic increase of R_0 and for increased cathode impedance. Both aspects lead to instability issues, which could limit the replicability of the AST protocol. A possible cause of detachment is related to mechanical surface degradation of the bare side of the YSZ electrolyte during redox cycling, leading to unsuccessful screen-printing. This could be avoided with an *in-situ* approach, carrying out the AST protocol on full-cells which should allow more stable performances albeit unavoidable cathode degradation during chemical redox cycling.

CONCLUSIONS

A preliminary assessment of accelerated testing of SOFC Ni-CGO fuel electrodes via chemical redox cycling with an integrated experimental approach has been carried out. Full cells with *ex-situ* pre-aged anodes show coherent results in terms of performance degradation (IV curves, EIS spectra, DRT analysis) with increasing number of redox cycles, suggesting that chemical redox cycling could be a viable AST pathway. The correlation of electrochemical results and post-test SEM images suggest that the main accelerated phenomena are related to Ni particle agglomeration within the fuel electrode, which affects both charge and mass transfer processes. The application of the cathode layer on pre-aged half cells led to detachment, especially for samples with higher numbers of cycles (8 and 12 cycles), which – together with anode delamination – could represent a strong limitation for the analysed Accelerated Stress Test protocol.

ABSTRACT

In Brazil, bioethanol is produced from sugarcane on a large scale and with high process efficiency. Characterized by simple logistics, low toxicity and small environmental impact, it represents a convenient fuel for Solid Oxide Fuel Cells (SOFCs). This perspective motivated the present research that aimed at developing theoretical and experimental analyses of ethanol-fueled SOFC micro-cogenerator. It included a stack designed for hydrogen and bearing conventional materials, running on ethanol under internal reforming regime, and a Balance of Plant (BoP) specifically designed to allow direct ethanol supply, avoiding carbon deposition on the BoP tubing. To validate the project and the components, the stand-alone system was tested with hydrogen and an ethanol/water mixture, demonstrating the capability of conveniently producing electricity and heat under such conditions. After determining the BoP efficiency, possible actions to improve it were identified and the projected efficiency that can be reached applying them was calculated, resulting close to pre-established targets. In addition, electrochemical performance results obtained with proprietary developed nickel-free anodes were promising for the direct utilization of anhydrous ethanol in an SOFC.

Keywords: Solid oxide fuel cells, Balance of plant, Micro-cogeneration, Direct utilization of ethanol, Nickel-free multifunctional SOFC.

INTRODUCTION

Solid Oxide Fuel Cells (SOFCs) directly convert the chemical energy of a fuel into electricity, with high efficiency and low environmental impact. Single cells are typically arranged in stacks, which work coupled to a Balance of Plant (BoP), the ensemble of all auxiliary devices that allow the operation of the stack and the conditioning of the energies produced. SOFCs run at high temperature and present fuel flexibility, being capable of operating with hydrogen and simple hydrocarbons: therefore, they are particularly suitable for stationary cogeneration [1]. An interesting biofuel in the Brazilian context is sugarcane bioethanol: characterized by low toxicity and small environmental impact. It is produced on a large scale and with high process efficiency [2], without competing with food production. Moreover, it is easily storable with simple logistics. Its use in SOFC-based micro-cogeneration systems would guarantee high efficiency and low pollutant emissions in a variety of applications: thus, this technology can help to expand Brazilian electrical generation capacity, further increasing the present high share of renewables in the energy mix. In this perspective, the present research concerns the development of theoretical and experimental analyses of a SOFC-based electricity generator fueled with ethanol. To use ethanol in a SOFC system, major technological modifications are required, particularly in the fuel supply line [3] and in the stack [4], which are otherwise designed to operate with gaseous fuels and utilize materials that are prone to carbon deposition. Numerical simulations evaluated the performance of SOFC operation with pure ethanol, as well as mixed with water [5]. This paper's content involves the conception of a BoP designed, built and tested with a conventional nickel-based anode stack designed for hydrogen, operated using an ethanol/water mixture as fuel, as well as the design and testing of multifunctional single SOFC cells bearing nickel-free anodic electrocatalyst that allow the direct utilization of anhydrous ethanol. The BoP materials, devices and operating conditions, as well as the nickel-free multifunctional SOFC single cells were designed to resist carbon coking and clogging upon the direct utilization of a carbonaceous fuel such as ethanol. The tests performed permitted to collect data regarding the real-life operation of a conventional SOFC stack in ethanol internal reforming regime, about the BoP needed for such operation and also on the direct utilization of ethanol in an SOFC with multifunctional anode. Similar data are not available in the literature.

MATERIALS AND METHODS

The SOFC stack employed had a nominal power of 700 W. One stack unit was tested in a test rig in order to characterize it and to identify its optimal operation point and another one was integrated to and tested in the BoP. The stacks were initially tested with hydrogen, to activate the catalyst and to ensure that they were functioning properly. Using data from the literature, computational simulations of the system and bench tests of the stacks, the characteristics of the stand-alone system and its components were defined. For multifunctional SOFC single cell

development, ceramic suspensions with different compositions were obtained from the following precursors: 8%$_{mol}$ yttria stabilized zirconia (8YSZ) catalyst powder; CeO_2-Al_2O_3 nanostructured ceramic electrocatalyst powder, synthesized through the amorphous citrates' method [6]; cornstarch pore former; terpineol-based vehicle. The anode was screen printed over an 8YSZ button-type electrolyte support with 20 mm in diameter and approximately 170 µm thick. Subsequently, the ceramic suspension was sintered at 1500 °C for three hours. After that, over the other electrolyte side, the ceramic suspension of lanthanum Strontium-doped Manganite, $La_{0.8}Sr_{0.2}MnO_3$, cathode was screen printed and sintered at 1100 °C for two hours. An aqueous solution of (Cu $(NO_3)_2.3H_2O$) was produced and cautiously dropped onto the anodes porous surfaces in order to attain 20 wt% of Cu inside the Cu-($Zr_xCe_{1-x}Y_{0.2}O_{2-\delta}$-$Al_2O_3$) system.

RESULTS AND DISCUSSION

The first SOFC stack unit bench tests were initially ran using hydrogen and air. After that, the stack was fueled with an ethanol/water mixture, maintaining the same fuel excess. The second unit was also initially tested in the test rig, only with hydrogen to avoid any damage prior to the installation in the stand-alone system. After that, the stack was coupled with the BoP and tested both with hydrogen and an ethanol/water mixture. Fig. 1a shows the best polarization and power curves obtained for the two stacks in the test bench and in the stand-alone system, with hydrogen and ethanol. Using the collected data, it was possible to estimate the power that the BoP components would consume if the stack produced 500 W of net power with ethanol. Moreover, possible actions to improve the BoP performance were determined, leading to a projection of BoP power consumption after such additional developments. The experimental power consumption of the BoP components is reported in Fig. 1b, together with the estimated and projected values.

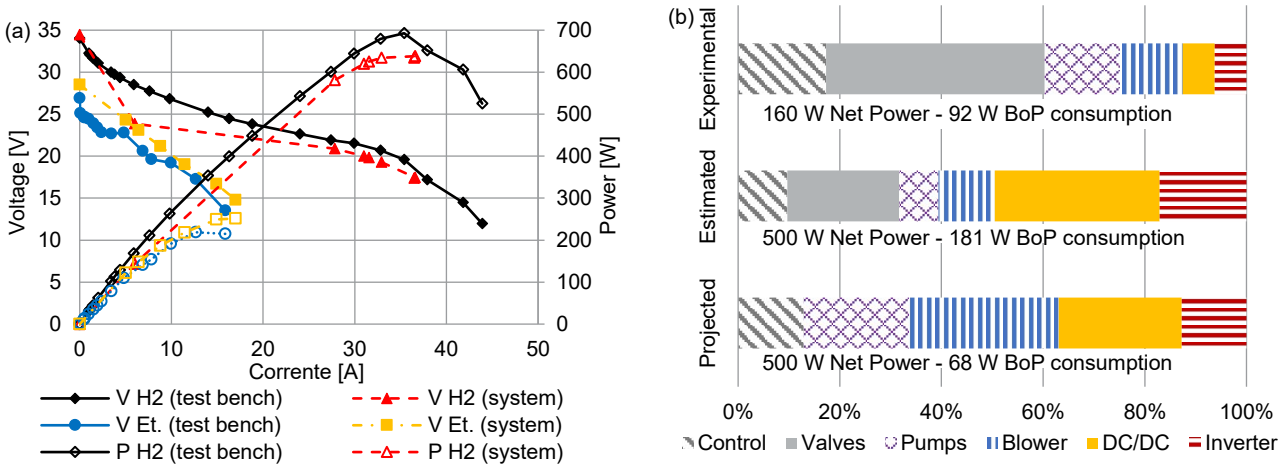

Fig. 1. Polarization and power curves of the stacks (a) and BoP power consumption with ethanol (b).

Data analysis supplied valuable information about the system operating modalities and the interdependence of the different parameters, evidencing some critical relationships between them that is important to consider in the design of the control system. This includes: the air flow should be as low as possible, to improve stack efficiency and make the system thermal management easier, but needs to be high enough to completely burn the excess fuel, unreacted in the stack; a fuel flow increase makes the stack power higher but reduces overall system efficiency and is associated to a higher water flow and consequent possible evaporation problems; a higher operation temperature increases the stack efficiency but needs a higher fuel flow to be sustained; battery charge at system start-up and shut-down must be above values that permits the safe conclusion of the transients. Using the test data, it was also possible to calculate the BoP electrical efficiency and to identify the devices responsible for most of the power consumption, as well as the actions necessary to improve the energy efficiency of the system. The projected overall BoP efficiency that can be reached applying conclusions of the theoretical analyses made reaches 88.1 %, very close to the industry target of 90 %. This confirms the validity of the BoP design and of the actions considered to reduce its power consumption.

Encouraging results were obtained with Cu-($Zr_xCe_{1-x}Y_{0.2}O_{2-\delta}$-$Al_2O_3$) nickel-free single cell anode materials (Fig. 2). Preparation and sintering procedures that promotes a high degree of interaction between CeO_2 and 8YSZ to form $Zr_xCe_{1-x}Y_{0.2}O_{2-\delta}$-$Al_2O_3$ resulted in anodes that exhibit redox properties highly favorable for direct utilization of anhydrous ethanol in SOFCs. In this material, Cu acts as electronic conductor, while the solid solution $Zr_xCe_{1-x}Y_{0.2}O_{2-\delta}$-$Al_2O_3$ is active for electrochemical oxidation of ethanol and/or of the products obtained from its thermal decomposition, while Al_2O_3 phase acts against thermal degradation, avoiding the coarsening of the solid solution at the high operating temperatures.

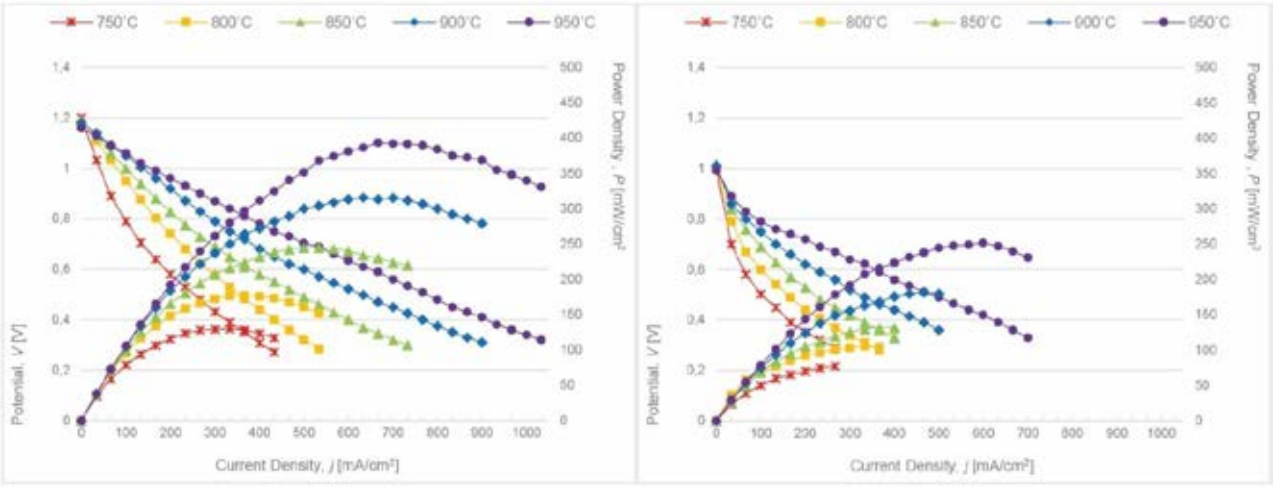

Fig. 2. Polarization and power curves for the nickel-free SOFC anode operated with hydrogen (a) and ethanol (b).

CONCLUSIONS

SOFC stacks designed for hydrogen were tested with hydrogen and with an ethanol/water mixture: one stack was tested only in a test rig, and a second one was also tested in a stand-alone system integrated to a complete BoP. Stack performance was similar in the test rig and in the stand-alone system, confirming the validity of the BoP system design. During operation with hydrogen the desired net electrical power of 500 W was reached, while the performance obtained with ethanol was considerably lower, due to the fact that the stack is a model designed to operate exclusively with hydrogen. Using the test data, it was also possible to calculate the BoP electrical efficiency, and to identify the devices responsible for most of the power consumption, as well as the actions necessary to improve the energy efficiency of the system. Key advances of this work with respect to the state of the art include: monitoring of real-life operation of a commercial SOFC stack with conventional nickel-based anode, fed with an ethanol/water mixture and working in internal reforming regime; design, construction and operation of a BoP for an ethanol-fueled SOFC-based generation system; elaboration of activation, steady state operation and deactivation routines for the stand-alone system. The results obtained confirmed the feasibility of the construction of an ethanol-fueled SOFC-based micro-cogenerator, which can be conveniently used for various applications in Brazil and worldwide.

ABSTRACT

Cobalt spinel oxide (Co_3O_4) and gadolinium-doped ceria (GDC) nanocomposite were prepared via sol-gel processing and were studied as cathode material for intermediate-temperature solid oxide fuel cells (SOFCs). XRD analysis confirmed separate precipitation of Co_3O_4 and GDC phases during the calcination process thus, producing a nanocomposite. Various nanocomposite compositions were tested for their electrical property where a nanocomposite having a Co to GDC mole ratio of 1 (CGC1) showed the highest electrical conductivity. Electrochemical impedance spectroscopy and DC polarization measurements were conducted to study the performance of SOFC consisting of CGC1 cathode. The SOFC showed an initial maximum power density of 484 mW cm^{-2} at 800 °C however, the cell performance gradually increased, and a maximum power density of 1380 mW cm^{-2} was observed after a 168 h operation.

Keywords: Solid oxide fuel cell, Cathode, Nanocomposite, Cobalt, Spinel.

INTRODUCTION

Solid oxide fuel cell (SOFC) is a promising green energy conversion technology that can convert fuel directly into electricity through electrochemical reactions across the interfaces [1]. However, to make the SOFC technology reliable and cost-effective it is imperative to reduce its operating temperature to an intermediate range i.e., ≤800 °C. However, SOFC shows a decreased performance at low operating temperatures due to the slow kinetics of its cathode for the oxygen reduction reaction (ORR). Hence, a highly active and stable cathode is required for low-temperature operation [2].

Researchers have made extensive efforts with the aim to acquire new cathode materials with high catalytic activity. In this regard, cobalt-doped perovskite materials have been one of the most famous topics in SOFC cathode research. This is because the cobalt-doped cathode materials show high electrical conductivity and outstanding electrocatalytic activity for the ORR. However, cobalt-doped perovskite oxides show high values of thermal expansion coefficient (TEC) (14.5–20 × 10^{-6} K^{-1}), producing high thermal expansion mismatch with the state-of-the-art electrolyte materials (12 × 10^{-6} K^{-1}). Therefore, there is a risk of structural instability that can cause high-performance degradation during the thermal cycling of the SOFCs [3].

Spinel oxide with cubic structure has attracted high attention as an alternative cathode material in the SOFCs due to its appropriate electrical conductivity, high ORR activity as well as compatible values of thermal expansion coefficient (11–12.5 × 10^{-6} K^{-1})[4,5]. Spinel oxides are also attractive because they do not contain rare-earth elements and therefore, reduce the material cost. Previously, various authors have reported spinel oxide as cathode materials for the SOFC consisting of two or more transition elements. In this work, we present a simple and cost-effective approach to produce a Co_3O_4 spinel-GDC nanocomposite. SOFC consisting of the newly developed nanocomposite cathode was tested for its electrochemical performance and durability at 800 °C.

MATERIALS AND METHODS

For the synthesis of Co_3O_4-GDC nanocomposites, nitrate salts ($Co(NO_3)_2 \cdot 6H_2O$, $Ce(NO_3)_3 \cdot 6\ H_2O$, and $Gd(NO_3)_3 \cdot 6H_2O$) and citric acid were purchased from Sigma-Aldrich in South Korea. Nanocomposites were prepared by using Co to GDC molar ratio of 0.05, 0.1, 0.25, 0.5, 0.75, and 1. The nanocomposites were named CGC0.05, CGC0.1, CGC0.25, CGC0.5, CGC0.75, and CGC1 according to the molar ratio Co and GDC. To synthesize a nanocomposite, stoichiometric amounts of metal nitrates and citric acid were dissolved in de-ionized water and stirred onto a hot plate until a gel was formed. The gel was then burnt and calcined at 250 and 800 °C, successively and finally a black powder, Co_3O_4-GDC nanocomposite, was obtained.

The phase composition of nanocomposites was characterized by X-ray diffraction (XRD, 2500 D/MAX, Rigaku) using Cu*Kα* radiation. The electrical conductivity of the nanocomposites was measured by standard 4probe technique using rectangular bar prepared by compacting and sintering of nanocomposite powders at 1050 °C. For the electrochemical performance measurement, a nanocomposite cathode (CGC1) was fabricated onto an in lab prepared anode-supported half cell. The fabrication process of the anode-supported half cells can be found elsewhere. To fabricate the nanocomposite cathode, an ink paste was prepared by centrifugal mixing of CGC1 powder with appropriate amounts of α-terpinol and ethyl cellulose. The CGC1 ink paste was screen printed onto the fully dense YSZ electrolyte of the anode supported half cell and sintered at 1050 °C for 1 h in air. After sintering, the nanocomposite cathode had an active area of 1 cm^2. For cell tests, Ag and LT-CCC (kceracell, South Korea) pastes were used to create electrical contacts for the anode and cathode, respectively. Ag mesh and wire were used for current collection from the electrodes. The electrochemical performance was recorded by measuring the current-voltage (*I–V*) and electrochemical impedance data at 800 °C using hydrogen as a fuel and air as an oxidant. A DC load device was used to gather the *I–V* data.

RESULTS AND DISCUSSION

In this work, Co_3O_4-GDC nanocomposites were acquired by sol-gel processing and calcination at 800 °C. The resulting black powders were characterized by XRD to observe the phase composition as shown in Fig. 1b. Although Co, Ce, and Gd were initially dissolved together as nitrate salts, Co_3O_4 and GDC phases were separately crystallized during calcination at 800 °C thus, producing the required nanocomposite. It can be observed from Fig. 1a that the peak intensity of the Co_3O_4 has continuously increased as the molar ratio of Co is increased in the precursor. Fig. 1b shows the electrical conductivity plots of various CGC nanocomposites. The electrical conductivity of the nanocomposite showed a decline as initially the amount of Co_3O_4 increased in the nanocomposite from CGC0.05 to CGC0.25. However, the electrical conductivity increased rapidly after that as it went from 2.5 to 23 S cm^{-1} for CGC0.5 and CGC1, respectively, at 800 °C. The reason for the initial decrease observed in the electrical conductivity even though the amount of conductive phase was increased is not known at this point, but it is under investigation. Due to its highest electrical conductivity, CGC1 was selected to be employed as cathode material for performance measurement in a SOFC.

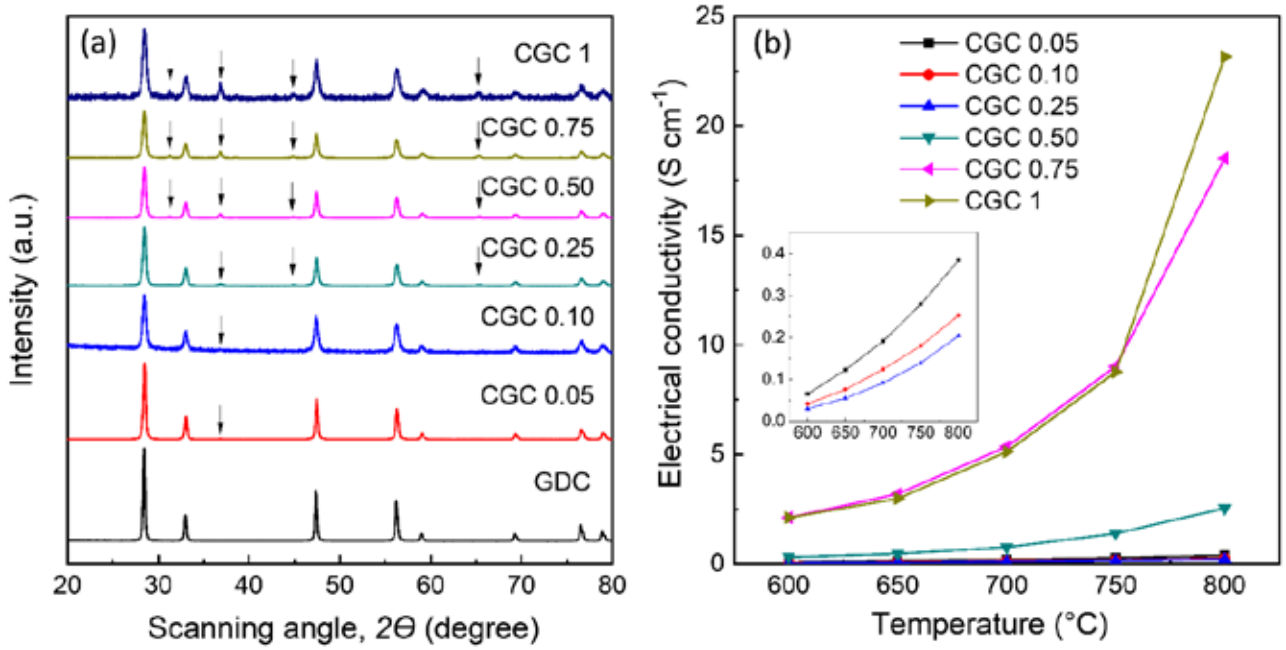

Fig. 1. (a) XRD analysis of various Co_3O_4-GDC (CGC) nanocomposites obtained after calcination at 800 °C. (b) Electrical conductivity plots of CGC nanocomposite rectangular bar samples obtained by 4probe method.

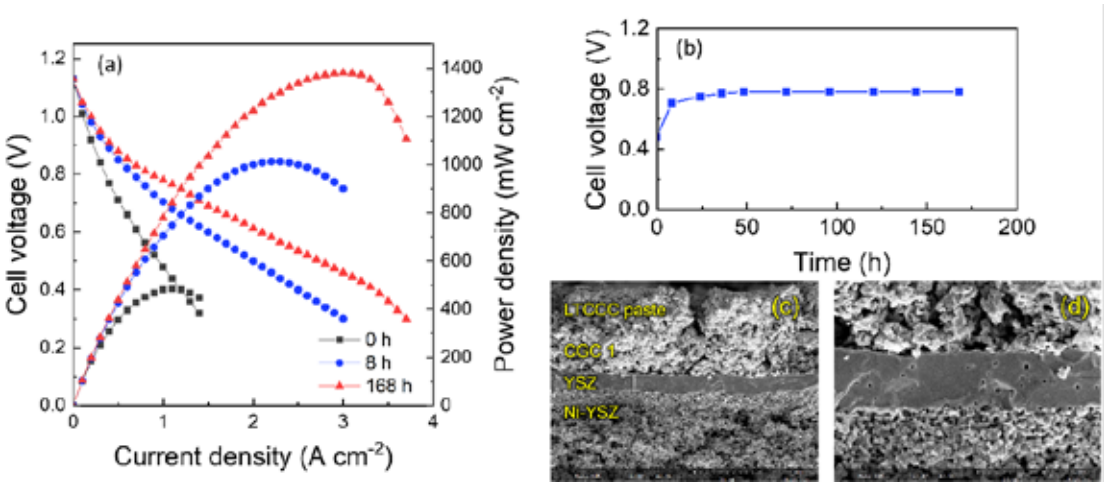

Fig. 2. (a) *I–V–P* plots obtained at 800 °C at different times for the SOFC consisting of CGC1 nanocomposite cathode while using hydrogen as a fuel and air as an oxidant. (b) long term stability data acquired at 800 °C while operating under a galvanostatic load of 1 A cm^{-2}. (c, d) Cross-sectional SEM images of the anode supported SOFC after stability test.

Anode-supported SOFC consisting of a nanocomposite CGC1 cathode was tested for its electrochemical performance (Fig. 2). Fig. 2a shows the *I–V–P* plots of the anode supported SOFC indicating high open-circuit voltage observed at different times while operating at 800 °C. Initially, the SOFC showed a relatively low maximum power density of 484 mW cm^{-2}. However, the SOFC was operated at a high current density of 1 A cm^{-2} and the performance was noticed to increase rapidly and a maximum power density of 1012 mW cm^{-2} was observed after an 8 h of operation. The SOFC was kept under a high current density of 1 A cm^{-2} continuously for 168h at the end of which the SOFC showed a high power density of 1380 mW cm^{-2}. Performance of the SOFC consisting of CGC1 nanocomposite cathode increased by 185% during the 168 h operation. Fig. 2b shows the stability data obtained during the 168 h operation which indicates a highly stable performance obtained even in such extreme operating conditions. Fig. 2c and d show the microstructure of the SOFC after the stability test illustrating a typical SOFC morphology. Electrochemical performance and stability results indicate that the new nanocomposite is promising as high performing and durable SOFC cathode material, and it should be explored for more exciting results.

CONCLUSIONS

A simple and cost effect Co_3O_4-GDC nanocomposite was synthesized by sol-gel processing and was evaluated for its electrochemical performance as a SOFC cathode material. A SOFC consisting of the nanocomposite cathode initially showed a low performance (484 mW cm^{-2}) at 800 °C however, a continuous operation under a high current resulted in rapid performance enhancement, and finally, after a 168 h operation, the SOFC showed a high power density of 1380 mW cm^{-2}. The results indicate that the new nanocomposite shows potential for fabricating high-performing and robust SOFC cathodes and it should be further matured for industrial-scale applications.

ABSTRACT

Passive direct methanol fuel cells (pDMFCs) appear as a promising alternative for power portable electronic devices, since they use a liquid fuel, which is easy to handle, storage and distribute and have a quick refuelling, high efficiency and low environmental impacts. However, some issues need to be solved before the introduction of this technology in the market, such as methanol and water crossover through the membrane, low lifetime and high costs. In this way, the present work studies the effect of reducing the catalyst loadings, on both anode and cathode sides, on the performance of a mini passive DMFC towards a reduction of these systems costs. Moreover, the different phenomena that affect the cell performance were identified based on the polarization measurements and quantified using the electrochemical impedance spectroscopy (EIS) technique. The main goal of this study was to reduce the costs of these systems without a significant lost on their performance and analyse in detail the different losses that negatively affect the cells under the light of the EIS technique. Therefore, it was proposed an innovative equivalent electric circuit (EEC) that reproduces with accuracy the system under study.

Keywords: Passive direct methanol fuel cell, Catalyst loading, Power output, Electrochemical impedance spectroscopy, Equivalent electric circuit

INTRODUCTION

Alternative power sources with low environment impacts are urgent in the society. Additionally, the growing interest in portable electronic devices motivate the research on finding alternative technologies to overcome the batteries limitations. The passive direct methanol fuel cells (pDMFCs) appear as a promising solution to achieve that due to their low environmental impacts, high efficiency, simplicity and quick refuelling. Nevertheless, these fuel cells present some limitations, such as slow anode kinetics, methanol and water crossover through the membrane, high costs and low lifetime [1]. The pDMFC catalysts, where the electrochemical reactions occur, are responsible for a major fraction on these systems costs since the most common used catalysts are noble metals, such as Platinum and Ruthenium. The present work studies the effect of a significant decrease on both anode and cathode catalyst loadings, to reduce the cell costs, without a significant decrease on these systems efficiency. The performance is evaluated through the polarization and power density curves and the electrochemical impedance spectroscopy data. The EIS technique provide useful information to identify and quantify the different phenomena that occur on the fuel cell and have a negative impact on its performance [2]. As the methanol concentration has a clearly impact on the pDMFC performance, the effect of the methanol concentration for the different loadings used at both sides was also evaluated. The methanol concentration that leads to a higher performance results in a balance between the negative effect on the methanol crossover rate that increases with an increase of the methanol concentration, and the positive effect on the anode oxidation reaction rate that increases with the methanol concentration. Another target of this work was to identify the different losses that negatively affect the system (ohmic, activation and mass transfer) at the anode and cathode sides under the light of the EIS measurements.

MATERIALS AND METHODS

The mini passive DMFC (mini pDMFC) used in this work has an active area of 2.25 cm^2, two acrylic end plates (opened at the cathode side and with a fuel reservoir at the anode side (1.8 cm^3)), two isolating plates, two stainless steel current collectors (with an open ration of 28% at the anode and 17% at the cathode), carbon cloth with a microporous layer (MPL) as anode and cathode diffusion layers (thickness of 0.410 mm and a porosity of 0.8), a Nafion 117 membrane, Pt-Ru as anode catalyst and PtB as cathode catalyst (Fig. 1).

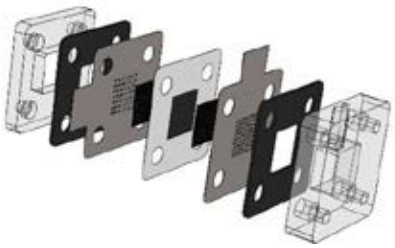

Fig. 1. Schematic representation of the mini pDMFC

The experimental tests were performed at ambient conditions, with different methanol concentrations and different anode and cathode catalyst loadings, setting a loading on one side of the cell and using different loadings at the other side, towards a cost reduction without a significant decrease on the cell performance.
The cell performance was evaluated by polarization curves and electrochemical impedance spectroscopy data. The experimental tests were performed with a commercial fuel cell test station, Zahner Elektrik GmbH &Co. kG. The EIS measurements were conducted at different fuel cell voltages, with an amplitude of 10 mV and a frequency range between 0.01 Hz to 100 kHz. The impedance results were fitted to an equivalent electric circuit (EEC).

RESULTS AND DISCUSSION

As the Nafion membrane is permeable to methanol and due to the alcohol concentration gradient between the anode and the cathode side, the cell suffers from methanol crossover leading to an open circuit voltage much lower that the ideal one (1.21 V). This methanol loss to the cathode side leads to a decrease of the available fuel on the anode side, decreasing the methanol oxidation rate and increasing the anode losses. Additionally, the methanol that reaches the cathode is oxidized at this side, poisoning the cathode catalyst by the intermediate compounds of the incomplete methanol oxidation reaction, as Platinum (the cathode catalyst) is not the most proper one to this reaction. Consequently, a mixed potential is formed at the cathode side increasing the cathode losses and decreasing the overall fuel cell efficiency. Even though higher methanol concentrations lead to a higher methanol concentration gradient between the anode and cathode side, increasing the methanol crossover, it also increases the availability of methanol at the anode side, favouring the methanol oxidation reaction at this side. Therefore, the optimal methanol concentration arises from a balance between these two phenomena, the negative effect on the methanol crossover rate and the positive effect on the anode oxidation reaction. Figure 2 shows the effect of methanol concentration on the mini pDMFC performance using 4 mg/cm^2 Pt-Ru as anode catalyst and 4 mg/cm^2 PtB as cathode catalyst.

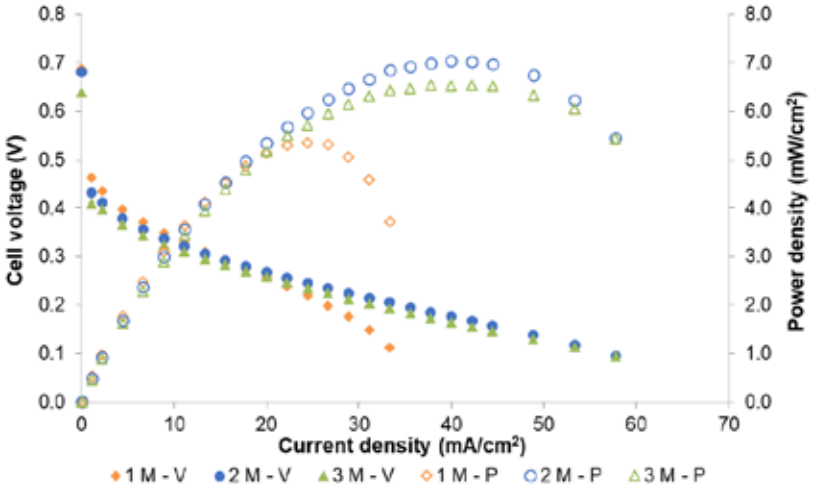

Figure 2. Effect of the methanol concentration on the mini pDMFC performance

Table 1 presents the different resistances of the EEC for the different methanol concentrations and voltages tested using an anode catalyst loading of 4 mg/cm^2 Pt-Ru and a cathode catalyst loading of 4 mg/cm^2 PtB.

Table 1. Values of the different resistances of the EEC for the different methanol concentrations and voltages tested.

		Methanol Concentration		
	Voltage (V)	1 M	2 M	3 M
Rohm (Ω)	0.40	0.45	0.41	0.41
	0.30	0.45	0.41	0.41
	0.20	0.45	0.41	0.41
R1 (Ω)	0.40	2.4	1.1	0.79
	0.30	1.9	0.92	0.75
	0.20	-	0.76	0.49
R2 (Ω)	0.40	6.5	8.0	11
	0.30	2.2	2.1	2.2
	0.20	3.6	1.2	1.2
Power Density (mW/cm^2)		5.3	7.0	6.5

As can be seen in Fig. 2 and Table 1, the best methanol concentration, the one that leads to a higher performance and consequently lower losses (lower resistances) was 2 M.
This work allowed studying the effect of methanol concentration and the anode and cathode catalyst loadings on the performance of a mini passive DMFC and the identification of the different system losses. An EEC was proposed showing a good agreement with the experimental EIS data, which allowed the quantification of each loss that negatively affects the cell performance.

CONCLUSIONS

Costs and lifetime are key challenges to overcome towards the introduction of the pDMFC in the market to replace the lithium batteries in portable applications. A mini passive DMFC with an active area of 2.25 cm^2 was studied through polarization curves and EIS. A reduction of the catalyst loadings on both anode and cathode layers was evaluated in order to reduce the fuel cell costs and analyse the different losses that affect its performance. The system allowed working with high methanol concentrations and the EEC proposed showed a good agreement with the experimental results.

ABSTRACT

Following a pioneering study on (La,Sr)CoO_3- (La,Sr)$_2CoO_4$ amorphous cathodes which was synthesized via sputter deposition, a similar work was carried out for (La,Sr)FeO_x – (La,Sr)MnO_3 composite cathodes to see if the cathode can be used in amorphous form with acceptable ORR. First a thorough search was made in LSM/LSF/ScSZ ternary system to identify most favorable compositions. Unfortunately, even in most favorable cathode composition, an acceptable ASR value of 0.15 ohm cm^2 was obtained at temperature not lower than 800 ^oC where the cathode, was already crystalline. This study however showed that a thorough investigation is needed in LSM-LSF binary system where a more favorable results may be obtained. Accordingly a set of 6 cathodes were sputter deposited in combinatorial geometry using LSM and LSF sputter targets where the cathode make-up varied over a wide range. Electrochemical performance of the cathodes were measured using symmetric cell. The tests were performed starting from 450 ^oC at 50 ^oC interval and stopped when ASR <=0.15 ohm *cm^2. Cathodes which were amorphous in the deposited state were monitored so as to determine the temperature of crystallization. The aim is to identify compositions where the cathode is still amorphous with an acceptable ASR values. The role of ScSZ addition in improving the stability of amorphous cathode was also investigated.
Keywords: SOFC, Cathode, LSM, LSF, Magnetron sputtering.

INTRODUCTION

There is a considerable interest in the reduction of operating temperature of solid oxide fuels cell (SOFC). Thus, numerous studies have been conducted to develop the so-called intermediate temperature SOFCs [1,2]. The bottle neck in IT-SOFCs is the cathode material as there are suitable alternatives for anode and electrolyte that could operate with acceptable kinetics at temperatures as low as 600 °C. In the case of cathode materials, the main problem is oxygen reduction reaction (ORR) which becomes unacceptably slow at reduced temperatures.

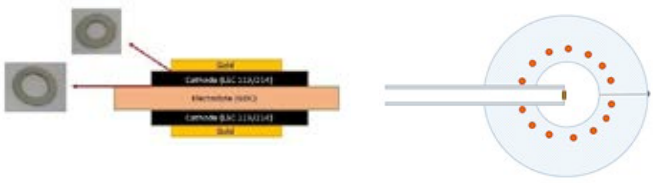
Although there are various strategies in reducing the operation temperature of SOFC, one notable approach is based on the use of a MIEC oxide in polyamorphous cathode [2]. This was illustrated in composite (laSr)CoO3- (La Sr)2CoO4 cathode synthesized via sputter deposition in amorphous form. The cathode had an acceptable ORR performance at temperatures as low as 570°C . In addition the structure was still amorphous/nanocrsytalline at these temperature with added benefit contributing to the stability of the cathode [3].

The current work was undertaken to develop cathode material of improved ORR performance to be used with scandia stabilized zirconia(ScSZ) as electrolyte. Based on thermal mismatch consideration, two oxides were selected, namely $(La_{0.8}Sr_{0.2})FeO_3$ (LSF), a well known MIEC oxide and $La_{0.5}Sr_{0.5}MnO_{3-\delta}$ (LSM). The purpose is to see if an amorphous cathode could be synthsized with improved ORR and stability. A third oxide, namely $Sc_{0.15}Zr_{0.8}5O_{2-\delta}$ (ScSZ) may also be added to this system, though the fraction of this oxide will not be more than 0.15.

MATERIALS AND METHODS

Active materials $(La_{0.8}Sr_{0.2})FeO_3$ ($La_{0.5}Sr_{0.5}MnO_{3-\delta}$) and $Sc_{0.15}Zr_{0.8}5O_{2-\delta}$ were synthesized using Pechini method. by mixing their nitrates in stoichiometric proportions. Having synthesized the powders and checked their composition, they were compacted and sintered at elevated temperature in the form of discs to be used as target for sputter deposition.

The sputter deposition were carried out in a prismatic vacuum chamber in 500X500X500 mm dimension. Sputter targets were 300 mm apart with an inclination of approximately 45^o. Schematic representation of the sputter deposition is given in Fig. 1. Distances and inclination of sputter targets were adjusted in such a manner that thickness of sputter deposited cathode were almost the same. Deposition was carried out with a duration that cathodes were approximately 500 nm thick.



(a) (b)

Fig. 1 Sputter deposition of cathodes inn combinatorial geometry a) photograph of the deposition unit in operation- 3 sputter guns are in operation. b) Geometry of deposition used in the current work using two sputter targets

Two sets of substrates were deposited; one set was borosilicate glass discs for structural investigation and the other set was ScSZ electrolyte. Both had a diameter of 18 mm. The latter, i.e. electrolyte was in the form of 4 mm thick discs. EIS measurements were carried out on symmetric cell, dimensions of which are given in Fig. 2. Thus as shown in the figure, both sides of the electrolyte was coated with cathodes of diameter less than the electrolyte disc, on which a smaller diameter gold was coated for connection purposes.

RESULTS AND DISCUSSION

First, a ternary study was carried out using three sputter targets; LSF, LSM and ScSZ. A total of 21 cathodes were deposited covering a wide compositional range. Fig.2 taken from the work of Kılıç[4] shows the most promising compositions in this ternary system. The figure shows the temperature at which the cathodes would have an ASR value of 0.15 Ω cm^2 via extrapolation. It is seen that the best cathode had a composition of $LSM_{0.77}$ $LSF_{0.11}$ $ScSZ_{0.12}$ with an expected operational temperature of 805 oC. It was further found that the cathodes which were amorphous in the as-deposited state crsytallized when the the symmetric cell was heated to 800^{o}C.

(a) (b)

Fig. 2 Schematic presentation of symmetric cell used in EIS measurement. a) cell , b) cell mounted on alumina tube in a furnace for measurement

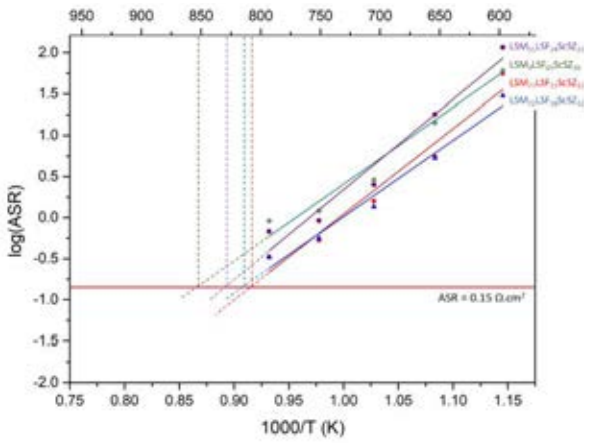


Fig. 3 log(ASR) vs 1000/T determined for cathodes in ternary LSM-LSF-ScSZ system. The best cathode (red) yields an operating temperature of 805 oC (ASR=0.15 Ω cm^2 and has a composition of $LSM_{0.77}$ $LSF_{0.11}$ $ScSZ_{0.12}$ [4]

The work is currently in progress where the binary LSM-LSF cathodes are deposited in two sets one on glass substrate to examine the maximum temperature at which they can be exposed without crystallization and the second set of deposition will be used for the symmetric cell to determine lowest ASR values in terms of composition while the cathodes were amorphous.

ABSTRACT
In this study, we report results of an investigation carried out on (La,Sr)CoO_3- (La,Sr)$_2CoO_4$ dual phase oxides as cathode for IT- SOFCs. Cathodes were produced via sputter deposition where the volume fraction varied over a wide range from 0.10 <(La,Sr)$_2CoO_4$ < 0.90 and screened electrochemically using symmetric cells. The study showed that the compositions with volume fractions in the range 0.40 < (La,Sr)$_2CoO_4$ < 0.60 were particularly significant in yielding cathodes of improved performance. Refocusing the combinatorial screening to this range yielded (La,Sr)CoO_3-(La,Sr)$_2CoO_4$=0.45:0.55 as the most favorable composition. Taking ASR=0.15 Ω · cm2 as a useful benchmark, the study showed that cathodes in this range may be used at temperatures as low as 575 °C. It was further shown that composite cathodes have amorphous structures in co-sputtered conditions and could remain so when used at reduced temperatures. At temperatures close to 700 °C the amorphous cathode turns into nanocrystalline two phase structure with grains not more than 10 nm in size. Moreover, these refined cathodes were extremely stable and resistant to Sr segregation. The results imply a new class of LSC based amorphous/nanocrystalline cathodes for IT-SOFCs.

Keywords: IT- SOFCs, ORR Catalysts, Amorphous cathodes, (La,Sr)CoO_3- (La,Sr)$_2CoO_4$ dual phase oxides,

INTRODUCTION
Increasing demand to energy and limited existence of fuels have directed investigations to find out new and novel routes for alternative and efficient energy conversion systems. Solid oxide fuel cells (SOFCs) as a more efficient alternative fall into this category in consequence of their ability to convert chemical energy directly into electricity in highly efficient way with fuel flexibility and without the limitation of Carnot cycle. However, this is at the cost of high operating temperatures (>800^{o}C) dictated by the requirement of sufficiently fast oxygen reduction rate, occurring at cathode side and constituting the main source of rate limitation in overall SOFC operation. High operating temperature not only constitutes a problem in terms rapid degradation of cell, i.e., reduction in lifetime of SOFC, but it also severely restricts the choice of interconnect materials. Difficult sealing conditions at high temperatures is another major source of stimulus for intermediate temperature SOFCs. Accordingly, there is a strong motivation in reducing operating temperature of the cell down to 700-500^{o}C, i.e., IT-SOFC, at which oxygen reduction kinetics becomes quite critical.

The introduction of mixed electronic and ionic conductive (MIEC) oxides has opened a new era in pursuit of realizing IT-SOFCs [1]. The impact of MIEC oxides in catalyzing the oxygen reduction reaction (ORR) and achieving temperature reduction have been well recognized. Furthermore, following the work of Sase et al. [2] on (La,Sr)CoO_3/(La,Sr)$_2CoO_4$ (LSC113/214), there has been considerable interest in dissimilar interfaces as a way of further accelerating ORR at cathode. The improvement that occurred by 3-4 orders of magnitude in oxygen exchange coefficient at the hetero-interface have focused studies on composite cathodes [2,3]. Studies, therefore, have concentrated on maximization and utilization of the dissimilar interface in SOFC cathodes [3,4]. By maximizing the dissimilar interfaces, the resulting accelerated ORR, could lead to lower polarization resistance in the cathode which in turn could lead to a lower SOFC operating temperatures. Studies aiming for maximization of dissimilar interfaces has mainly relied on thin film work [e.g., 3].

In maximizing the interfacial regions, the volume fraction is an important parameter as well as the scale of structure. Therefore, the current study was undertaken to investigate how the cathode performance is affected by the phase fractions, while keeping the structure at nanoscale. For this purpose, we adopt a combinatorial approach where the volume fraction of (La,Sr)$_2CoO_4$ varied from 0.10 to 0.90.

MATERIALS AND METHODS
LSC-113 as well as LSC-214 powders were synthesized using Pechini method [5]. Details regarding the preparation of the sputter targets from the synthesized powders were described by Sari et al. [6]. Thin film cathodes of mixed oxides were produced via sputter deposition in a specially designed vacuum deposition system. Detailed description of the deposition system and method used combinatorial sputtering were described in Ref [6]. Fig.1 illustrates the

combinatorial sputtering where 6 samples each with different cathode compositions were obtained simultaneously by co-sputtering of (La,Sr)CoO3 and (La,Sr)2CoO4 targets . EIS responses of the thin film cathodes were measured on symmetric cells. Schematic drawing of the symmetric cell used in this study is given in Fig. 2. Here, it is seen that the symmetric cell is made up of three layers. Top and bottom layers were cathodes which were deposited on the mid-layer, i.e., electrolyte. The electrolyte used was gadolinium doped ceria (GDC) typically 1mm in thickness and 19 mm in diameter. Two sets of masks were used to control the surface area of the cathodes and the current collectors. These masks were stainless steel flat rings with 12mm (cathode) and 10mm (current collector) in inner diameter.

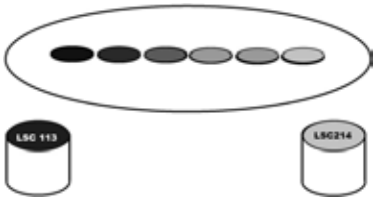

Fig.1 Schematic representation of combinatorial sputter deposition geometry used to obtain a library of thin film cathodes.

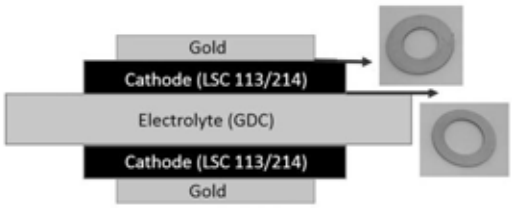

Fig.2 Schematic representation of symmetric cell used in electrochemical impedance spectroscopy measurement.

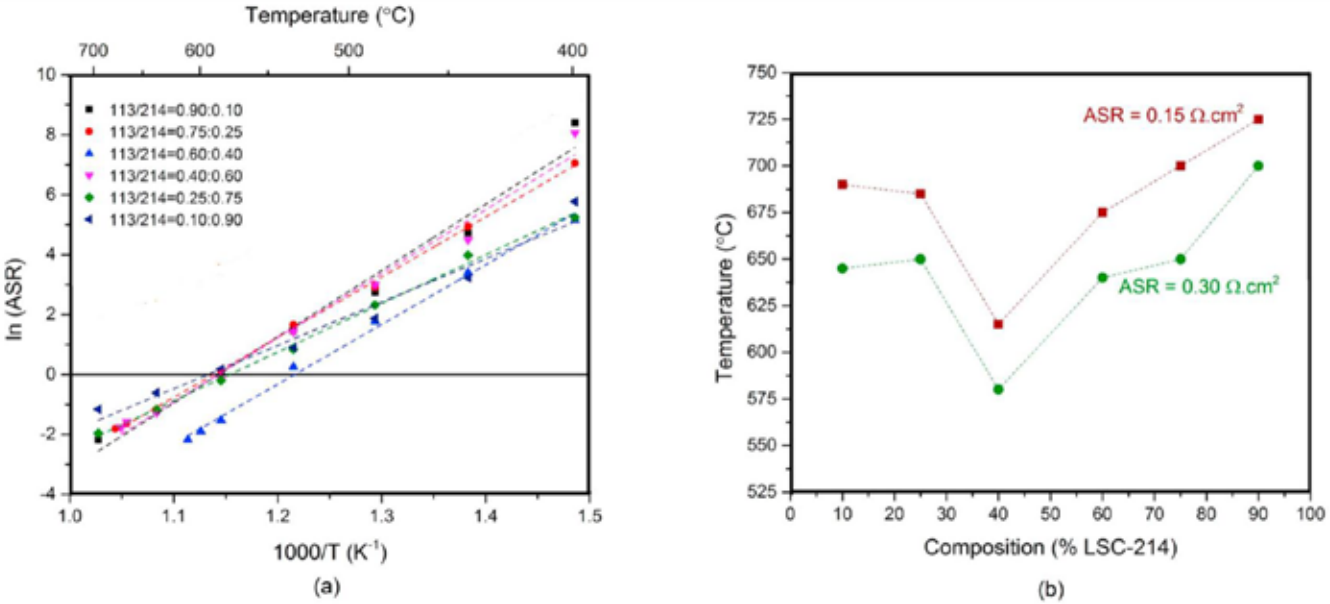

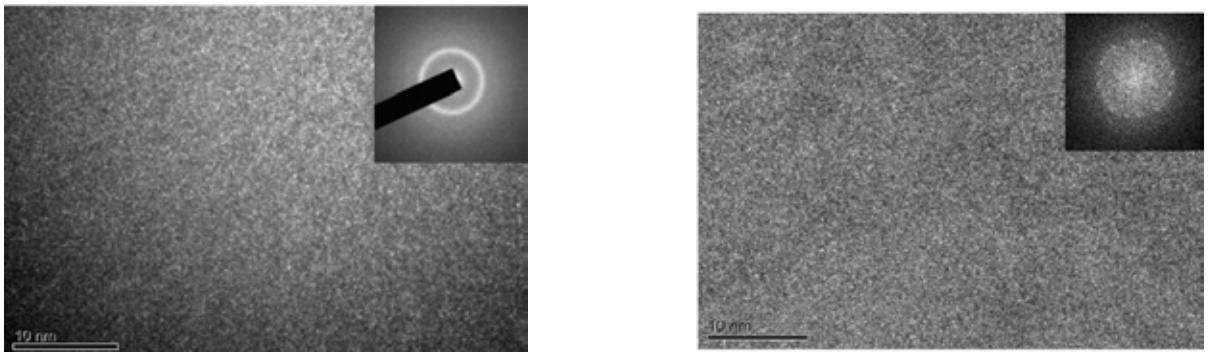

Fig. 3 a) The relationship between ln (ASR) vs 1/T [K−1] for the co-sputtered cathode library in the composition range of LSC-113:LSC-214=0.90:0.10–0.10:0.90. b) Temperatures at constant values of ASR as a function of cathode compositions. Temperatures refer to ASR values of 0.15, and 0.30 Ω·cm2. Note that minimum operating temperatures occur at mid-compositions.

RESULTS AND DISCUSSION

Area specific resistance values determined from symmetric cell are shown platted as a function of temperature in Fig.3. Figure 4 is derived from Fig. 3 where temperature at which specific values of ASR are shown plotted as a function of the cathode composition. ASR= 0.15 ohm cm^2 is usually taken as a benchmark for cathode. Using this value it is seen that the temperatures are quite low at compositions close to $(La,Sr)_2CoO_4$ = 0.4-0.5 Refocusing the compositions onto this range yields a dual phase cathode (La,Sr)2CoO4 = 0.45 where the temperature reaches its lowest value, namely 575°C.

Structural examination showed that the cathodes in as deposited conditions were amorphous.Fig. 4(a). When used at elevated temperature e.g., 700°C, the structure is quite stable. As shown in Fig.4(b), the cathode tends to crystallize at. 700°C forming two phase structure but it is ill defined and clear crystallized grains cannot be seen.

(a) (b)

Fig.4 High resolution transmission electron microscope (HRTEM) image of co-sputtered cathode with composition (La,Sr)CoO_3: (La, Sr)$_2CoO_4$=0.50:0.50. a) the cathode in as sputtered condition and b) the cathode sputtered and annealed 700 °C for 10 days.

CONCLUSIONS

Results reported above imply that the improved cathode performance in mid-compositions as reflected to favorable ASR values may be due to the refined homogenous structure arising from co-sputtering of (La,Sr)CoO_3 and (La,Sr)$_2CoO_4$. This structure when used at elevated temperatures, e.g., 700°C, is in the form of refined crystalline structure of extremely small grain size. The improved performance might, then, originate from interfacial maximization. Overall, the current study implies LSC based cathodes of amorphous/ nanocrystalline structure as a new class of cathode material for IT SOFCs.

ACKNOWLEDGEMENT

The work reported in this paper was carried out within EU FP7 ERAfrica program with the project title HENERGY. The support was provided by the Scientific and Technological Research Council of Turkey (TUBITAK) with a project number 114M128 and 217M628 which the authors gratefully acknowledge. Authors are also thankful to Serkan Yılmaz for his help with TEM analysis.

ABSTRACT

$La_{0.7-x}Ln_xCa_{0.3}MnO_3$ (Ln = Pr or Sm) perovskites synthesized by Pechini method with different stoichiometries (x = 0.1, 0.3, 0.5 and 0.6) were analyzed in order to evaluate the effect of cationic substitution and final composition on thermal properties; specific heat, thermal conductivity and thermal diffusivity at different temperatures are specifically reported. The results are discussed in terms of the potential use as a cathode material to be applied in solid oxide fuel cells (SOFCs) applications at intermediate temperatures (600 to 800°C). The results showed that thermal conductivity decreases as Pr doping increases; but a different trend is observed with samarium: first, a decrease is observed from x = 0.1 to x = 0.3, and then, from x = 0.3 to x = 0.6, an increase is determined. Also, thermal diffusivity presents a marked behavior when Sm-based perovskites display a high cation substitution (x = 0.6). Thermal expansion coefficient studies are in progress.
Keywords: ABO_3 perovskites, thermal conductivity, solid oxide fuel cells.

INTRODUCTION

Solid oxide fuel cells (SOFCs) are electrochemical energy conversion devices that can produce electrical energy through oxidation and reduction reactions and are considered a clean and renewable solution for the electric energy generation from hydrogen, providing higher efficiencies than conventional systems [1 - 5]. Due to high operating temperatures (800-1000°C) produce structural changes in the electrode material, the development of materials with a perovskite-type structure (ABO_3) has been encouraged, establishing that by doping the A-site with rare earths (praseodymium and samarium, in this case), the overpotential at the cathode could be reduced, and the electrocatalytic activity, increased. Several authors have studied doping at the A-site and found that substitution with Ca increases the electrical conductivity by more than three orders of magnitude, while at the same time the thermal conductivity is reduced; therefore, the reduction in thermal conductivity is due to the heavier mass of dopant ions [6, 7]. However, one of the major issues to be evaluated during operation of perovskites (as cathode in SOFCs) is the mismatch in the thermal properties that cause thermal stress. Temperature gradients and thermal expansion coefficients can provoke hot spots and curling of the components. Although its importance is evident, few studies are related to evaluating the changes in the thermal properties of ABO_3 perovskites depending on the cation-type or composition at intermediate temperatures, particularly of $La_{0.7-x}Ln_xCa_{0.3}MnO_3$ perovskites (Ln=Pr or Sm, x = 0.1, 0.3 0.5 and 0.6) which is the goal of this research.

MATERIALS AND METHODS

The $La_{0.7-x}Ln_xCa_{0.3}MnO_3$ perovskites were prepared using the Pechini method from metal nitrates. Lanthanum (III) nitrate hexahydrate ($La(NO_3)_3*6H_2O$, 99.99% purity), praseodymium (III) nitrate hexahydrate ($Pr(NO_3)_3*6H_2O$, 99.9% purity), samarium(III) nitrate hexahydrate ($Sm(NO_3)_3*6H_2O$, 99.9% purity), calcium nitrate tetrahydrate ($Ca(NO_3)_2*4H_2O$, 99.0% purity) and manganese(II) nitrate tetrahydrate ($Mn(NO_3)_2*4H_2O$, 97.0% purity), were acquired from Sigma Aldrich and stoichiometric amounts were weighed according to desire final nominal composition (x = 0.1, 0.3 0.5 and 0.6).The precursors were mixed with citric acid, CA, (3:1 CA/metal cations) and ethylene glycol, EG, (2:1 EG/CA) in molar ratios. The salt mixture was dissolved in deionized water by heating to 90°C to 110°C and kept under stirring for 4 to 5 hours, until removing excess solvent, forming an intermediate resin. Continuing with a calcination stage of 3 h at 450°C obtaining a dark powder, to finally take it to a heat treatment at 1000°C.

Thermal Properties Measurements

The thermal properties of synthesized perovskites were determined by a laser flash technique obtaining specific heat, thermal conductivity, density and thermal diffusivity measurements from room temperature to 800°C.

RESULTS AND DISCUSSION

Table 1 and 2 list the results obtained through laser flash analysis of all the samples at two different temperatures. It can be observed that thermal conductivity is reduced while the doping increases, according to work reported in literature, where A-doped samples has a tendency to reduce this parameter. Thermal conductivity (k) is correlated to the availability in oxygen vacancies and is determined from the measurement of thermal diffusivity (α), specific heat (Cp), and density (ρ) of the sample using the relation $\kappa = Cp\alpha\rho$ [6, 7]. The thermal conductivity values obtained are those expected for a crystalline solid, since they are above the range reported for non-crystalline. A low value of this parameter could be originated from the distortions of the lattice resulting in high degree of disorder. In case of manganites such scenario may be attributed to the Jahn-Teller distortion of the MnO_6 octahedra [8].

To praseodymium, the thermal diffusivities increase with the rise in temperature and decrease in relation to the cation amount. On the other hand, with samarium the diffusivity decreases when a rise in the temperature its applied and even when the tendency in 0.1, 0.3 and 0.5 it seems to be reduced, highest value is observed in x = 0.6, which means that the site substitution increases the thermal diffusivity, also according to previous reports the substitution of Ca in La site slightly increases the measurement. The thermal changes in the SOFC components occur due to differences in thermal properties of them. Especially, the heat diffusivity plays an important role during transient heat production and local heat transference [9].

New cathode materials must have matched thermal expansion coefficients (TEC) and sufficient chemical stability. These two characteristics are influenced by the concentration of oxygen vacancies within the perovskite lattice, according with the literature. The TEC of the perovskites decreased with increasing Ca content up to 20 mol-% and then increased. $LaMnO_3$ perovskite with highest TEC, can be explained by either of the two following reasons, the loss of oxygen and the accompanying decrease in the cation vacancy concentration led to a larger thermal expansion in $LaMnO_{3+\delta}$ or, the average ionic radius of B-site metals in the perovskites increases due to the change from Mn^{4+} to Mn^{3+} [10].

CONCLUSIONS

In the praseodymium samples, a reduction in thermal conductivity is observed when the value of x increases, but it shows a small increase with respect to the change in temperature. The diffusivity measurements have a similar trend, maintaining the lowest values when x = 0.6. On the contrary, with the samarium doping and with the same value of x, a higher conductivity is observed even though the first trend of this value seems to be reduced. The thermal diffusivity presents the same behavior giving us the highest value in a higher doping of the sample. Evaluation of thermal properties is still ongoing to confirm these observations.

ABSTRACT

Direct ethanol fuel cell (DEFC) is a subcategory of proton exchange membrane fuel cell (PEMFC). Ethanol as a fuel for DEFC is easier to obtain, store and transport than hydrogen. Additionally, ethanol has advantages over methanol due to lower toxicity, easier usability, and renewability. Therefore, DEFC is more suitable for mobile and portable power supplies if the disadvantages such as low efficiency and high total operating costs are resolved in the future. In this study, the use of Pd coatings on nickel foam in DEFC was investigated. SEM and EDS analyzes were performed for the characterization of the foam coatings. Also, the effect of Pd coatings made on nickel foam on the efficiency will be investigated by using highly-sulfonated SPEEK membranes in DEFC, the anode electrode for DEFC will be developed and its performance parameters will be examined in detail.

Keywords: Direct ethanol fuel cell, Electrocoating, Metal foam, SPEEK membrane, Hydrogen energy

INTRODUCTION

Fuel cell is a power generation element that is efficient, quiet, environmentally friendly and converts fuel energy into electrical energy in the electrochemical principle. Fuel cells do not contain fuel and combustors like batteries. Instead, it constantly receives these two chemicals from an external source where they are stored. Fuel cells can be operated continuously as long as the source flow is provided, and batteries contain their fuel and burners in their own internal structure. As one of the promising portable batteries, the direct ethanol fuel cell (DEFC) has attracted great attention due to the impressive properties of high-power and renewable, non-toxic ethanol fuel. Much of the work in recent years has focused on anode and cathode catalysts. Many new precious metal-free carbon-containing and low-cost transition metal-based ORR electrocatalysts have been developed for the cathodic oxygen reduction reaction (ORR). However, their electrocatalytic activity or durability still did not surpass the noble metal (Pt-based) catalysts. For the most effective Pt-based ORR catalysts, using various effective Pt carriers such as heteroatom-doped carbon nanomaterials or adding transition metals to reduce the amount of Pt and increase the Pt activity, studies have been carried out to reduce the high cost of the Pt catalyst [2,3]. Direct ethanol fuel cells (DEFCs) have been predicted to be strong candidates to compete with advanced batteries, with advantages such as the use of clean fuel, abundant biomass resources, high efficiency, large energy density, small design, compactness, quietness and low temperature operation [4]. However, the performance and stability of DEFC in particular, and fuel cells in general, face many hurdles and challenges in commercialization. One of the most important factors affecting the effectiveness of DEFC is the electrochemical catalysts for the oxidation and reduction processes taking place at the anode and cathode, respectively. Pd-based electrocatalysts offer similar conversion properties to Pt and are therefore widely used for the oxidation of EOR and other alcohols, but in alkaline medium, Pd-based electrocatalysts have shown better results than Pt-based electrocatalysts. Therefore, Pd-based electrocatalysts are a good alternative for use in alcohol oxidation-based fuel cells [5]. However, despite their respective activity on a DEFC, important structure-activity relationships are still not well understood in such bimetallic systems, and much progress is required to tailor DEFC performance. Moreover, given that electrocatalytic reactions usually involve the adsorption process of reactants, intermediates and products, the role of electronic effects as a function of catalyst microstructure is of great importance for understanding the overall electrochemical behavior [6,7].

MATERIALS AND METHODS

PEEK has some thermal and chemical stability problems at high degree of sulfonations (DS). Concentrated sulfuric acid was used as the sulfonating agent. All membranes were prepared by solvent-casting method by using dimethylacetamide (DMAc). In this study, membranes prepared by different degree of sulfonation processes [1]. The membranes were characterized for their proton conductivity. The anode electrode coating process was carried out with the following process steps. With 20 g degreasing chemical and 350 ml degreasing solution prepared with pure water cause the surface of the foam material had to purified from oils and chemicals. The positive end of the DC power supply in the stainless-steel anode, the negative end is connected to the foam material and degreasing is

performed by giving 3 V voltage from the power supply for 20 seconds. After the degreasing process, the metal foam is cleaned from the degreasing bath by washing with pure water. Then the metal foam part is dried with the help of heater and compressor and made ready for the next process. Ni foam is removed from the oxide layer on its surface by immersing in 11,2 gr Ammonium bifluoride, 175 ml Nitric acid and 350 ml etching bath prepared with pure water for 20 seconds. After the etching process, the metal foam is washed with pure water and purified from the etching bath. Then the metal foam part is dried with the help of heater and compressor and made ready for the next process. Before proceeding to another stage, the foam material is weighed to determine the weight before coating. The platinum anode immersed in the Pd solution between 50-55 ° C is connected to the positive end of the DC power supply, and the foam material is connected to the negative end of the power supply, and Ni foam is coated at different coating times by applying 3 V voltage from the power supply. After the coating process, the metal foam is cleaned from the coating bath by washing with pure water. The metal foam is then dried with the help of a heater and a compressor and weight measurement are taken after coating. Coating amounts are given in Table 1.

Table 1. Coating Measurement Results

Sample No:	Before Coating: (g)	After Coating (g)	Coating Time (in sec.)
1	5,00	5,16	60
2	5,48	5,57	45
3	6,68	6,84	75
4	5,57	5,73	90
5	6,41	6,57	120

RESULTS AND DISCUSSION

Figures 1a and b show SEM images of the fabricated electrode. Figure 1 shows that the catalyst on the surface of the approximately 1 cm nickel foam electrode is evenly supported on the nickel foam skeleton, taking full advantage of the unsupported noble metal catalyst. Uniform coupling of the catalyst and nickel foam skeleton can also increase the rate of electron transfer. Electrons released by the ethanol oxidation reaction (EOR) on the outer surface of the catalyst particles can be quickly transferred through the metal foam skeleton, reducing the resistance of electron transfer. In the SEM image for Sample 2 (Figure 1a&b), it is seen that there is a smooth coating on the surface. Thanks to the roughness on the surface, the active area is increased. It is coated at 3V and the coating weight is low due to the low current it draws. EDS analysis is a point analysis and by measuring the radiation (Figure 2), it is possible to determine the element or elements K alpha L alpha et al. It encounters the values and tells which element it is. As can be seen from the peaks in the figure, Pd was successfully coated on the nickel foams. In the sample, the coating appears to be homogeneous in the both micro and macro scales.

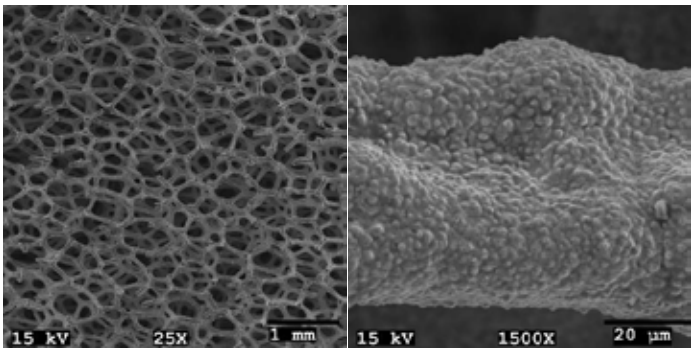

Fig 1. SEM image for sample 2 in (a)1 mm and (b)20 µm diameter

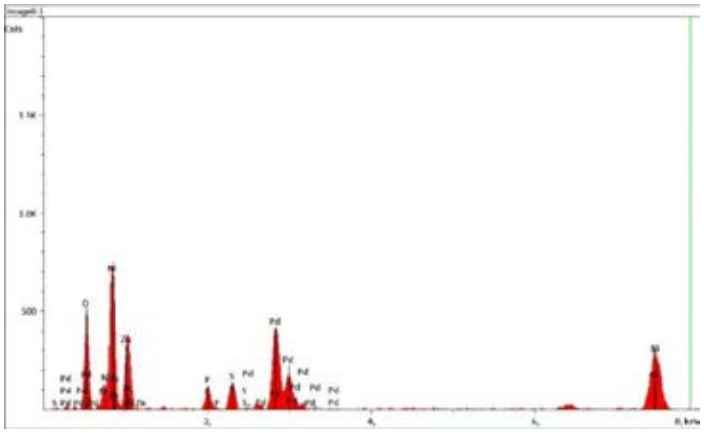

Fig 2. EDS analysis for Sample 2

Membrane's ionic conductivities were determined in potentiostatic mode using the "4-probe through-plane" ionic conductivity system by electrochemical impedance spectroscopy (EIS) method. In this study, measurements were made at 80% humidity at room conditions and at the same humidity level at 80 °C. SPEEK with a high degree of sulfonation was measured as 0.309 mS/cm. The thickness of the membrane used is 45 micrometers.

CONCLUSIONS

As a result of the studies, SPEEK polymers with desired sulfonation degrees were obtained. It was made into a membrane and various characterizations were carried out. As a result of these characterizations, it was confirmed that the produced membrane was produced with or very close to predetermined properties both electrochemically and morphologically. In addition, a literature study was conducted on the preparation of system and MEA. The catalysts and MEA components to be used ultimately have been precisely determined. SPEEK membrane prepared with a high degree of sulfonation (~80%) will be used in single cell tests. Foams with high coverage ratios will be used in MEA production. When the Pd coated foams prepared using different coating times were examined, it was seen that the coating time did not show a significant difference in the use of constant voltage, since sufficient coating saturation was provided. In future studies, handles will be made at different voltage values and different parameters.

ABSTRACT

Development and commercialization of fuel cells, as an alternative to fossil fueled engines, are at its highest importance and urgency due to global climate change crisis. Proton Exchange Membrane Fuel Cells (PEMFC) made a huge technological leap with the breakthrough of development of Nafion® membranes however its high catalysts and membrane costs hinders further developments. Anion Exchange Membranes Fuel Cells (AEMFC) doesn't require expansive Pt group catalysts to be efficient which can solve the cost problem, but it is still needed to develop a cheap, durable membrane with high anion conductivity and ion exchange capacity. Membranes with radiation-induced grafted polymers can provide good ion exchange capacity and conductivity while weakens the mechanical robustness. Therefore, we used dual electrospinning technique to fine tune mechanical properties without sacrificing the functionality. We have prepared anion conducting membranes for AEM fuel cells by a dual-electrospinning technique using inert poly(vinylidene fluoride) (PVDF) powders and radiation induced grafted PVDF with vinyl benzyl chloride (VBC) with various compositions. The dual fiber-based mats are hot-pressed, aminated and ion exchanged in this order. We have investigated and optimized the grafting levels, mechanical properties and morphologies of the duel electrospun membranes.

Keywords: Electrospinning, Radiation induced grafting, Anion exchange membrane, Fuel cells

INTRODUCTION

Climate change crisis is the new generations' doom and gloom unless greenhouse effect due to carbon dioxide emissions are hindered or at least slowed down. One of the main contributor of carbon dioxide emissions is the fossil fuel usage, especially in transportation and energy sectors in which we need a feasible alternative to fossil fueled engines. PEM Fuel cells are the main competitors of the fossil fuels engines but acidic media in which only expensive catalysts can work efficiently, and cost of membrane made PEMFC lose its competitive edge financially. Alkaline medium of AEMFC can solve the bottleneck cost problem due to opening up more alternative and cheaper catalysts as long as an ideal membrane is developed. The requirements of an ideal membrane for AEMFC are as follows:

i) High ion conductivity and high ion exchange capacity;
ii) High mechanical and chemical stability;
iii) Low water absorption and swelling.

If these requirements can be made without sacrificing any one of them, one can obtain high performance and efficient AEMFCs. Because sacrificing any aspect of an ideal membrane would result in either very low durability or low efficiency. In order to solve the problems mentioned above, first, we radiation induced grafted the PVDF powders in an optimized reaction with VBC to control the ion exchange capacity and the ion conductivity of the final membrane, however, radiation-grafting is generally decreasing the mechanical robustness of the membranes because of the chain scissions of the backbone polymer [2]. Hence, we have used the electrospinning technique and fabricated dual-fiber-based electrospun mats which include the inert and grafted PVDF powders to control the mechanical properties of the final membrane by adjusting the ratio without a dramatic decrease in ion conductivities. Firstly, the characterizations of the grafted PVDF-g-VBC to understand the grafting levels of the PVDF powder with VBC such as NMR, FT-IR, FT-Raman; and SEM and EDS to investigate morphologies and elemental analysis of the electrospun fibers as well as the ion exchange capacities and ion conductivity of the aminated mats are provided in this work.

MATERIALS AND METHODS

Figure 1 shows the experimental procedure steps. First, the commercial PVDF powders are irradiated with 50 kGy gamma rays and grafted with VBC to prepare PVDF-g-VBC powders while changing the parameters such as temperature, reaction duration, mixing rate to optimize the grafting levels which are calculated by before-after weight change of the powders. Using these powders and inert commercial PVDF, two different solutions is prepared and

used at the dual-spin setup which can be seen in the 4th inset of Figure 1. In order to reduce the permeability of fuels, these electrospun fibers are hot-pressed to the thickness of 50 µm and confirmed a non-porous structure by SEM and aminated with trimethylamine solution for one day, and finally alkanizated with potassium hydroxide.

Nuclear magnetic resonance spectroscopy (NMR), Fourier-transform infrared spectroscopy (FT-IR), and Fourier-transform Raman spectroscopy are used to the characterization of the molecular structure of the PVDF-g-VBC and its grafting levels.

Additionally, scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) are conducted with electrospun mats to investigate the morphology and elemental mapping of the fibers. The mechanical tensile test, ion exchange and ion conductivity tests are done for the mats after the hot-pressing and amination, and alkalization steps.

Figure 1. Schematic of dual fiber-based mat production setup

RESULTS AND DISCUSSION

Figure 2A shows the successful grafting of the VBC into the PVDF backbones with FT-Raman peaks at the 1450 cm^{-1} shows the CH_2 scissor mode of vibration for the inert PVDF powder. The VBC grafted powders were showing additional peaks at 1001 cm^{-1} and 1611 cm^{-1} which were due to aromatic peaks of VBC. Additionally, the peak at the 1266 cm^{-1} the broad peaks between 600-800 cm^{-1} are showing the C-Cl bonds.

In Figure 2B. we can observe 2 different fiber structures with different morphologies (inset) One type of the fibers showed more wrinkled surface morphology while the others showed less wrinkled surface but more porous fiber morphology. We have speculated that two fiber types are due to inert PVDF and PVDF-g-VBC. In order to confirm these two fiber types are indeed has different chemical structure we have used EDS to investigate Cl presence on each fiber types.

In figure 3 the SEM micrographs of the electrospun fibers are given at the 5000X magnification as well as their elemental analysis is shown with the spectrums that are obtained from the single points on top of the two fibers with different morphologies. The images indicate a good fibrous structure without any beads and homogenous distribution of the dual-fibers which were confirmed by the elemental analysis of the fibers with EDS. EDS results indicated that there are two types of fiber with and without Cl atoms which resulted in different morphologies.

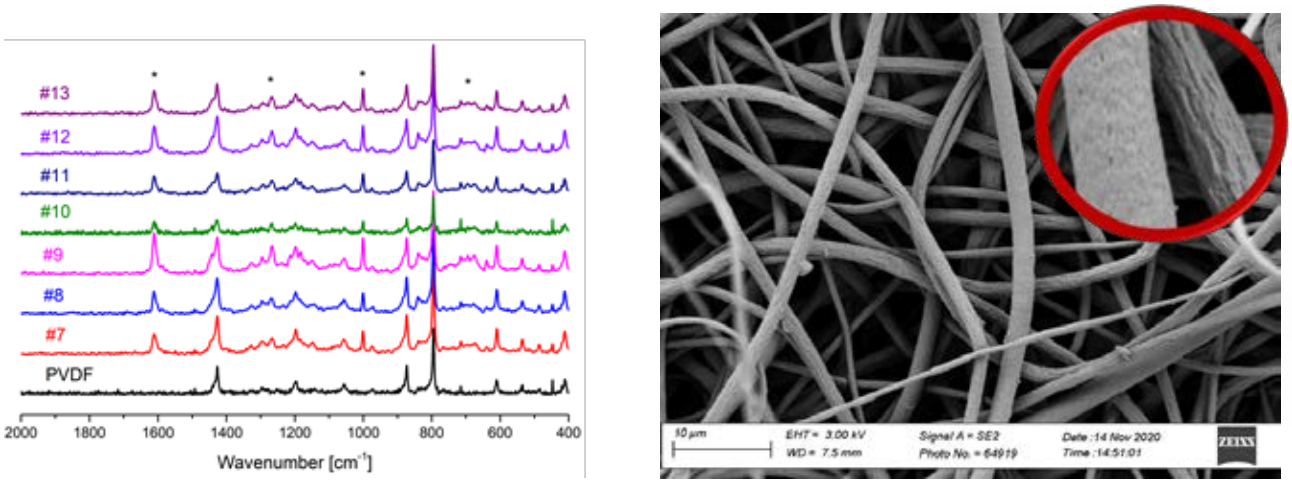

Figure 2. A. FT-Raman results of the PVDF-g-VBC and B. SEM images of dual fiber structures.

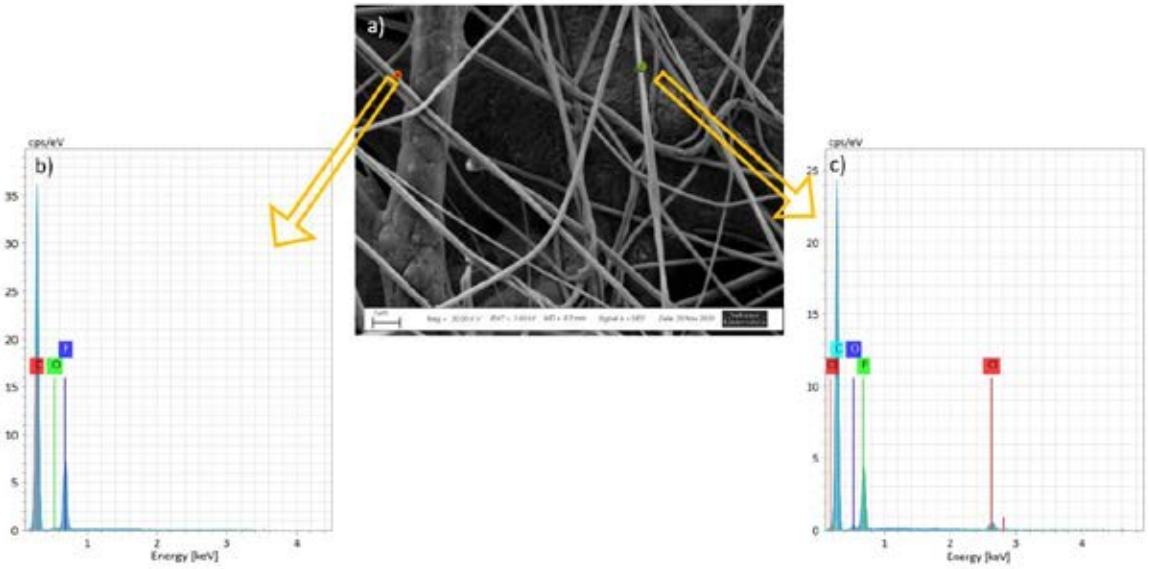

Figure 3. SEM micrographs of the two different fiber structures and their corresponding EDS results

CONCLUSIONS

In this study, radiation-induced grafting and electrospinning techniques were used to fabricate dual fiber-based electrospun anion exchange membranes. These membranes were characterized and prepared to be used in a fuel cell for the first time in literature. To fabricate anion exchange membranes with promising ionic conductivity and mechanic strength, we have developed a two-step procedure: First, VBC monomers were grafted into irradiated PVDF powders. Then, the grafted and inert PVDF powders were solved and electrospun into dual-fiber mats which were later aminated and alkalized into the anion exchange membrane forms. Characterization techniques such as NMR, FT-Raman and FT-IR were conducted to show the grafting steps were successful. SEM imaging and EDS spectroscopy were used to indicate homogenous morphologies with a good distribution of dual-fiber structures. After the hot-pressing and compacting the membrane, amination and alkalization steps are conducted, the ionic conductivity and the ion exchange capacity measurements of the dual-fiber-based electrospun anion exchange membranes showed promising results.

DEVELOPMENT OF BROMINE RESISTANT ANODE CATALYST FOR HYDROGEN OXIDATION AND REDUCTION REACTIONS IN HYDROGEN BROMINE FLOW BATTERIES

ABSTRACT

Hydrogen-bromine flow cell system is considered a highly advantageous electrical energy storage system due to its high energy capacity, high charge-discharge efficiency, and low cost. The hydrogen oxidation reaction (HOR) that takes place on the anode side of the hydrogen-bromine flow cell is generally catalyzed by high-activity (platinum) catalysts. The bromine reduction reaction (BRR) on the cathode side can be catalyzed with platinum-based high-performance catalysts to obtain high power density, while it can also be directly catalyzed by carbon structures. Bromine ions passing from the cathode to the anode side via the ion-permeable membrane poison the anode catalyst, causing a decrease in anode kinetics and thus battery performance. A new anode catalyst resistant to the bromine environment needs to be developed to eliminate this crossover problem, which significantly reduces the catalyst performance and lowers the hydrogen oxidation reaction (HOR) kinetics. This project, it is aimed to improve the kinetics of the hydrogen oxidation reaction by developing bromine resistant anode electrocatalysts with high catalytic activity.
Keywords: Bromine tolerant electrocatalyst, hydrogen bromine flow batteries

INTRODUCTION

The increasing energy demand in recent years has significantly increased the interest in renewable energy sources. Most renewable energy sources (such as solar, wind) are intermittent by nature and cannot provide the necessary continuity in meeting the need. This has increased the need for large-scale, low-cost, and durable electrical energy storage systems. Hydrogen/bromine flow cell systems, one of the electrochemical energy conversion systems, are advanced and innovative energy conversion systems because they both produce electrical energy and can store the generated electrical energy [1]. Flow batteries are a promising technology as an energy storage system because they are scalable, long-lasting, and do not pose a safety risk. Flow cells such as zinc/bromine, vanadium/redox, polysulfide/bromine, hydrogen/bromine are among the important flow batteries that have been researched and studied in recent years [2]. Hydrogen bromide flow batteries are a liquid-gas system. It is an electrochemical system in which electrolytes containing gaseous hydrogen (negative side), aqueous Br_2, and HBr (positive side) are fed from storage tanks to the battery cell. The hydrogen bromine flow system is shown below.

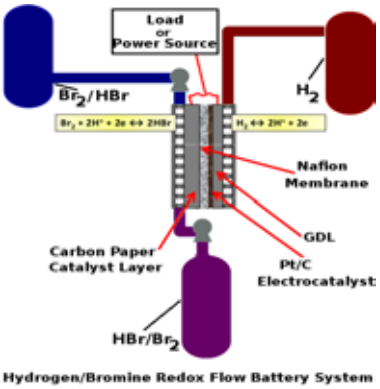

Fig 1. Hydrogen/Bromine Redox Flow Battery System

Despite all these positive aspects of hydrogen bromine flow batteries, several challenges must be overcome to become more widely available. One of the main problems of this flow battery is that as a result of the crossover of bromine chemicals, the performance of hydrogen oxidation and evolution catalysts on the anode side is significantly reduced and the anode electrode kinetics becomes unstable. This problem can be solved by using membranes to reduce crossover or by developing an anode catalyst with bromine-type stability and high catalytic activity. Another problem arises from the need for relatively low-cost catalysts as an alternative to noble high-cost metal-based catalysts with electrode kinetics during the reduction and oxidation reactions on the cathode side of bromine, which

has a corrosive effect. To overcome the problem here, carbon structures with high surface area and mesopores are used at the cathode [3]. Wei et al. examined a series of Ir alloy nanoparticles and it was found that IrNi had the highest HOR activity [6]. Satsuma et al. It showed that the Ir-Ru alloy catalyst has higher HOR activity than Ru, Ir, and Pt single metal catalysts, which is comparable to the state-of-the-art Pt-Ru alloy catalyst [7]. Abruna et al. It was found that $Ir_3Pd_1Ru_6$ / C exhibited high activity and durability for HOR in the alkaline environment [8]. Recently, Shao et al. an IrNi@PdIr core-shell was prepared, showing superior HOR activity than commercial Pt/C [9]. However, there is still room to further improve the HOR activity of Ir-based catalysts, and this can be achieved by fine-tuning the structure of the catalysts. Based on these studies, IrNi @ Ir core-shell nanoparticles with high HOR activity in alkaline electrolytes were developed. The core-shell nanoparticle will be synthesized by a simple one-pot synthesis using two Ir sources with different reactivities. The HBE of the Ir shell will be weakened by the IrNi core [5]. In another study, carbon nanotubes (SWCNTs) were tried to be grown by CVD technique using a few nanometer-sized Ir particles as catalysts and they were able to grow vertically aligned SWCNTs with small diameters less than 1.2 nm [10]. The syntheses of the catalysts synthesized for these different methods and situations will be designed and developed.

MATERIALS AND METHODS

$IrCl_6.6H_2O$ and $NiCl_2.6H_2O$ salts with carbon consumption iridium and nickel core nanoparticles in equal molars will be used. It will be mixed with high surface area XC-72 carbon black to achieve 20% total metal loading. After washing with pure water, it will be purified in an ultrasonic bath and under gas. Sodium borohydride ($NaBH_4$) is added to reduce the salts. After ($NaBH_4$) is added, it is washed again with distilled water and dried. The samples obtained are purchased in a tube furnace under Ar gas at 600°C for 2 hours [11]

RESULTS AND DISCUSSION

In the development of the bromine resistant anode catalyst for the hydrogen bromine flow cell, carbon-supported IrNi/C bimetallic was first used. IrNi/C bimetallic was obtained by the core-shell method, which is one of the determinant synthesis methods. The electrochemical characterization of IrNi/C bimetallic synthesized by the core-shell method was investigated in cyclic voltammetry analysis. Cyclic voltammograms of Ir@Ni/C bimetallic synthesized by the core-shell method at scanning rates of 10mV/s and 25 mV/s, respectively, in the potential region of 0.0-1.1V are shown in the figure.

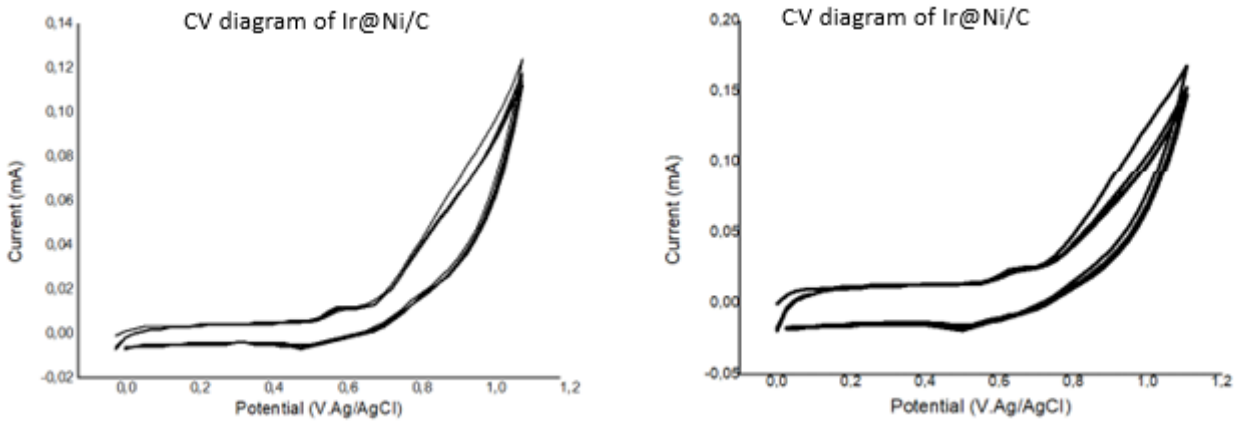

Fig 2-3. CV diagram of Ir@Ni/C catalyst at a sweep rate of 10-30 mV/s respectively, in the 0.0-1.1V potential region

The obtained CV was taken from a voltage peak of 0.4-0.6 from the voltammogram at a rate of 10 mV according to the scan/s scan. A voltammogram date to 25 mV/s scanning rate was observed as 0.6-0.8 potential. Other electrochemical and physical characterizations of IrNi/C catalyst will be presented at the congress.

ABSTRACT

In this study, a new method to manufacture anode supported SOFCs (solid oxide fuel cells) with AFL (anode functional layer) is proposed. To manufacture the anode supports, anode mixture with polyethylene glycol (PEG) is prepared and anode mixture is fed into a twin screw extruder and extruded in the shape of tubes. PEG in the anode tubes is selectively removed to by water debinding and sweat debinding methods and AFL layer is obtained with different microstructure and porosity. SEM (Scanning electron microscope) images of the manufactured SOFCs show AFL layers with the thickness of approximately 7 µm, which is akin to the values given in the literature. Electrolyte and cathode layers are added to the anode tubes using dip coating. Effects of AFL on performance of the manufactured cells are tested.

Keywords: Solid oxide fuel cells, Anode functional layer, Anode supported SOFCs

INTRODUCTION

There are problems regarding usage of the fossil fuels as the main energy source for power generation. The most important problems regarding fossil fuels are high environmental impact and the possibility of depletion of the said fuel sources. These problems make the usage of renewable energy and clean energy sources more appealing, ultimately causing development of systems and devices which uses renewable energy and clean energy sources. Solid oxide fuel cells (SOFCs) are one of the many promising systems which generates electricity with electrochemical processes at high efficiencies.

SOFCs are energy conversion devices, they can use a variety of fuels (hydrogen, natural gas etc.) to generate electricity with electrochemical processes. These systems have a plethora of advantages such as high efficiency, modularity, fuel flexibility, operation with low noise and without vibration, low emission of pollutants. Main drawbacks of SOFCs are high manufacturing costs, high unit cost of energy, long start-up times and high operating temperature [1,2]. The high operating temperature problem of the SOFCs can be solved by employing a thinner electrolyte in the SOFC, thus reducing the ohmic loss caused by the electrolyte. To employ a thinner electrolyte, anode supported designs have been investigated [3,4].

In anode supported SOFCs, thickness of the anode support must be sufficient to ensure the required the mechanical strength to the cell. Because of the increased thickness of the anode support, the concentration polarization resistances are also increased, which in turn limits the power density of the cell. In literature, it has been shown that employing an anode functional layer (AFL) between anode and the electrolyte of the cell overcomes this problem. AFL can be described as an anode layer with specially tailored microstructure [5,6].

Triple phase boundary (TPB) is the juncture of electrons, oxygen ions and gaseous species where the electrochemical reactions of the SOFC occur. AFLs increase the performance of the SOFC by enlarging the TPB thus lowering the activation polarization resistance of the anode, the enlargement of the TPB is achieved by the decreased porosity of the AFL. In addition to increase in performance, employing AFL causes matching thermal expansion coefficient between electrolyte and anode which in turn increases the stability of the SOFC [7–10]. The properties and performance effects of the AFL have been a topic of interest and thoroughly investigated. Chen et al. have manufactured an anode supported SOFC with AFL and concluded that the optimal thickness of the AFL is 7,6 µm. The reported a peak power density of 0,906 Wcm^{-2} at 700 °C [8].

Yamaguchi et al. have investigated the effect of AFL on performance at 650 °C. They constructed 3 anode supported cells, one without AFL and two with AFL. They reported a power density value of 0,18 Wcm^{-2} in the cell without AFL, 0,22 Wcm^{-2} and 0,27 Wcm^{-2} in the cells with 4 µm and 10 µm AFL thicknesses, respectively. They concluded that the increased thickness of the AFL increases the power density and decreases ohmic resistances. They also reported enhanced area specific resistance (ASR) which suggests an increase of the triple-phase boundaries (TPBs) at the electrolyte-anode interface [11].Suzuki et al. have investigated the effect of AFL on energy efficiency of a fuel cell. They reported an energy density increase from 0,27 Wcm^{-2} to 0,45 Wcm^{-2} and 0,35 Wcm^{-2} to 0,52 Wcm^{-2} at 650

°C and 700 °C respectively by employing AFL in the fuel cell. They also reported an increase in the energy efficiency [12]. Kagomiya et al. have prepared cells with AFL thicknesses varying from 5 μm to 100 μm by using tape casting method. They reported that the AFL thickness of 10 μm had the best electrochemical properties and the highest power density [13].

In literature, several methods for forming AFL have been investigated. Kong et al. developed AFL with sub-layers using dry pressing, Kim et al. used dip coating to NiO-YSZ particles, Reitz and Xiao used spray coating. Methods such as slurry spin coating, vacuum slip casting and tape casting are also used. In this study a new method to develop AFL in anode supported SOFCs is investigated [14–16].

MATERIALS AND METHODS

The pilot-scale SOFC manufacturing line in the Institute of Energy Technologies in Gebze Technical University was used in the production of anode supported tubular SOFC.

Materials

In the extrusion process, Nickel Oxide - 8YSZ composite powder (Fuel Cell Materials), Polymethylmethacrylate (PMMA, Alfa Aesar) powder and polyethylene (PE) powder with a low density (Petkim - Turkey) were used as anode pore former and binder, respectively. Additionally, PEG 400 (Alfa Aesar) was used as plasticizer.

Extrusion

The anode powder, binder and pore former were mixed in ethanol via a turbula mixer (TM-100, DMR – Turkey) for 4 hours. Nalgene jars were used as container and one third of the jar was filled with zirconia beads. After the mixing, the solvent was evaporated at 70°C under stirring. The dried powder was sieved and fed to a twin screw extruder (Rondol Technology, UK) to produce small granules. PEG 400 was continuously added during the extrusion of the anode mixture. The extrudate, which was in the form of filament, were granulated by a rotating cutter. Then, the granules were fed into a single screw extruder (Rondol Technology, UK) and extruded in the form of a tube. The extrusion system had 4 different temperature controllers in total; 3 zone with separate temperature control unit along the screw and barrel, and an external temperature controller unit was used for the extrusion die.

The extruded tubes were separated into two sets. Set 1 was subjected to additional water debinding before firing in a container at 30°C. Both ends of the tubes were sealed by Parafilm plugs from the inside of tube to protect the inner walls of the tubes from water. Water soluble PEG 400 is removed in this step to prevent the deformations during the thermal debinding by using water solubility of PEG 400. Set 2 was subjected to a waiting period at 25 °C in open atmosphere. The PEG was ejected from the green body by sweating mechanism. The weight loss of the samples was recorded before and after for both treatment methods.

The pre-sintering temperature was selected as 1000°C. The half of the pre-sintered tubes were sintered consequently at 1400°C to mimic the effect of electrolyte layer sintering. Sintering profiles were determined by TG analysis. The effects of temperature and debinding methods on the microstructure and mechanical properties of the pre-sintered and sintered anode supports were investigated using SEM (Philips XL30 SFEG) and a universal mechanical tester (Instron 5569). The porosity rates of the anode tubes were determined using the Archimedes method performed in an aqueous environment.

RESULTS

The investigation on the debinding types suggested that water debinding is more effective as the final mass change is higher than the sweat debinding.

The extrudates of Set 1 and Set 2 were investigated via TGA for determination of the sintering profiles. For both sets, the rates of the mass loss were low before ~215°C, then, accelerated until the burnout process was completed. The dwelling temperature was selected as 210°C to avoid cracking due to the fast burning of the polymeric content within the samples.

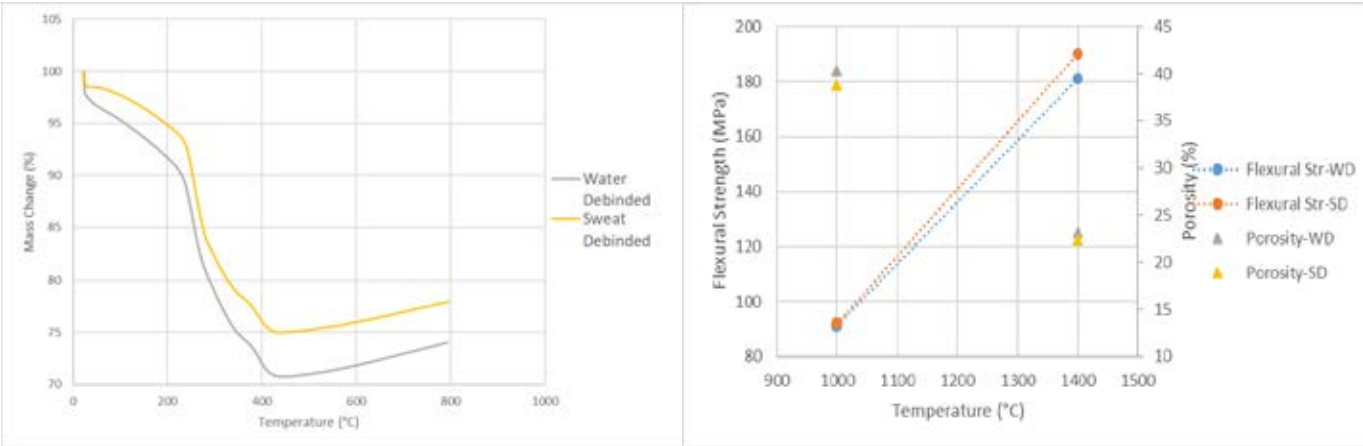

Fig 1. Results of TGA (a), and flexural strength-porosity measurements.

It was evident that the outer layer of both sample types had a different microstructure compared to the main body could act as anode functional layer (Fig 2). The AFL of Set 1 differed from Set 2 in terms of microstructure. The different debinding processes were resulted in different microstructures. A sponge like structures can be seen in Fig 1 for Set 1. Water debinding resulted in thicker AFL and lesser density was observed compared to the AFL of Set 2. On the other hand, the AFL of sweat debinded sample had needle like structures with higher density compared to the water debinded sample. The dissolution of the PEG was enhanced by the presence of the water; thus, the layer structure was preserved due to the absence of the contraction. Contrarily, the sweat debinding caused mechanical stress, the green density was thought to be increased even during the debinding phase. The density of measurements indicated that water debinding resulted in higher porosity (Fig 1b). The mechanical strength of the samples was almost inseparable (Fig 1b).

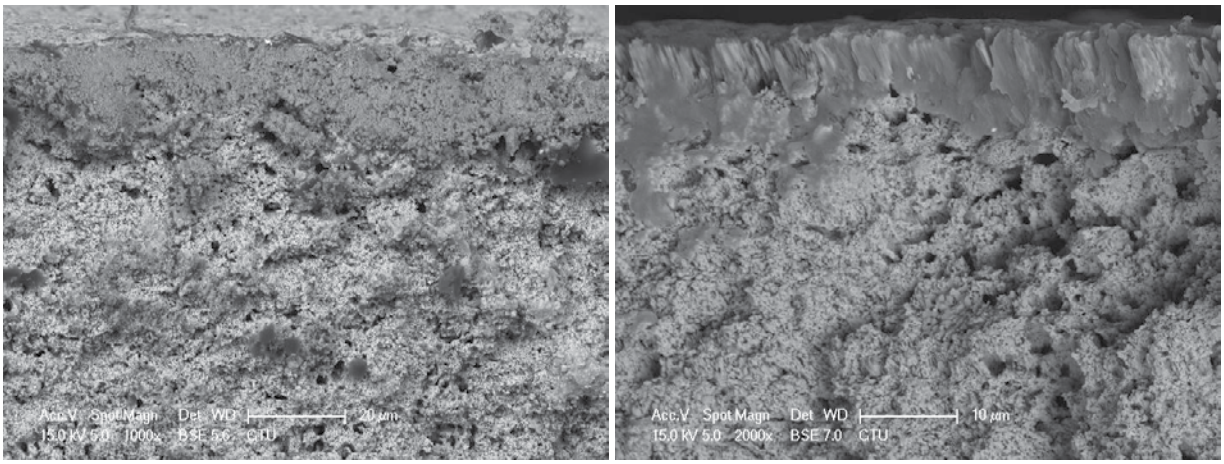

Fig 2. The micrographs of water debinded sample (a) and sweat debinded sample (b).

CONCLUSIONS

Two different debinding methods were used to obtain anode supports with two different microstructures. The mechanical properties of both types were similar. The water debinding resulted in deeper penetration compared to the sweat debinding method, hence, the thickness of the AFL was higher for the Water debinded anodes. The thickness of 7-8 micron AFL was attained by sweat debinding, which was in accordance with the optimum AFL thickness given in the literature. The AFL thickness for water debinding can be controlled by dwelling time and bath temperature. A more detailed study should be conducted to optimize the water debinding process. The cell performances of both types were comparable to the literature results for the given thicknesses.

ABSTRACT

In this study, a thermodynamic and mathematical model for an internal reforming and anode-recirculated SOFC fed with reformate gas is developed. Experimental testing of SOFC fed with reformate gas is also performed in order to validate the model. A parametric analysis is conducted to study the effect of the SOFC operating temperature, current density, and steam-to-carbon ratio (S/C) on the the exergy destruction of the SOFC. In addition, XRD and EIS analyses results for SOFC obtained from the experimental studies are presented.

Keywords: Experimental test, Mathematical modeling, SOFC, Anode recirculation, Reformate gas

INTRODUCTION

Solid oxide fuel cell (SOFC) is a highly efficienct electrochemical system operating at high temperatures (typically between 600°C to 850°C). As shown in Fig. 1, SOFC consists of two electrodes separated by an electrolyte made of ceramic material. Oxygen fed from the cathode is reduced to oxygen ions thanks to the presence of free electrons coming from an external circuit. The oxygen ions can move between the electrodes through the electrolyte. At the anode side, reformed hydrogen combines with oxygen ions from the cathode generating water vapor and electrons. The movement of electrons through a load, connecting the anode and the cathode of the SOFC, generates electricity.

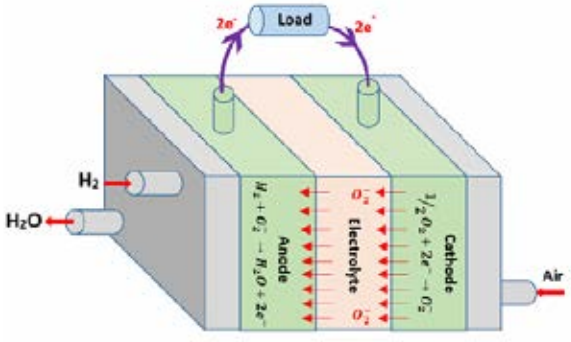

Fig. 1. The schematic of a SOFC

SOFCs have many advantages over other types of fuel cells [2–5]. These are (1) water management problems do not occur due to the operation at high temperature levels; (2) cheap materials and production methods can be used; (3) SOFCs can be thermally integrated with other systems (e.g. Rankine cycle, Brayton cycle, gas turbine, and biomass gasifiers) thus increasing the system efficiency from the thermodynamic point of view; (4) SOFCs have a wide range of fuel types such as hydrogen, hydrocarbons, methanol, biomass produced gas mixtures called syngas, and reformate gas mixtures; (5) carbon-containing fuels pass on chemical transformation inside the SOFC and are converted into hydrogen/CO, which are converted into electricity. Some challenges for the SOFCs are: (1) the mechanical robustness of ceramics that is limited and (2) in case of carbon-containing fuels, the anode can be deactivated by carbon deposition that might occur and also by impurities like sulfur. The main application of these fuel cells is combined power and heat generation. SOFCs are also used in other areas such as transportation, military, stationary, and portable applications [6,7].

EXPERIMENTAL TESTING OF SOLID OXIDE FUEL CELL

Experimental studies on SOFC were performed in the Electrochemistry Laboratory of the Technical University of Denmark (DTU), Department of Energy Conversion and Storage using state-of-the-art (SoA) SOFC. Detailed information and test protocol of SOFC are explained in Refs. [8,9]

MODELING OF SOLID OXIDE FUEL CELL

The diagram of SOFC used in the model is given in Fig. 2. In the analysis of the SOFC, firstly, electrochemical equations (Eqs. (1) and (2)) and the energy balance equation (Eq. (3)) enclosing the control volume of the SOFC are combined

to determine the inlet and exit streams of SOFC. Then, to determine the exergy destruction of the SOFC, the exergy balance (Eq.(4)) is applied to the control volume of the SOFC [10,11].

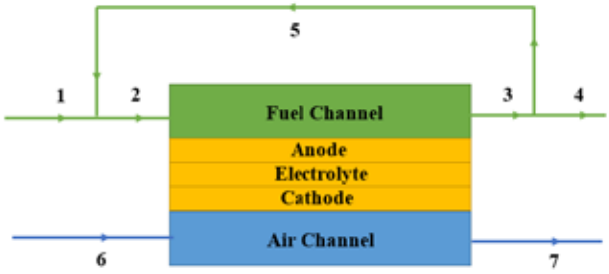

Fig. 2. The schematic of the SOFC used in the model

$$V_{cell} = V_{Nernst} - V_{ohm} - V_{act} - V_{conc} \quad (1)$$

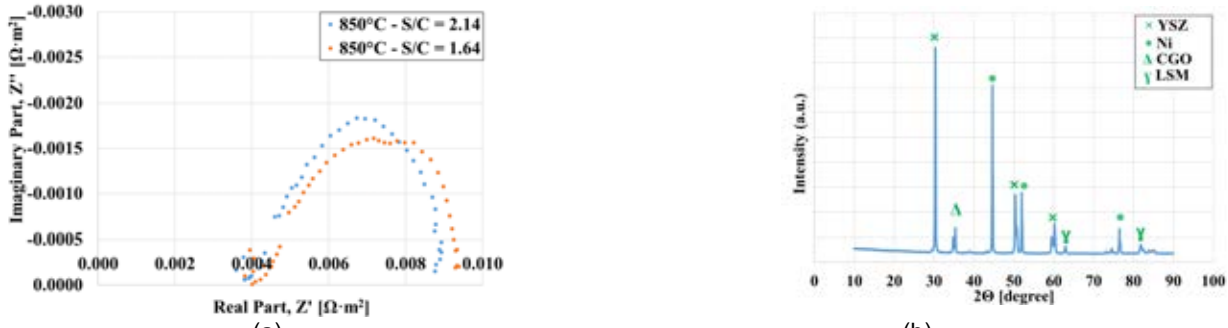
$$\dot{W}_{SOFC} = i_{cell} \cdot A_{cell} \cdot V_{cell} \quad (2)$$

$$0 = -\dot{W}_{SOFC} + \left(\left(\dot{n}_1 \cdot \bar{h}_1\right) + \left(\dot{n}_6 \cdot \bar{h}_6\right)\right) - \left(\left(\dot{n}_4 \cdot \bar{h}_4\right) + \left(\dot{n}_7 \cdot \bar{h}_7\right)\right) \quad (3)$$

$$0 = -E\dot{x}_W + \left(\dot{n}_1 \cdot \left(\overline{ex}_{PH,1} + \overline{ex}_{CH,1}\right) + \dot{n}_6 \cdot \left(\overline{ex}_{PH,6} + \overline{ex}_{CH,6}\right)\right) - \left(\dot{n}_4 \cdot \left(\overline{ex}_{PH,4} + \overline{ex}_{CH,4}\right) + \dot{n}_7 \cdot \left(\overline{ex}_{PH,7} + \overline{ex}_{CH,7}\right)\right) - E\dot{x}_D \quad (4)$$

RESULTS AND DISCUSSION

Validation Results



In this section, the results obtained from the study are discussed. The developed model is validated through experimental study. The validated results are given in Table 1. As can be seen in Table 1, the values obtained from the odelling study are agreeable with the experimental study.

Table 1. The comparison of cell voltage and power values between the experimental and the modelling studies

Current Density [A/cm²]	Voltage Experiments [V]	Voltage Model [V]	Power Experiments [W]	Power Model [W]
0	0.95	0.98	0	0
0.1	0.94	0.93	1.50	1.49
0.2	0.93	0.92	2.96	2.94
0.3	0.91	0.90	4.38	4.31
0.4	0.90	0.89	5.76	5.68

Experimental Study Results

The obtained electrochemical impedance spectroscopy (EIS) results as function of the S/C ratios and XRD results for cell testing in order to analyze the structure of crystalline materials, and its phases are presented in Figs. 3(a) and 3(b), respectively. As the S/C ratio increases, the polarization resistance, as well as the total cell resistance decreases.This happens because steam enhances the cathalityc activity on Nickel. It was found from the EIS that there is an important presence of Ni, and indeed the polarization resistance is affected by the steam/carbon ratio considerably.

(a) (b)

Fig. 3. Experimental study results (a) EIS according to the different S/Cs at 850°C, (b) XRD pattern for cell used in the experimental (compounds were labeled according to the Ref. [12])

Parametric Study Results

In this subsection, the parametric study results obtained from the model are presented. The effect of the current density on the exergy destruction rate according to the different S/C ratios is shown in Fig. 4(a). Increasing the S/C

ratio has a positive effect on the SOFC performance. It was obtained that under the same current density (e.g. 1.6 A/cm^2), the exergy destruction rate decreases by 19.71% when the S/C changes from 1.5 to 2.5. Fig. 4(b) shows the effect of current density on the exergy destruction rate of SOFC according to the different operating temperatures. When the operating temperature varies between 750°C to 850°C, the exergy destruction rate decreases for all current densities.

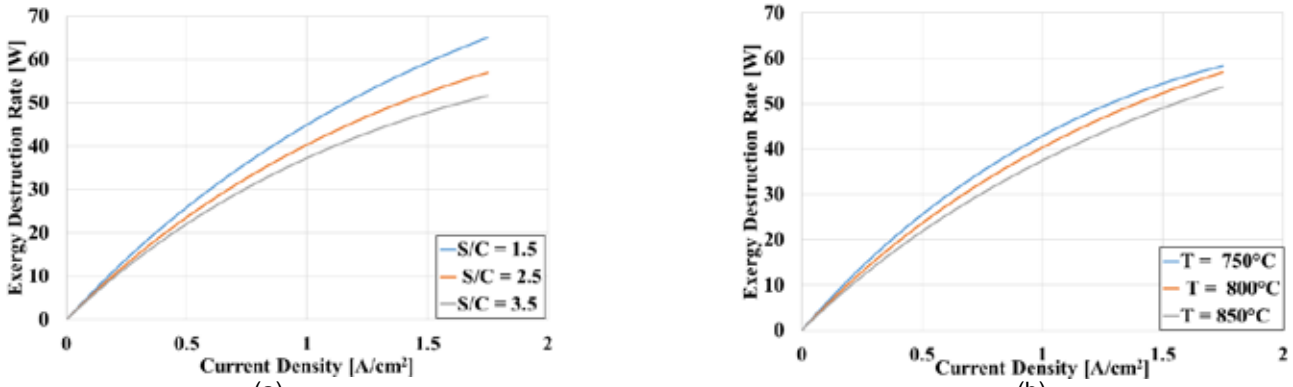


Fig. 4. The effect of current density on the exergy destruction rate according to the (a) different S/Cs, (b) different operating temperatures

CONCLUSIONS

In this study, an experimental test for SOFC is conducted in order to validate the model and assess the cell used in the study. Then an exergy analysis is conducted for SOFC to find the magnitude of the exergy destruction of the SOFC. The results derived from the study conducted are given as follows.

- According to the EIS study, increasing the S/C ratio decreases the total cell resistance.
- As the S/C ratio increases, the exergy destruction rate decreases.
- As the operating temperature increases, the exergy destruction rate decreases.

ABSTRACT

Combined with the use of renewable energy sources for its production, hydrogen represents a possible alternative gas turbine fuel within future low emission power generation.
Kawasaki Heavy Industries, LTD. (KHI) has research and development projects for future hydrogen societies; production of hydrogen gas, refinement and liquefaction for transportation and storage, and utilization with gas turbines / gas engines for the generation of electricity.
Due to the large difference in the physical properties of hydrogen compared to other fuels such as natural gas (NG), well established gas turbine combustion systems cannot be directly applied for Dry-Low-Emission (DLE) hydrogen combustion. Thus, the development of DLE hydrogen combustion technologies is an essential and challenging task for the future of hydrogen fueled gas turbines.
The DLE Micro-Mix combustion principle (MMX) for hydrogen fuel has been in development for many years to significantly reduce NOx emissions. This combustion principle is based on cross-flow mixing of air and gaseous hydrogen which reacts in multiple miniaturized flames. The major advantages of this combustion principle are the inherent safety against flashback (stable flame) and the low NOx-emissions due to a very short residence time of the reactants in the flame region of the micro-flames.

Keywords: Hydrogen gas turbine, Micro-mix combustion, Dry low mission (DLE), Carbon free

INTRODUCTION

Within the last decade the global demand for renewable energy has increased rapidly, which leads to new challenges for conventional power generation systems. For nuclear and coal power plants it will be very difficult to be part of the future power generation, especially in Europe. In case of overcoming the new challenges, the gas turbine technology has realistic chances to solidify and expand its role in future power generation. Thus, future gas turbines must offer more operational flexibilities, such as a higher number of starts, lower emissions at partial load, hot start capability, short start time, low maintenance and fuel flexibility to meet the requirements of the renewable energy market.

To enhance fuel flexibility, hydrogen has great potential as a renewable and sustainable energy source derived from wind or solar power and gasification of biomass and therefore substituting the limited resources of fossil fuels. It represents a possible alternative gas turbine fuel within future low emission and carbon free power generation. Due to the large differences in the physical properties of hydrogen compared to other fuels such as NG, the combustion of hydrogen gases is a very challenging task, especially for the DLE combustion. Nevertheless, KHI overcame these challenges and developed 3 different H2-combustion systems, which are illustrated in Fig.1.

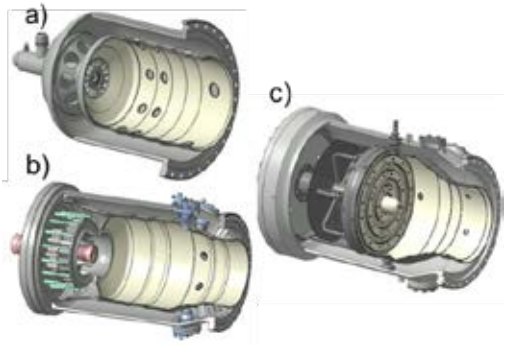

Fig. 1. Different hydrogen combustion systems: a) Diffusion flame-, b) Supplemental-, c) Micro-Mix-Combustor (MMX)

The diffusion flame combustor (Fig. 1a) can operate with 100% hydrogen and 100% natural gas and also with mixtures of both. Water injection is used to achieve low emissions. The first gas turbine with this diffusion flame combustor has been used in the project “Development of smart community technology by Utilization of Hydrogen CGS (Co-Generation System)”. This project is subsidized by NEDO (New Energy and Industrial Technology Development Organization). The successful commissioning took place on the 19th and 20th of April 2018 in a demonstration plant in Kobe. Fig. 2 shows the process control interface, during the 100% hydrogen fuel operation mode. The electrical power output is approx. 1.5MW. The amount of measured NOx emission during 100% hydrogen combustion is 50ppm (16%Vol.O2).

In total, three different fuel modes are available at the touch of a button, which leads to very high flexible operation. The first fuel mode “Natural Gas Only” is the conventional operation with natural gas. The second mode “Blend Gas” is the operation with mixture ratios of natural gas and hydrogen. The mixture ratio can vary from 1%-99% hydrogen. The third mode “H2 Gas Only” is the innovative pure hydrogen fuel mode, as visualized below.

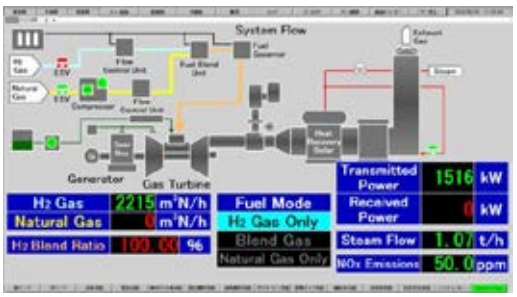

Fig. 2. Process controlling interface of Kobe plant

The second development in Figure 1b is the so-called M1A-17 DLH combustor. It based on a conventional DLE combustor with hydrogen injection over the supplemental burner up to 60Vol% hydrogen, which corresponds to 30% of the total thermal input. Basically, the DLE combustor of KHI has pilot, main and supplemental burners. And usually natural gas is supplied from the supplemental burners. Within this combustor, it can be switched from natural gas to hydrogen or natural gas and hydrogen mixing gas fuel via the supplemental burner. The NOx emission can be kept below the 25 ppm (O2-15%) guaranteed level. This combustor has also been tested successfully at Akashi Works.
Using hydrogen in conventional DLE combustors increase the NOx emission values as well as the risk of flashbacks. The established gas turbine combustion systems cannot be directly applied. Thus, the development of DLE-H2 combustion technologies is indispensable for pure hydrogen (100Vol%) combustion. Therefore, the innovative DLE-MMX combustion chamber (Fig. 1c) has been developed.

THE DLE-MMX COMBUSTION PRINCIPLE FOR HYDROGEN

Kawasaki Heavy Industries, Ltd. has developed in cooperation with the Aachen University of Applied Science and B&B-AGEMA, the DLE-MMX combustion principle for hydrogen fuel to significantly reduce NOx emissions [1]. This combustion principle is based on cross-flow mixing of air and gaseous hydrogen which reacts in multiple miniaturized “diffusion-type” flames with a usual size of 5-10mm in length. Within the development and optimization process the number of holes was reduced from 1600 flames to 410 flames with fuel injector diameters of 0.3-0.8mm. The multiple micro flames at the test burner are visualized in Fig. 3 (left). The H2-injection holes and the air guiding panels are also visible.

On the right side, the prototype of the combustion chamber and MMX burner with its three ring segments is shown. Each ring is supplied with hydrogen from the center and can be individually controlled depending on the power load. The major advantages of this combustion principle are the inherent safety against flashback and the low NOx-emissions due to a very short residence time of the reactants in the flame region of the micro-flames.

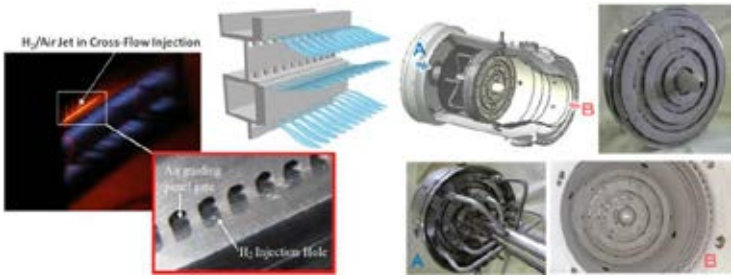

Fig. 3. H2-Micro-Mix test burner (left) and prototype (right) [2]

Fig. 4 shows the NOx emission and the total pressure loss ratio (TPLR) distribution for two different prototype combustors under operating pressure. From idle to 30% load, the inner hydrogen rings were used and from 30% load to full load, all rings were used. It can be seen, that low NOx values are also achievable at partial load. The NOx values are below the project target value of 35ppm over the whole load range only for 0.55MMX. The TPLR project target level is achieved for both configurations.

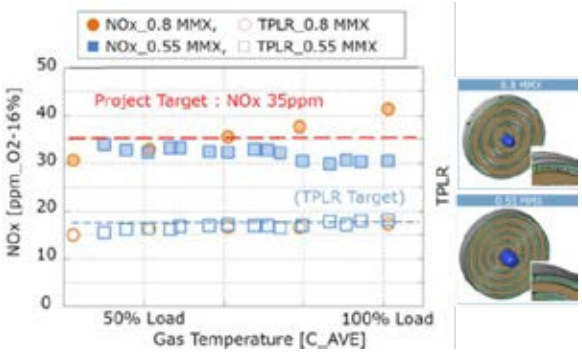

Fig. 4. NOx and TPLR distribution over load for prototype combustor under operation pressure [3]

Figure 5 shows an innovative future power plant with combined heat and power (CHP) and integrated renewable energy supply. The system consists of a H2/NG fueled gas turbine with integrated hydrogen production and storage. The surplus energy from the renewable sources such as wind and solar is used for hydrogen production via an electrolyzer. This is temporarily stored and can be used for generating power and heat via the hydrogen gas turbine anytime as needed, with low NOx emissions and zero carbons.

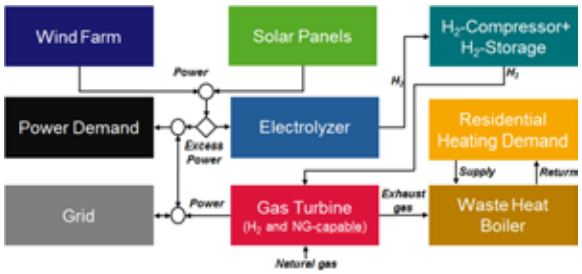

Fig. 5. Innovative CHP power plant with renewable energy supply

CONCLUSION

The commissioning of the world's first diffusion flame combustor with a 100% hydrogen fueled gas turbine has been carried out successfully in Kobe, Japan.
In addition, the hydrogen fueled DLE Micro-Mix Prototype combustor has been tested successfully under atmospheric and pressurized conditions and has proven its dry low NOx ability over a wide operating range. The Micro-Mix combustion principle leads to significantly reduced NOx emissions due to the miniaturized micro flames with inherent safety against flashback.
The MMX-Technology is a technological breakthrough for hydrogen combustion within gas turbines. It ensures, that gas turbines have realistic chances to solidify and expand their roles in future CHP generation. Thus, with this innovative and unique technology the gas turbine is ready for the upcoming energy transition.

ABSTRACT

In this contribution different reactor types are evaluated in the context of the synthesis of alternative fuels like methanol and dimethyl ether (DME) from carbon dioxide and renewable hydrogen produced via water electrolysis. The evaluation is based on a theoretical approach, which combines computational fluid dynamics (CFD) simulations of the synthesis reactors with ANSYS Fluent® and process analyses with ASPEN PLUS®. Multiple optimization strategies were applied to the synthesis reactors to increase the productivity. A membrane reactor setup could show a maximal increase of 181 % in space time yield for the direct synthesis of DME form CO_2. By this result the significance of tailor-made reactors and processes for fuel synthesis from CO_2 and renewable hydrogen are highlighted.

Keywords: Power-to-fuel, Hydrogenation, Methanol, Dimethyl ether (DME), Reactor engineering

INTRODUCTION

To counter the effects of anthropogenic climate change and in line with the process of energy transition and the climate protection goals of the German government, higher amounts of renewable energy generation capacities are installed and more renewable energy is introduced into Germany's energy supply grid [1]. To reach the defined climate protection goals, it is necessary not only to change the ways of power generation, but also the supplying infrastructure. Especially in the transport sector it is hard to reach the goals for the emission of greenhouse gases and pollutants, since in the last decade there have been no or only slight reductions [2, 3]. One promising approach to connect the renewable energy generation and the transport sector is the concept of power-to-fuel [4]. According to this concept chemical energy carriers are synthesized from hydrogen and carbon dioxide. In this approach, the power, industry and transport sectors are connected via sector coupling and thereby the emissions of greenhouse gases and pollutants are reduced significantly [6]. Hydrogen is produced by water electrolysis and carbon dioxide can be supplied from carbon capture from industrial sources (multiple use of carbon dioxide) or the ambient air (full carbon recycling). The described reference frame shows a fully sustainable supply chain for the production of synthetic fuels and therefore a defossilization of the transport sector [7]. In terms of alternative electro fuels chemicals like alcohols, ethers and advanced synthetic fuels e.g. $OME_{3\text{-}5}$ [8], synthetic diesel or kerosene (MtG/ MtK/ MtD-processes) are promising [9, 10]. The aim of this work is to analyse the production pathways of methanol and DME among other possibilities with the focus on the reactor development.

MATERIALS AND METHODS

The two fuel alternatives mentioned above are evaluated regarding their technical feasibility and energy efficiency using process simulation with Aspen Plus®. The process models of these production processes are based on the determination of the chemical equilibrium for the given boundary conditions. The reactors are therefore modeled as Gibbs-reactors, which determine the chemical equilibrium by minimizing the Gibbs energy. The boundary conditions of these reactors can be extracted from the process simulations and be used in the CFD-simulations of the reactors (with ANSYS Fluent®). This approach supports the design of innovative reactors for methanol and DME synthesis. Since the aim is to produce bulk materials like fuels, these reactors need to be scaled to industrial sizes within great production capacities.

The modeling approach for the CFD simulations is based on a pseudo-homogeneous modeling of the fixed bed catalyst zone. In these regions kinetic models can be applied to describe the reaction rates in detail. Various kinetic models have been published for both methanol and DME synthesis. The most suitable models are selected on the basis of consistency and best agreement with literature. An important aspect in the modeling process is the integration of mass transport limitations, which are not included in the kinetic models. The limitations of mass transport come from the diffusive flux through the diffusive boundary layer and within the catalyst particle. The internal and external catalyst effectiveness factors are derived from physics to model these limitations. According to Lommerts et al. [11] the modified Thiele-modulus is used to calculate the internal catalyst effectiveness. The external catalyst effectiveness factor refers to the usage of the second Damköhler number [12]. All these different aspects (kinetics, mass transport) have to be integrated into the CFD simulations by self-developed user-defined-functions (UDF).

RESULTS AND DISCUSSION

The simulation results are divided into the different pathways and modeling approaches that have been presented in the methods part. The very first step is to determine the overall potential of the production processes based on the process analysis. This evaluation includes the carbon dioxide-based production of methanol and DME synthesis. Methanol and DME show high efficiencies (52-59 %) and therefore offer a very effective way to store hydrogen-based renewable energy. Thus, a more detailed look into the mechanism of syntheses should be done by CFD simulations. Since methanol synthesis is the basis for DME synthesis, this process is investigated first. Kinetic models from Graaf [13], Bussche and Froment [14] as well as Seidel et al. [15] are tested. The model of Graaf [13] is selected to be the base model. In case of methanol synthesis, a broad study of various reactor types determines the reactor types with the greatest potential. In this simulation study, reactors that are classified as quasi-adiabatic (e.g. quench reactors (QR)) and quasi-isothermal (e.g. Lurgi-type reactor (LR) and Mitsubishi Superconverter (MSC)) are included. In addition, an innovative membrane reactor (MR) is designed on the basis of MSC and LR. With the help of simulations the previously described modeling approach was validated using data from an industrial scale reactor [16]. Finally, the quasi-isothermal reactor types show far more potential for the application in hydrogenation of carbon dioxide. The study of methanol synthesis can be seen as a starting point of the analysis of DME synthesis. There are two different ways to synthesize DME. The first one is called indirect synthesis where methanol is used as an educt. The second one is called the direct synthesis and it starts with hydrogen and carbon dioxide. Both production pathways need to be included and compared in this analysis.

For the indirect synthesis of DME different models or parameter settings have been extracted from literature and tested against experimental data. Most relevant models are updated parameter sets for low temperature DME synthesis [17-20] of the original kinetic model by Bercic [21]. These modified parameters lead to an increased conversion in a lowered temperature regime in comparison to the original model by Bercic [21]. In conclusion to that, these adapted parameter sets lead to a far better agreement with the experimental data and thus the adapted version is chosen for the further study. Parameter studies on weight hourly space velocities (WHSV), temperatures, pressures and catalyst properties show the effects of the mentioned parameters on the DME synthesis. Boundary conditions like inlet temperature (260 °C), wall temperature (300 °C) and WHSV (1-5 1/h) are results from this study that can be transferred to the direct synthesis. A first look at the results is shown on the left side of Figure 1.

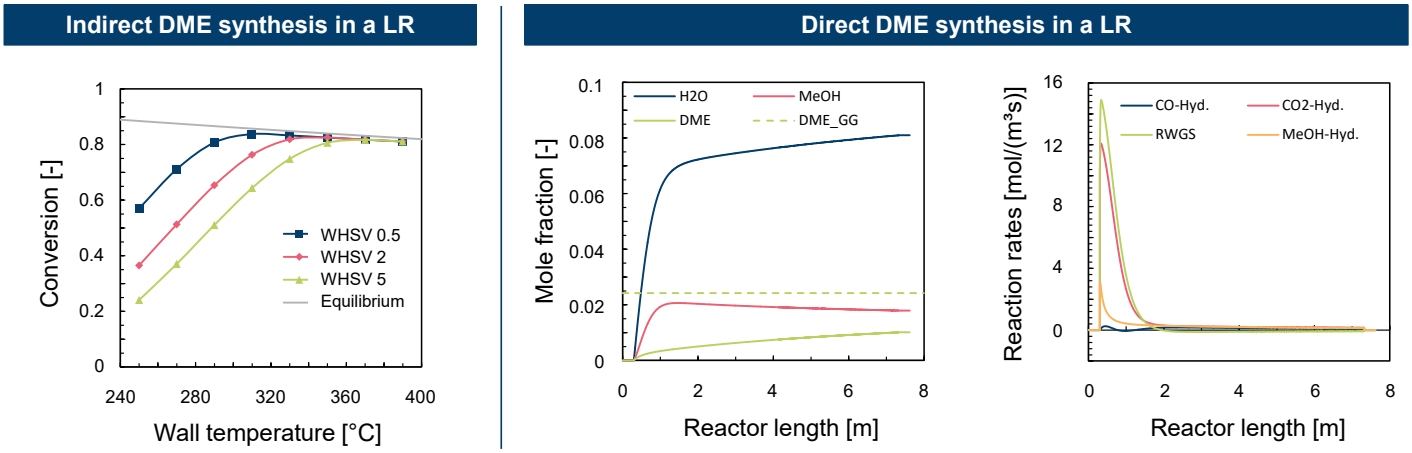

Fig. 1. Simulation results of direct DME synthesis in a lurgi-type reactor (LR)

Most of the simulations of the direct synthesis of DME are carried out by the Lurgi-type reactor model. Exemplary results are presented in the middle and on the right side of Figure 1. As a first result it can be seen that the DME synthesis is much more affected by product inhibition due to the formation of water in comparison to the CO_2-based methanol synthesis. This mechanism is pointed out by the rapidly decreasing reaction rates on the right side of Figure 1. After just 2 m within the reactor the reaction rates drop to nearly 0 mol/(m³s). Process simulations are carried out and used to determine the equilibrium conversion for the given boundary conditions. These equilibrium conversions (marked DME_GG) in the middle of Figure 1 indicate the limitations of the direct synthesis. From this starting point, the analysis of the direct synthesis of DME has to show the optimization potential by various methods. This includes operating conditions like wall temperatures/ cooling, pressures and feed compositions as well as spacial distributions of the two active catalyst sites. These analyses show that a tight temperature control of the reactor is crucial for an effective synthesis of DME. Furthermore, an increased CO ratio of the feed gas improves the reaction conditions significantly.

Nevertheless, in order to overcome the observed limitations for the CO_2-based DME synthesis, innovative technologies have to be applied. For that reason, a CFD-simulation model of a membrane reactor was implemented. The membrane reactor offers an in-situ water removal. The in-situ water removal is a counter technique to the product inhibition and enables better kinetics and higher performances of the synthesis reactor. The performance of the membrane regarding mass transport is the key element within this theoretical study and is also analyzed by a detailed parameter variation. All the mentioned studies will be discussed in detail in the oral presentation.

CONCLUSIONS

As it can be seen from the simulation results the overall crucial aspect of hydrogenation of carbon dioxide is the depletion of product water. The effect of in-situ water removal by a semi-permeable membrane is shown for both, methanol and DME synthesis and will be highlighted in the oral presentation as well as an enhancements by increased CO feed ratio. As a result, the membrane reactor concept enables far higher conversion rates than the conventional fixed bed reactors. In case of methanol synthesis this potential is limited by reduced space-velocities. In contrast to this, the direct DME synthesis from CO_2 is far more challenged by product inhibition and the membrane reactor concept increases the conversion and the space time yield as well. Nevertheless, the direct synthesis of DME shows in addition to the pointed-out challenges in the synthesis further challenges in terms of product separation and overall process design. The resulting conclusion from process and reactor analysis is to optimize the 2-step process or develop completely new direct synthesis route for example via reactive distillation.

ABSTRACT

It has become imperative for the power and energy engineers to look out for the renewable energy sources such as sun, wind, geothermal, ocean and biomass as sustainable, cost-effective and environment friendly alternatives for conventional sources. However, since they are inherently unreliable, during the last decades the scientific community addressed research efforts to their integration with the main grid by means of properly designed energy storage systems (ESSs). However, due to the complexity of the involved systems in terms of number of inputs, number of outputs, number of decision variables, constraints and costs this topic is still open. In particular, advanced control strategies for the management of ESSs in order to take into account all the reported aspects need to be designed.
In this paper we present a model predictive controller (MPC) which operates a hydrogen-based ESS (HESS) within a wind farm fence. The controller is derived in order to minimize the operating and economical costs of the HESS and the difference between the available power and that required by the grid operator through a suitable reference, while satisfying physical constraints and considering the dynamics of the system. In order to capture both continuous/discrete dynamics and transitions among different operating modes, the plant is modelled as a mixed logic dynamic system. The study has been developed within the EU-FCH 2 JU funded project HAEOLUS aiming at building and integrating advanced control strategies for a ESS within a wind farm. Numerical simulations show the feasibility and the effectiveness of the proposed approach.

Keywords: Hydrogen-based energy storage systems, Energy management, Model predictive control.

INTRODUCTION

Nowadays, renewable energy resources are subject to considerable attention as being in principle possible replacement of fossil fuel. In this regard, wind and solar resources are commonly considered the most promising options. Many studies have been carried out to improve the technologies aiming at easing their exploitation in real scenarios and to overcome their limitations.

With regard to the wind, energy production and consumption mismatches due to its inherent stochastic nature and possibly high capital and operational costs, are the main hurdles for its utilization at large scales [1]. Further, the use of specific and advanced technological solutions, such as electrolysers and fuel cells, increases the complexity of actual plants which then require well-designed management strategies. For this reason, control algorithms for energy management systems (EMSs) are addressed in relevant works, e.g., in Valverde et al. [2] a supervisory MPC for a HESS with optimal power market management is implemented.

According to the authors' knowledge, relevant aspects of HESSs with electrolyser, tank and fuel cell peculiarities, such as degradations, operating modes transitions and stand-by consumptions, have not been modelled in the literature. Our paper develops preliminary operational models with constraints for a HESS to be integrated in a wind farm fence under the EU-FCH 2 JU funded project HAEOLUS-Hydrogen-Aeolic Energy with Optimized eLectrolysers Upstream of Substation [3].

Specifically, the plant is modelled considering mixed logic constraints and switching dynamics. Depreciation costs when switching among on, off and stand-by operating modes are also taken into account. Then, a controller whose goal is to track and meet a reference demand with the available system power in the most economical and effective way is derived.

SYSTEM DESCRIPTION AND MODELING

The electrolyser and the fuel cell can be operated in 3 different physical modes, namely the on, the off and the stand-by mode. Specifically, as shown in Fig. 1, each machine can be modeled as an automaton of 5 states: ON, OFF and STB correspond to the on, the off and the stand-by modes, respectively, while CLD and WRM are added in order to account for cold and warm starts when switching among the three different modes.

DISCRETE OPERATIONAL STATES OF THE ELECTROLYZER AND THE FUEL CELL

The discrete operational states of the devices are presented in this section. As shown in Fig. 1, each node represents a particular state and the edges represent transitions among them. The states and the edges are linked to

corresponding mutually exclusive binary variables $\delta_i^{\alpha}(k)$ and $\sigma_{\alpha,i}^{\beta}(k)$, respectively, with $\alpha, \beta \in$ {OFF, CLD, STB, WRM, ON} and $i \in \{e, f\}$, that are used in order to translate the models of the electrolyser and the fuel cell into mixed logic constraints to be included into an optimization based controller. The overall system assumes the so-called form of a mixed logic dynamical (MLD) system.

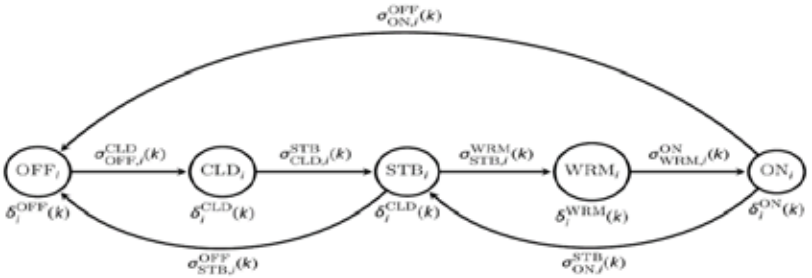

Fig. 1 Automaton of the electrolyser (i=e) and the fuel cell (i=f).

Mathematical Model and Constraints Formulation of the States

The states OFF,CLD,STB,WRM and ON of each automaton are characterized by the product of one logical variable and one power, which is relevant for that state, to be different from zero. For instance, whenever the electrolyser is in the ON state, the corresponding input power is limited within the range $[P_e^{min}, P_e^{max}]$. Thus, by defining $P_e(k)\delta_e^{\mathrm{ON}}(k) = P_e^{\mathrm{in}}$ and since in this case we set $\delta_e^{ON} = 1$ it results $P_e(k) = P_e^{\mathrm{in}} \in [P_e^{min}, P_e^{max}]$. On the other hand, whenever the electrolyser is in the STB state, the relevant power to be considered is the stand-by power P_e^{STB}. Therefore, by defining $P_e(k)\delta_e^{\mathrm{STB}}(k) = P_e^{\mathrm{STB}}$ it follows that $P_e(k) = P_e^{STB}$ and, accordingly, $\delta_e^{\mathrm{STB}}(k) = 1$, while all other logical variables δ_e^{α}, $\alpha \neq$ STB are again null. Similar considerations apply in case of WRM and CLD states. Finally, when the electrolyser is in OFF state, its corresponding input power along with the power consumption are null, resulting in $P_e(k) = 0$.

Mathematical Model and MLD Constraints Formulation of the State Transitions

In principle, each automaton depicted in Fig. 1 enables the referred device to 20 possible transitions. However, only those reported concur to the corresponding operational costs, while the others are unfeasible for either practical or technological considerations and will be constrained to zero in the proposed controller. The state transitions can be defined in terms of logical states and logic connectives as

$$\sigma_{\alpha_i}^{\beta}(k) = \delta_i^{\alpha}(k-1) \wedge \delta_i^{\beta}(k), \tag{1}$$

with $\sigma_{\alpha_i}^{\beta} \in [0,1]$, $\alpha, \beta \in$ {OFF,CLD,STB,WRM,ON} and $\alpha \neq \beta$. Then, based on the formulation in [4], (1) is recast into inequalities that are included as constraints into the proposed MPC.

State Space Model of the Hydrogen Storage Dynamics

Hydrogen dynamics are given in terms of the hydrogen level $H(k)$ in the tank, the efficiencies of the electrolyser and of the fuel cell η_e and η_f, their respective power in the on state P_e and P_f, and the corresponding logic variables δ_e^{ON} and δ_f^{ON}. The resulting formula is

$$H(k+1) = H(k) + \eta_e P_{\mathrm{e}}(k)\delta_e^{ON}(k)\, T_s - P_{\mathrm{f}}(k)\delta_f^{ON}(k)T_s/\eta_f, \tag{2}$$

where $\boldsymbol{T_s}$ is the sampling period.

Power Balance Equation

The power balance

$$P_w(k) - P_{\mathrm{e}}(k)\delta_e^{ON}(k) + P_{\mathrm{f}}(k)\delta_f^{ON}(k) - P_{\mathrm{avl}}(k) - P_{\mathrm{dump}}(k) = 0, \tag{3}$$

achieved through operating the HESS, is included as constraint into the proposed MPC algorithm. Eq. (2) highlights that the available power P_{avl} depends on the power P_w achieved through wind generation, the balancing action of the HESS and the dumping load.

RESULTS

Simulations have been carried out for a horizon of 24 hours. We wish to emphasize that the main contribution of this paper relies in the derivation of the preliminary operating models useful for running the hydrogen-based storage plant according to the project Haeolus [3].

In our numerical examples, the wind power production and the reference power demand are such that both surplus and deficit powers are considered, with a power flow towards or from the storage.

Fig. 2(a) and 2(b) show the power by wind generation P_w and the reference P_{ref} provided by the grid operator, respectively. It can be seen that the difference between the wind power and the reference demand is positive for the first 5 hours, so that the reference demand is met through the wind power only and the surplus power is shunted to

the electrolyser for hydrogen production. Accordingly, changes to the current level of hydrogen occurs, while the physical constraints regarding the storage are fulfilled, as depicted in Fig. 2(f). Fig. 2(e) shows the fuel cell power. It can be clearly observed that during the daily hours the available power P_{avl} is less than the reference demand P_{ref} and the fuel cell provides power to the grid through re-electrification (hours 9, 10, 14, 17 and 21).

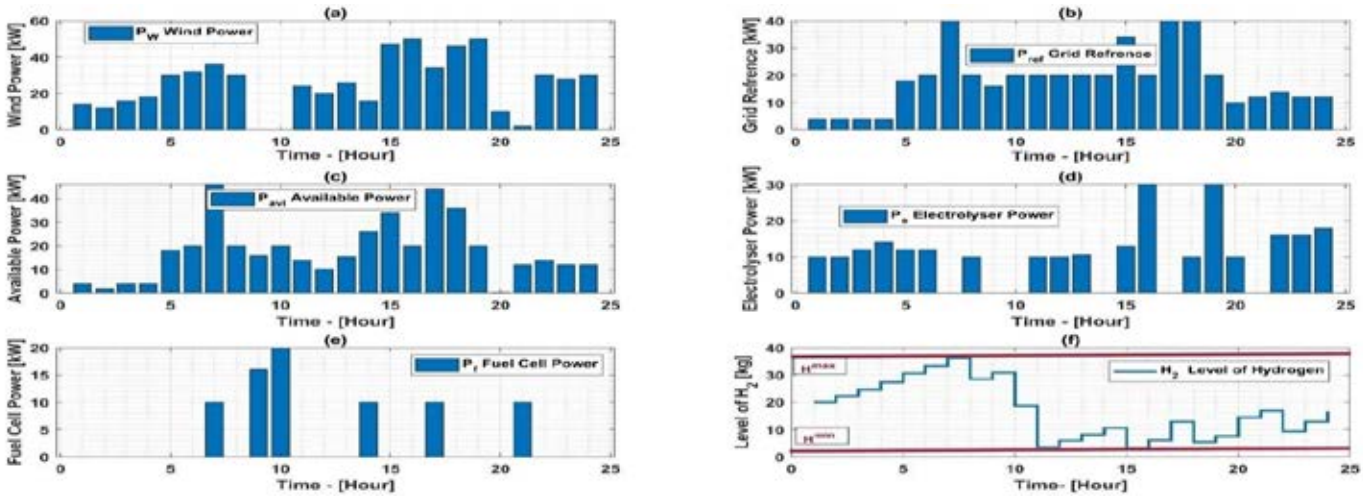

Fig. 2. Numerical results: (a) Forecasted wind power. (b) Grid operator reference. (c) Available power. (d) Electrolyser power. (e) Fuel cell power. (f) Hydrogen level.

CONCLUSION

In this work we developed models for operating, with optimal control strategies, an ESS to be coupled to a wind farm. The models of both the electrolyser and the fuel cell encode discrete logical states representing the devices operating modes while the continuous dynamics refer to the hydrogen level in the tank.

The proposed MPC scheme considers the cost that the electrolyser and the fuel cell introduce each time they switch between different operating modes, thus decreasing the corresponding number of life cycles and efficiencies. Furthermore, all other physical constraints and costs, such as the power consumption in stand-by, cold and warm starts, are considered, among the others.

The costs related to the operations of each device and the developed mixed logic dynamic models have been included in an MPC scheme. Simulations have been carried out by tracking a reference power provided by the grid operator, over an optimization horizon of 24 hours. Numerical results show the correct behaviour of the devices and their commutations among the different operating modes. The power is correctly stored or injected via hydrogen conversion to help the wind production in determining the total available power complying with the operator requirements.

ABSTRACT

Internal combustion engines (ICE) can be fuelled with hydrogen rich waste streams coming from industry providing good performance and low emissions. Coke oven gas (COG), a by-product of coke manufacture, has a high volumetric percentage of H_2 and CH_4 and can be used as auxiliary support for electric generation. Computational fluid dynamics (CFD) simulation tool has been used to assess the combustion and performance of COG compared to pure H_2 and pure CH_4. Simulations were validated with experiments in a Volkswagen Polo 1.4 L port-fuel injection spark ignition (SI) engine varying engine speed from 2000 to 5000 rpm at wide open throttle (WOT), optimum spark advance for maximum brake torque (MBT) and air-fuel ratios (λ) between 1 and 2. Comparison is made through power, heat release, pressure and temperature combustion variables. Results show that COG combines benefits of both pure fuels, widening the operation range, with good performance and low wall heat transfer at intermediate λ values. Furthermore, the energy content of an industrial waste stream can be harnessed for the industrial plants where is produced.

Keywords: Coke oven gas, Hydrogen, Internal combustion engine, Computational fluid dynamics (CFD), Methane

INTRODUCTION

Facing climate change, alternative cleaner fuels in ICE are being studied, predominating H_2 and CH_4 [1]. As each of these fuels has different advantages, they can be used complementary in mixtures with interesting properties. However, industrial waste streams with high percentages of H_2 are also very attractive, as they can provide good performance and low emissions, harnessing the energy content and being converted into electricity for auxiliary support to industries. Clean COG, a by-product of coke manufacture with the typical composition shown in Table 1, is sometimes flared in periods of low energy consumption within the coke plant [2]. Some studies with this gas have been carried out in SI engines [3–5]; however, a comprehensive analysis of the combustion of COG compared with its main components (H_2 and CH_4) in a SI engine through CFD at a wide range of engine speeds (2000 – 5000 rpm), different λ values (1 to 2) at WOT and MBT lacks in the literature and is carried out in this work. Combustion is assessed with power, heat release, pressure and temperature variables to understand deeper the behavior and advantages of this waste stream.

Table 1. Composition of synthetic COG in percentage by volume and by weight used in this study.

Composition	H_2	CH_4	CO	N_2	CO_2
vol%	57	30	6	5	2
wt%	11.6	48.5	16.9	14.1	8.9

MODELLING

A CFD model of a symmetrical single cylinder (Fig. 1) from a Volkswagen Polo naturally aspirated port-fuel 1.4 L SI engine converted to work with gases [6] has been developed with Ansys® Forte® to study the combustion of COG, pure H_2 and pure CH_4.

Simulations were conducted at the same operating conditions as a previous work [5], varying the engine speed between 2000 and 5000 rpm, λ between 1 and 2 and optimum spark timing to obtain MBT. The detailed Gri-Mech 3.0 mechanism was selected to compare the three fuels. Gaseous fuels were injected with a time-varying velocity profile, assuming the fuel density at 3 bar and mass flow rates according to the fuel (0.6 g/s for H_2, 1.4 g/s for COG and 2 g/s for CH_4). A mechanical efficiency correlation was applied, decreasing linearly with the engine speed: 90% at 2000 rpm and 75% at 5000 rpm.

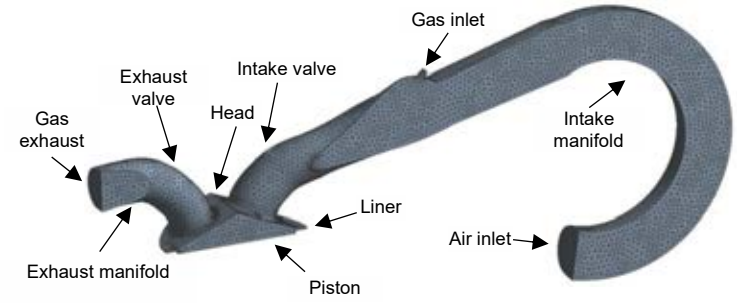

Fig. 1. 3D symmetric mesh of the CFD model of a single cylinder from the engine.

RESULTS AND DISCUSSION

In Fig. 2, the experimental and simulated brake power values of COG, CH_4 and H_2 are graphed at different λ values and in the entire speed range, confirming a good agreement. In addition, Fig. 3 shows the chemical heat release (CHR) and wall heat transfer (WHT), both in J, at the same operating conditions. As the mixture becomes richer (lower λ), the power increases due to higher CHR, though higher WHT is also produced. At λ values of 1 and 2, similar performance is achieved with COG compared to CH_4 and H_2, respectively, widening the operation range. However, at λ=1.5, COG delivers similar CHR than CH_4 and H_2, but produces the lowest LHV values (Fig. 3b), increasing the resulting brake power. The main reason is the reduction of the maximum in-cylinder temperature (Fig. 4b) because COG has a higher flame growth speed than CH_4, delaying the spark timing. At 5000 rpm, COG releases 40.1% of WHT less than CH_4 and 14.3% of WHT less than H_2. At higher engine speed, higher power is achieved because the total amount of mass dragged into the cylinder increases.

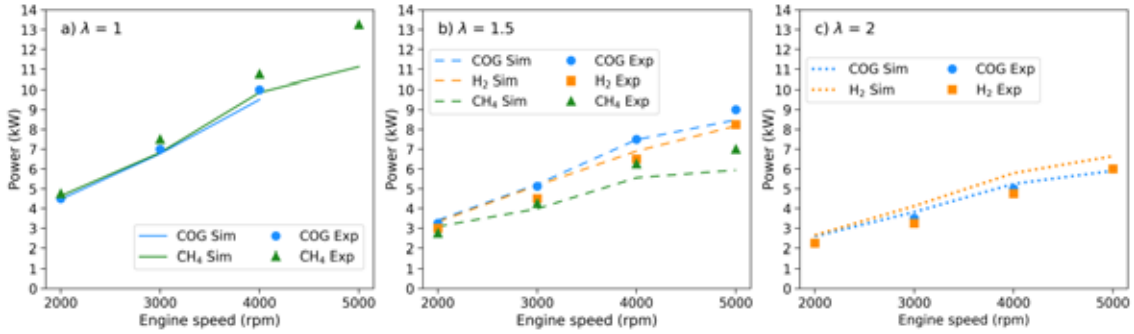

Fig. 2. Experimental (discrete values) and simulated (lines) brake power (kW) of COG, CH_4 and H_2 vs engine speed at a) λ=1, b) λ=1.5 and c) λ=2.

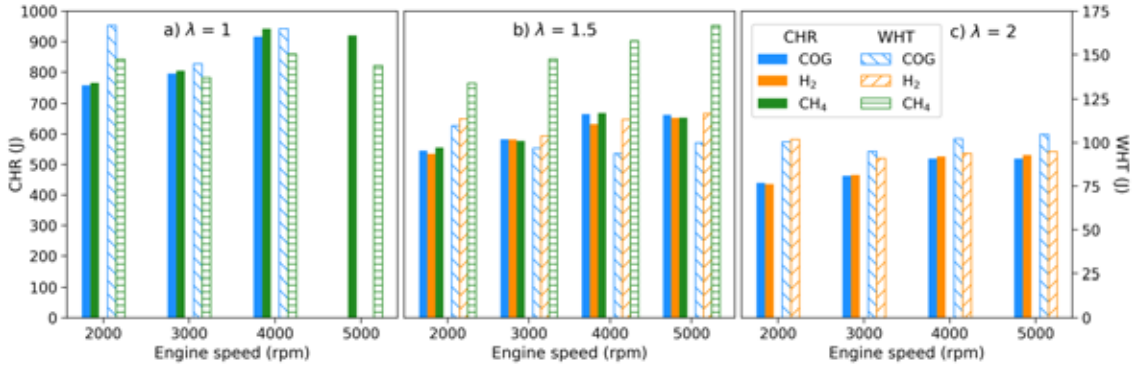

Fig. 3. CHR (solid bars) and WHT (dashed bars) of COG, CH_4 and H_2 vs engine speed at a) λ=1, b) λ=1.5 and c) λ=2.

Fig. 4 shows the evolution of the average in-cylinder pressure, temperature and the apparent heat release rate (AHRR, in J/CAD) graphed at 3000 rpm and different λ values for COG, H_2 and CH_4. Leaner mixtures reduce the maximum values due to lower CHR. Higher H_2 contribution in fuel reduces the combustion duration increasing the slope of pressure and temperature curves. CH_4, with the highest spark advance, increases the maximum values of pressure and temperature. H_2 has the highest AHRR values due to high flame speed, increasing the temperature and the WHT. Suitable pressure peak but lower temperature maximum values of COG reduce WHT but increase brake power.

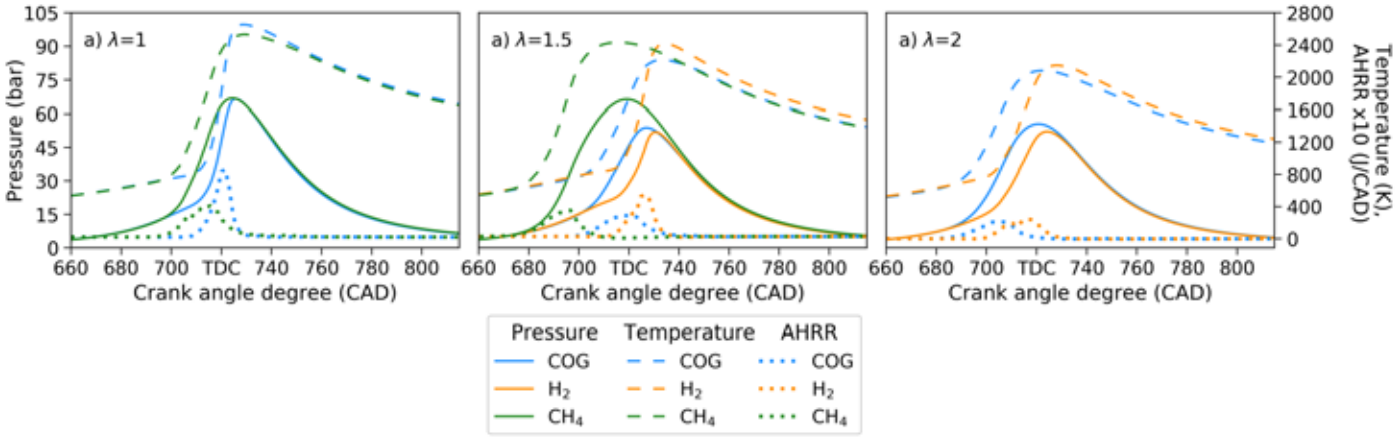

Fig. 4. Pressure (bar), temperature (K) and AHRR (J/CAD) of COG, CH_4 and H_2 inside the cylinder at 3000 rpm and at a) λ=1, b) λ=1.5 and c) λ=2.

CONCLUSIONS

A CFD model of a port-fuel 1.4L SI engine at WOT, MBT, engine speeds between 2000 and 5000 rpm and λ values between 1 and 2 has been developed. A comparison of COG, pure H_2 and pure CH_4 gaseous fuels with combustion variables was carried out, analyzing the performance.

- Leaner mixtures reduce the pressure, temperature, CHR and WHT values inside the cylinder.
- COG delivers the highest power at λ=1.5 due to high pressure and intermediate spark advance, decreasing WHT.
- CH_4 requires high spark advance due to lower flame speed, increasing the peaks of pressure and temperature and maintaining high values for a longer time, raising the WHT and NO emissions.

COG combines advantages of pure H_2 and pure CH_4, increasing the operation range, with higher power performance and lower emissions, becoming an interesting fuel for ICE in industry plants coupled to generator systems as auxiliary support for electricity production.

ABSTRACT

The widespread use of especially solar, wind, geothermal and biomass investments for electricity generation coincides with the Paris Climate Agreement and the European Green Deal Act decarbonization targets and is supported by the whole world now. Green hydrogen can produce from renewable energy sources; it has been attracting attention recently because it is more environmentally friendly and in line with decarbonization targets. Geothermal power plants have the highest capacity factor among renewable energy plants, and they are systems that can produce electricity all day long without interruption.

In this study, a perspective towards green hydrogen production from geothermal power plants is discussed with the Kızıldere geothermal power plant (GPP) in Denizli, Turkey. This concept study is proposed for hydrogen production by Proton Exchange Membrane (PEM) type fuel cell at multi-flash geothermal power plants.

Keywords: Green hydrogen, hydrogen production, PEM, geothermal energy, Kızıldere GPP

INTRODUCTION

Geothermal energy is a substantial indigenous energy resource on the earth, which is believed to originate in geo-nuclear activity. Geothermal fluids consist of three phases such as brine, steam, and non-condensable gases like CO_2, H_2S, CH_4, H_2 and trace gases at liquid-dominated systems. The chemical composition of geothermal fluids changes with heat source, fluid rock interaction and reservoir temperature. Electricity generation is dependent on the geothermal reservoir temperature and if temperatures higher than >150°C it is used for flash and combined cycle, while it is lower than 150°C is suitable for binary cycle. The Western Anatolia is rich in medium-high geothermal sources for electricity production and there are large graben systems which have good geothermal energy potential such as Büyük Menderes Graben, Gediz Graben and Simav Graben [1]. In addition to required energy for H_2 production, which is not found alone in nature, from renewable energy sources [2, 3], it is possible to produce H_2 from H_2S by different methods such as thermochemical, photo-catalytic, biological and membrane technologies in geothermal systems. Especially, steam-reforming process is one of the important options to produce H_2 and the reaction of H_2S with CH_4 can be thought of as sulphur analogue of steam-methane reforming process. The process is represented by the overall reaction above will produce carbon disulphide and it can be used to produce sulfuric acid (and carbon tetrachloride H_2S-methane reformation is more suitable for utility type of operation with large-scale production rates [4]. H_2 production is from H_2S can be converted into electricity generation with proton exchange membrane (PEM) type fuel cell, which is integrated with the PEM electrolyser, and will be in storable purity and the end member sulphur can also be used for the industrial purposes.

There are more than 60 numbers of geothermal power plants in Aydin, Denizli, Manisa cities at the Western Anatolia (Turkey). 98.5-99 % of the non-condensable gases emitted from the geothermal power plants are CO_2. Due to the structure of the geological formation in Aydin city, these gases of organic origin, enriched by the paleo-sea effect, pH of the reservoir and hydrocarbon effects [1] and it attracts the attention of local people and researchers due to the obvious smell and toxic effects of H_2S. Due to its toxic effect, H_2S may cause negative environmental effects besides CO_2 and to solve this problem, H_2S (20.4 kJ/mol), which requires a lower decomposition enthalpy than water (286 kJ/mol) and methane (75 kJ/mol), can be used for H_2 production by consuming less energy or using electro-chemical energy. Non-condensable gas production at the values given in Table 1 for the Western Anatolia that shows there is a potential that can contribute to the hydrogen economy in the region in future.

The second option is to use only geothermal energy to produce hydrogen. PEM electrolyzers can generate hydrogen (and optionally oxygen) at pressures up to 200 bar, with very little additional power consumption, which may be attractive for the application where hydrogen needs to be stored or used at elevated pressure. PEM type electrolyzers produce hydrogen with very high purity (up to 99.999), which may be used in a fuel cell (Fig.1).

Table 1 The amount of non-condensable gas production in Aydın and Denizli provinces geothermal power plants (Gas amounts are calculated from [1])

Location	CO2 (kg)	H2S (kg)	CH4 (kg)	N2 (kg)
Kızıldere (Denizli)	25	0.0105	0.06	0.15
Salavatlı (Aydın)	9.8	0.0112	0.025	0.091
Germencik (Aydın)	14	0.0315	0.105	0.066

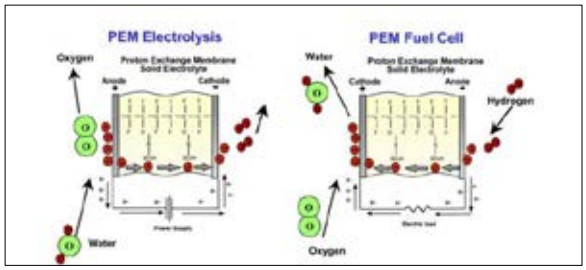

Fig.1 The working principles of PEM electrolysis and PEM fuel cell [5]

THE CASE STUDY

Kızıldere (Denizli) geothermal field was the first discovered high temperature system in the Western Anatolia (Turkey). The first power plant was established as single flash cycle in 1984 and the capacity expeanding studies continued between 2008-2018 years and the total installed geothermal power is reached to 260 MWe with a one single, three flash and combined three binary organic Rankine cycles in the field [6].

In this study, it is assumed that one of the triple flash geothermal power units in the field can be used for hydrogen production. The proposed design for hydrogen production from the flash cycle GPP is given in Fig.2. Since there is no vacuum process in the flash system, the utilizable energy is re-injected back to the ground. In the system, the temperature is reduced to the extent of mineral saturations allow, mostly amorphous silica saturation is used for energy extraction limits. In proposed case, geothermal water, which is re-injected to the ground at 109 ^{0}C, can be reduced to 80 ^{0}C with the help of a heat exchanger and ORC integrated into the main geothermal power plant and extra energy can be produced. The required energy for the hydrogen production will be provided from the additional geothermal power unit. This provides 1.3 MWe for roughly 1000 tph geothermal fluid. While it is sufficient to use resources such as low pH condensed steam, electricity, and heat from geothermal fluid to produce H_2 in the electrolyzer, chemical or biological integrated methods may be required to produce H_2 from H_2S.

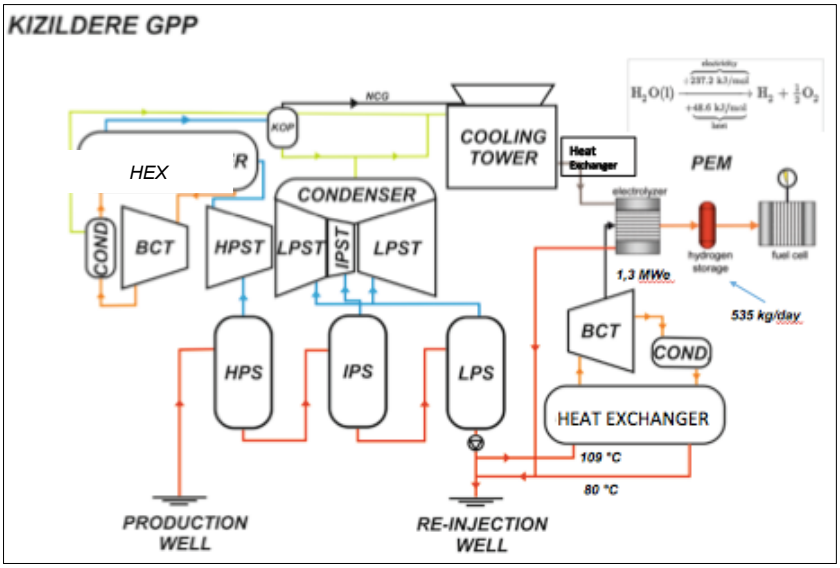

Fig. 2 Hydrogen production by PEM at Kızıldere triple flash geothermal power plant (HPST: High pressure steam turbine, LPST: Low pressure steam turbine, IPST:Intermediate pressure steam turbine, Cond: Condenser, HPS: High pressure seperator, IPS: Intermediate pressure seperator, LPS: Low pressure separator, HEX: Heat exchanger, NCG: Non-condensible gas, BCT: Binary Cycle Turbine , KOP:Knock-out Pot

CONCLUSION

It is expected that the global decarbonization targets will enable more widespread use of hydrogen energy. Considering decarbonization targets while producing hydrogen requires evaluating options for green hydrogen production, geothermal power plants being one of these options.

Green hydrogen production There are two main alternatives to produce hydrogen from geothermal power plants. The first one is to use H_2S gas, which is emitted from cooling towers at geothermal power plants, and the second way is to use only geothermal power to electrolysis.

In this study, it is preferred to decrease the reinjection water temperature and gain additional energy and use this energy for H_2 production in PEM type electrolyser. The required pure water is provided from cooling tower for hydrogen production and 535 kg/day H_2 is produced by this system in the selected geothermal power plant with a specific condition.

ABSTRACT

Hydrogen storage and its efficiency is one of the key challenges, which has been developed in line with the popularity of the fuel cell systems. However, fuel cells operation is linked with intensive heat release, which should be utilised by the cooling system to prevent membrane damage. With on-board cooling system, the overall efficiency of the vehicle decreases further. This paper provides design of a novel system to utilise heat of the fuel cells, drivetrain elements and ventilation system to vaporize liquid hydrogen and reach higher efficiency of the system with cooling system capacity decrease.

Keywords: Fuel cells, Liquid hydrogen, Thermal balance

INTRODUCTION

Hydrogen fuel cells (FC) has been seen as one of the balanced solutions for electric vehicles (EVs), including cars and rail-based systems due to its refuelling time, energy density and self-discharge rate in comparison with batteries and capacitors [1]. The key challenges of FC EVs are storage weight and size, reliability concerns regarding leakages and heat utilisation from the FC due to its efficiency [2].

There have been several solutions developed to meet certain technical objectives of the storage. Absorbent-based canisters prevent leakages, but have excessive mass, in comparison with alternatives and it requires very high purity of the hydrogen. Compressed gas bottles are easy to refuel and have relatively low weight, but their leakage characteristics prevent their application for long-term storage solutions. One of the alternatives can be seen in the cryogenic compressed hydrogen systems, however, storage cost and manufacturing process are very expensive [2, 3].

Alternative solution is to store hydrogen in liquid form [4]. This helps to reduce leaks in comparison with gaseous storage systems, and doesn't require complex expensive canisters to prevent high pressure explosions. Manufacturing process is not cheap, as for the compressed gas, however, it has comparable cost with the cryogenic compressed gas production. Considering better technical performance, it provides balanced solution for the FC EV. Operation of liquid storage requires additional system to be put in EV – evaporating and heating system for the hydrogen. Heating system should increase temperature of the gas to meet requirements of the FC and its efficiency range [4,5]. Overall, hydrogen storage systems have been combined in Figure 1.

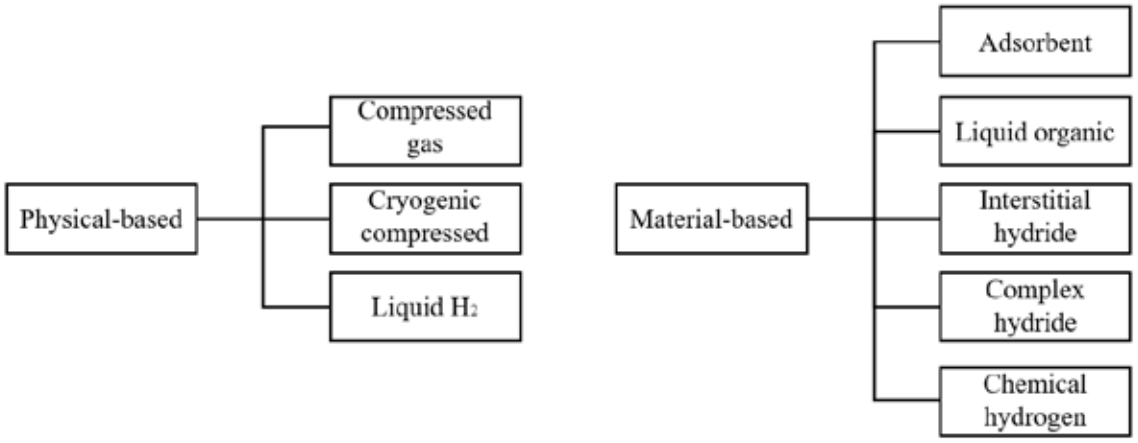

Figure 1. Hydrogen Storage Technologies

Another issue with FC EV is thermal management in the vehicle. FC has relatively low efficiency, in comparison with the battery and capacitors, and generate significant amount of heat, which can damage components of the system, including membranes, which can further reduce the production of electricity. Complex cooling systems have been

proposed in [6] to decrease thermal loading of FC. In comparison with battery-based EV, cooling losses in FC-based vehicles are significantly higher and can be compared with the sizes of cooling systems in conventional vehicles with internal combustion engines [4,6]. Large-scale cooling system requires larger FC to be installed, increases overall vehicle's mass and further impacting efficiency of the solution. In most proposed solutions, such system is combined with the cooling system of the drivetrain, however these two systems have different operating temperatures and different heat generation rates, so efficiency of such solutions is not high.

Furthermore, EVs have significant challenges in organisation of ventilation of the cabin due to the limited available resources and complex control strategies over the storage systems. Intensive use of ventilation system leads to the significant decrease in the operating range of EV. Utilisation of the heat, generated by the occupants, specially in the public transport, is a technical challenge [7].

This paper proposes a novel system, which utilises heat, developed in the drivetrain, cabin and FC of high speed train, to heat up liquid hydrogen from the relative storage system. Developed solution allows to reduce cooling system power consumption, organise effective cabin ventilation system and remove pre-heater for the liquid storage, based on the calculated thermal energy balance.

ENERGY BALANCE ANALYSIS

In the project, remotely moving high-speed stings-rail operating vehicle was developed. Such system has lower power consumption during the motion in comparison with the road vehicles [8]. The key savings come from the decreased rolling resistance in the contact couple rail – steel wheels in comparison with the rubber tires with high hysteresis losses. With the growth of speed, the required power in significantly smaller, even for the vehicles with higher capacity of passengers and goods. Remote access to the power was developed to reduce air drag of the contactors, which significantly increase power consumption of the current trains [9].

Developed solution on the operating speed has power consumption of 800 kW due to the high operating speed, dimensions and its capacity. As efficiency of the drivetrain system, including electric motors, power electronics and control system, is around 90% and all losses are generating heat, the heat generation rate was calculated as 80 kW. Based on the health standards and passengers' numbers, ventilation and air conditioning system was designed with the power rating of 5 kW.

Based on the power requirements, the power of the FC was chosen as 900 kW, to meet all requirements of auxiliary loads, maintain high speed and operate with the cooling system. The heat developed in FC, can be calculated using method from [10], and in the efficient range, FC heat generation is 612 kW.

In total, developed system shows the heat generation power of 697 kW of heat, including ventilation, drivetrain cooling and FC temperature maintenance. The flow of the hydrogen was calculated as in (1):

$$G_{H_2} = N \cdot g_{H_2} = 0.0194 \text{ kg/s} \quad (1)$$

Where G_{H_2} – mass consumption of the hydrogen, N – number of used cells, g_{H_2} – balanced consumption of one cell in the efficiency range.
The heat capacity of the liquid hydrogen can be assessed with equation (2), considering that the hydrogen is stored in Dewar vessels at 0.1 MPa at saturated state with the enthalpy h_1 and then is heated to gas with enthalpy of h_2:

$$Q = h_1 - h_2 = 4.1 \text{ MJ/kg} \quad (2)$$

Then for the given flow rate in the system, the heat capacity of the system is equal to 79 kW. This energy has constant flow requirements and doesn't change, depending on the environmental conditions.

RESULTS AND DISCUSSION

The heat exchange system was developed, as shown on Figure 2.

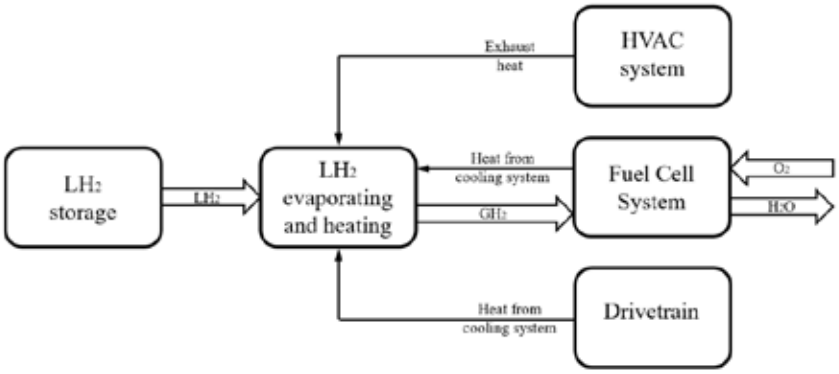

Figure 2. Designed Heat Exhchange System

As it can be seen, the heat generated in various parts of the vehicle, is re-directed to the evaporating chamber of the liquid hydrogen system. The heat dissipation rate in the chamber is 79 kW, however the total required size of the cooling system should have combined capacity of 697 kW. Developed system allows to scale down the required size of the cooling system by 12.9%, with the folloowing gain in the power consumption. Developed system allows to reduce overall complexity of the system, as there is no heating system required for the liquid hydrogen, as the heat is taken from the other systems of the vehicle. This solution can be scaled up or down, depening on the application.

CONCLUSIONS

The paper presents a novel system design, which utilises heat, generated in the various systems of FC EV, including FC, drivetrain and ventilation system, to heat up liquid hydrogen storage system. Developed solution allows to reduce power consumption of the cooling system by 12.9%, which leads to the higher efficiency of the overall system.

OPTIMIZATION OF ENERGY MANAGEMENT STRATEGY FOR FUEL CELL-RANGE EXTENDED ELECTRIC VEHICLE

[1*] *Yan Sun*, [1] *Changgao Xia*
[1] School of Automotive and Traffic Engineering, Jiangsu university, Zhenjiang, 212013, China

ABSTRACT

For the fuel cell-range extended electric vehicle (FC-REEV), the fuel cell system can work at a fixed output power point and have a good durability. However, the differences in output power and start-stop threshold can lead to a significant difference in energy loss and degradation of power sources. Based on the thermostat control strategy (TCS), the economy of vehicle is considered in the evaluation function. Furtherly, the artificial bee colony (ABC) optimization algorithm is used to increase driving range, in order to improve the durability of fuel cell, a penalty factor is added in the performance index function, and a novel optimized ABC-TCS (OABC-TCS) is proposed. Different strategies are tested under FTP-72 and WLTC drive cycle respectively, result shows that compared with TCS, the optimized driving range proportion of OABC-TCS is about 10.59% and 10.3%.

Keywords: Fuel cell vehicle, Range extend, Artificial bee colony algorithm, Thermostat control strategy

INTRODUCTION

In order to solve the problem of excessive greenhouse gas emissions of vehicles, the technology of electric vehicles (EVs) was proposed. However, limited driving range and slow charging problems cannot be fundamentally solved so far [1]. The plug-in hybrid electric vehicles (PHEVs) which is powered by internal combustion engines (ICE) can effectively solve the problems, but it still has a considerable amount of pollutant emissions [2]. Therefore, fuel cell-range extended electric vehicle (FC-REEV) is developed as an effective solution [3]. In this system, the battery works as the main power source, and the fuel cell works as an auxiliary power source. Energy management strategies (EMS) of multiple power sources has become a key problem in FC-REEV. Fuel economy is an important optimization goal of EMS. The performance of fuel cell will degrade gradually in long-term operation [4]. Therefore, it is important to balance fuel economy and component durability when formulating the EMS.

In this paper, a novel EMS for FCEV is proposed, and it considers the hydrogen consumption, lifespan of fuel cell. The SOC range of battery and output current of fuel cell are also considered in the strategy. The proposed strategy is an online strategy with the idea of offline optimization. The start-stop times of the fuel cell are taken into consideration as a key constraint, which is ignored by others.

POWER SOURCES MODELS

The battery uses the “RINT” model. The relationship among battery power, output current, internal resistance and SOC is shown in Eq. (1) and (2).

$$P_{bat} = U_{oc} I_{bat} - I^2_{bat} R_{bat} \tag{1}$$

$$\Delta SOC = \eta_c \frac{\int_{t0}^{t1} I_{bat} dt}{C_{bat}} \tag{2}$$

where, P_{bat} is the output power of battery. U_{oc} is the open circuit voltage. I_{bat} is the output current of battery. R_{bat} is the battery resistance. η_c is the coulomb efficiency of battery. C_{bat} is the max capacity of battery. The degradation of fuel cell is the key factor to be considered. In addition, the fuel cell degradation model is established, which mainly includes four parts: load changing cycles, start-stop cycling, idle and high-power load condition [5]. The fuel cell degradation model is as follows:

$$D_{fc} = \sum_{i=1}^{n} [d_{change}(i) + d_{on-off}(i) + d_{idl}(i) + d_{high}(i)] \tag{3}$$

where, D_{fc} is the total degradation of fuel cell. d_{change} is the fuel cell degradation caused by load change cycles. d_{on-off} is the fuel cell degradation caused by start/stop cycles. d_{idl} is the fuel cell degradation caused by idling/low power conditions. d_{high} is the fuel cell degradation caused by high power conditions.

The efficiency of fuel cell is related to the hydrogen consumption rate, the hydrogen consumption rate has a nonlinear proportional relationship with the output current of fuel cell. It is necessary to build the relationship among hydrogen consumption, output current and efficiency of fuel cell, as shown in Eq. (4) and (5).

$$m_{fc} = \left(N \cdot I_{fc} \cdot M_{\mathrm{H2}}\right) / 2F \tag{4}$$

$$\eta_{fc} = P_{fc} / (m_{fc} \cdot LHV_{\mathrm{H2}}) \tag{5}$$

where: m_{fc} is the instantaneous hydrogen consumption rate of the system. N is the number of single cells in the stack. I_{fc} is the output current of fuel cell. M_{H2} is the hydrogen molar mass. F is the Faraday constant. η_{fc} is the working efficiency of fuel cell. LHV_{H2} is the low calorific value of hydrogen.

ENERGY MANAGEMENT STRATEGY

TCS is mainly used in this paper, and five states are defined according to the SOC and the driving/braking state of the vehicle. Control rules and trigger conditions are shown in Fig. 1.

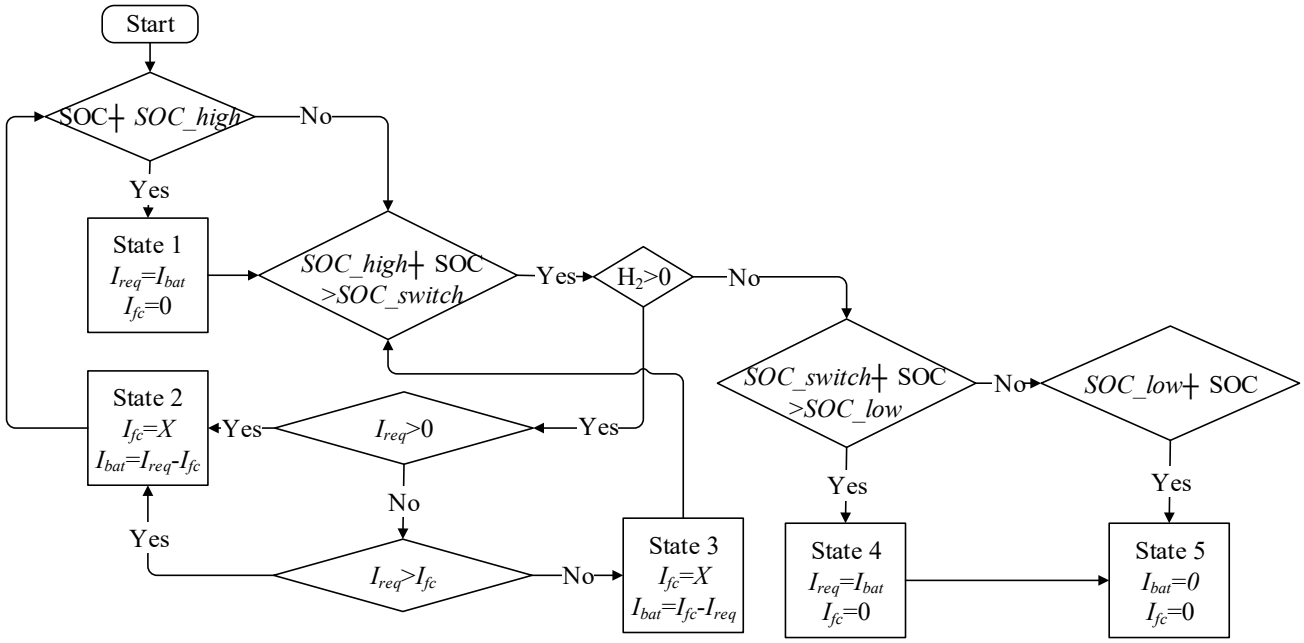

Fig. 1. TCS Process

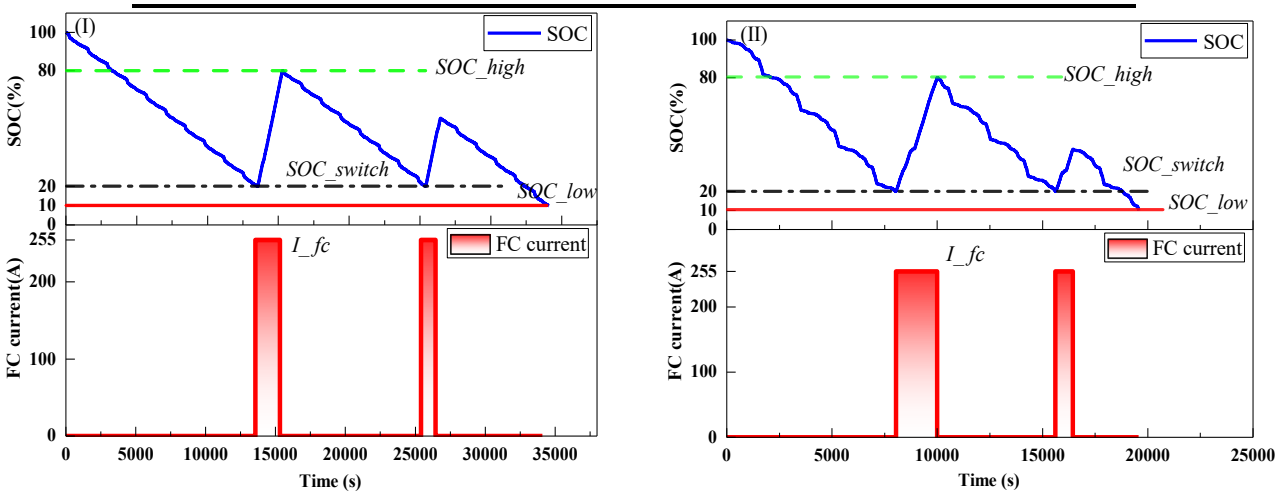
State 1: The battery SOC ≥ *SOC_high*, the battery meets the energy requirements of the vehicle alone, $I_{req} = I_{bat}$, $I_{fc} = 0$. State 2: When *SOC_high* ≥ SOC > *SOC_switch*, $H_2>0$ (hydrogen is not exhausted), and $I_{req} > 0$(braking mode). Or, *SOC_high* ≥ SOC > *SOC_switch*, $H_2>0$, and $0 \geq I_{req} > I_{fc}$ (driving mode), $I_{fc} = X$ (constant value), $I_{bat} = I_{req} - I_{fc}$. State 3: When *SOC_high* ≥ SOC > *SOC_switch*, $H_2>0$, and $I_{req} > 0$(braking mode), $I_{fc} = X$ (constant value), $I_{bat} = I_{fc} - I_{req}$. State 4: When *SOC_switch* ≥ SOC > *SOC_low*, $H_2=0$ (hydrogen is exhausted). $I_{req} = I_{bat}$, $I_{fc} = 0$. State 5: When *SOC_low* ≥ SOC, $H_2=0$ (hydrogen is exhausted). $I_{bat} = I_{fc} = 0$. *SOC_switch* and I_{fc} are the key parameters to be determined, the economy of vehicle and degradation of power sources are affected by these parameters seriously. The determination and optimization of parameters are shown below.

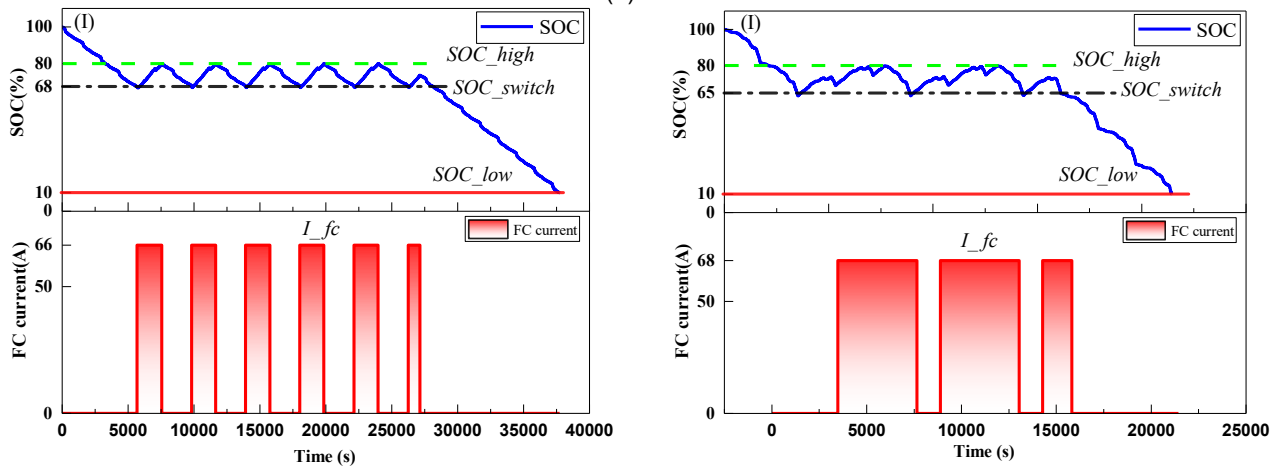
For TCS strategy, the start-stop frequency is the most important factor affecting the degradation of fuel cell. Based on TCS, this paper takes the number of start-stop cycling as a penalty factor in the evaluation function, and an optimized ABC-TCS (OABC-TCS) is proposed. The optimization parameters are *SOC_ switch* and *I_ fc*. The objective function of ABC algorithm is replaced by the actual running cost. In this way, the multi-objective optimization problem is transformed into a single objective optimization problem, and the optimization objective is the minimum value of the evaluation function. The evaluation function is as follows.

$$P = (con_{\mathrm{H2}} \cdot P_{\mathrm{H2}} + D_{fc} \cdot P_{fc} \cdot W_{fcmax} / 30\% + 90\% \cdot P_{ele} \cdot Q_{bat}) / mile \tag{6}$$



where, P is the equivalent cost per kilometer, W_{fcmax} is the maximum power of fuel cell. 30% represents the allowed degradation of fuel cell used in this paper. P_{fc} is the price of fuel cell.

RESULTS AND DISCUSSION



The strategy parameters and algorithm optimization results are shown in Table 1. $N_{on\text{-}off}$ is the start-stop times of fuel cell. Results shows that the start-stop times of original TCS is 4 times (2 start and 2 stop), but due to the large output current of fuel cell and the long time in the high resistance region of battery, the overall energy loss of the battery is large, the battery energy loss of FTP-72 and WLTC are 4632 kJ and 6523 kJ respectively. On the premise of reasonable start-stop times, OABC-TCS decreases the start-stop times to 12 times and 6 times under FTP-72 and WLTC. The energy loss caused by internal resistance of battery is decreased too, the battery energy loss of FTP-72 and WLTC is 2574 kJ and 4416 kJ. Fig. 2 shows the simulation results of FTP-72(Ⅰ) and WLTC(Ⅱ) drive cycle under TCS(a), OABC-TCS(b) respectively. The results include the SOC curve of battery and the output current curve of fuel cell.

Table 1 Strategy parameters

		SOC_ switch	*I_ fc* /(A)	$N_{on\text{-}off}$	Energy loss of battery /(kJ)
TCS	**FTP-72**	20%	254.6	4	4632
	WLTC	20%	254.6	4	6523
OABC-TCS	**FTP-72**	67.57%	66.4	12	2574
	WLTC	65.23%	68.2	6	4416

CONCLUSIONS

In this paper, Two EMS considering the economy of vehicle and the degradation of fuel cells are proposed. It can also satisfy the energy management requirements very well. Firstly, the power sources models are built, including degradation model of fuel cell. secondly, a new EMS is designed, which uses TCS to decompose the required power into output power of two power sources. Thirdly, in order to improve the economy of vehicle, the OABC-TCS is compared with TCS under FTP-72 and WLTC drive cycle. It is shown that the OABC-TCS can improve the durability of fuel cell with a slight increase in fuel consumption, and the service life of fuel cell can be effectively improved.

Compared with TCS, the driving range proportion of OABC-TCS in FTP-72 and WLTC conditions is increased by 10.59% and 10.3% respectively.

ABSTRACT

In the current study, a new hydrogen energy-based integrated powering system is designed and analysed for ferry applications. The system comprises photovoltaic (PV) solar cells and Darrieus type wind turbines mounted on the ferry's body to harness renewable energy and produce the required hydrogen on-board. A proton exchange membrane (PEM) electrolyzer, a PEM fuel cell, a thermal seawater desalination unit and a heat pump are some other major sub-components of the integrated system. The system offers green hydrogen, fresh water, heating, cooling and electricity as useful outputs. In the scope of the study, the system is evaluated energetically and exergetically. Impact of the primary design and operational parameters, e.g. solar irradiance and wind speed, on the system performance are investigated by conducting parametric studies. The system is capable of producing the required hydrogen on-board while operating with energy and exergy efficiencies of 26.75% and 18.20%, respectively.

***Keywords*:** Sustainability; Solar energy; Wind energy; Hydrogen; Hydrogen vehicles; Thermodynamic analysis.

INTRODUCTION

As the world moves towards green energy, hydrogen era is coming closer and faster than expected. Hydrogen allows to store, transport and distribute green energy effectively. It has a significantly higher energy density than batteries and even all other fossil fuels, which makes hydrogen a very attractive candidate to achieve an environmentally-benign transportation sector in all kinds. It should be highlighted that the technology to use hydrogen as fuel for transportation applications is already existing [1] [2]. Short charging times, low weights, zero harmful emissions on tailpipe, suitability for scale up projects and domestically production are some of many advantages that hydrogen promises to the global transportation sector and all others. CO_2 emission-dense conventional productions and the cost are the two main concerns with hydrogen in the current state. On the other hand, it is foreseen that the cost of hydrogen will decline dramatically decline from 16 US$ per kilogram at present to 6 US$ by 2025 [3]. It should also be noted that producing hydrogen from fossil fuels with carbon capturing and storing, so-called blue hydrogen, decreases the emission from production process of hydrogen by up to 95% [4]. Thus, low emission, cost-effective and a reliable hydrogen sector is even possible with existing hydrogen production and distribution infrastructures. However, development of hydrogen-based effective energy systems is crucial to diversify and enlarge the use of hydrogen.

In this study, a new hydrogen-based integrated power system is developed and analyzed for sea transportation. The system is configurated in a manner where the required hydrogen to generate power is produced by utilizing from renewable solar and wind energy on-board to achieve a green hydrogen-based nature friendly operation. The performance of the system evaluated from energy and exergy points of view by using thermodynamic approaches. The impact of primary design and operational parameters on the system's performance is investigated through parametric studies.

SYSTEM DESCRIPTION

Within the scope of the current study, a new hydrogen energy-based integrated power system is developed analyzed for ferry applications. The system comprises PV solar panels and wind turbines to harness renewable energy, a PEM electrolyzer to produce hydrogen, a PEM fuel cell to generate power, a single-stage thermal seawater desalination unit to produce fresh water, and a heat pump to provide space cooling. The thermal energy occurring during the operation of the PEM fuel cell is captured and utilized for seawater desalination and space heating. Table 1 summarizes the power need and design characteristics of the system. Figure 1 presents the developed hydrogen energy-based integrated power system.

Table 1: Integrated system characteristics.

Vessel length	30 m
Vessel Width	8 m
Engine power	60 kW
Heating load	4-6 kW
Cooling load	6-7 kW
Appliances (including lighting, tv and media units, fan, fridge and power supply)	4-6 kW

ANALYSIS

The main equations used in the energy and exergy efficieny analyses of the proposed system are summarized as follows:

$$\dot{W}_{Net} = \dot{W}_{FC} - \dot{W}_{Comp_{HP}} - \dot{W}_{Booster} - \dot{W}_{pumps} \quad (1)$$

$$\dot{W}_{Wind} = \frac{1}{2} \times \rho_{air} \times A_{WT} \times V_{Wind}^3 \quad (2)$$

$$\dot{Q}_{Solar} = I_{solar} \times A_{PV} \quad (3)$$

$$\eta_{overall} = \frac{(\dot{W}_{Net} + \dot{Q}_{Heating} + \dot{Q}_{Cooling} + \dot{Q}_{Dis})}{\dot{Q}_{Solar} + \dot{W}_{Wind}} \quad (4)$$

$$\psi_{overall} = \frac{(\dot{W}_{Net} + \dot{E}x_{Heating} + \dot{E}x_{Cooling} + \dot{E}x_{Dis})}{\dot{E}x_{\dot{Q}_{solar}} + \dot{W}_{Wind}} \quad (5)$$

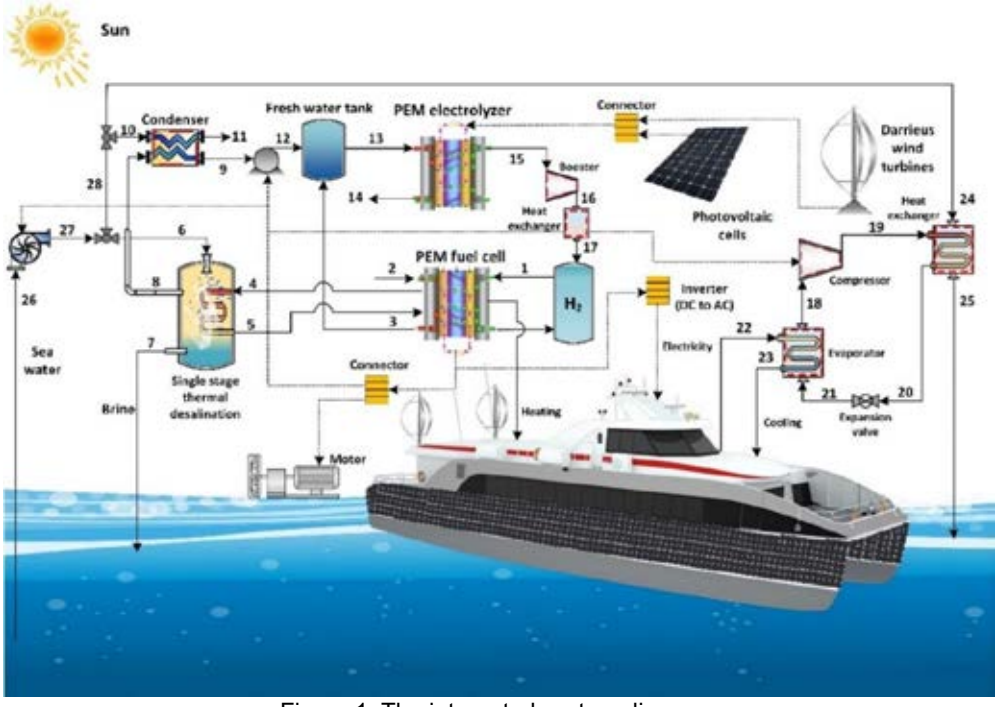

Figure 1. The integrated system diagram.

RESULTS AND DISCUSSION

The required hydrogen mass flow rate for the PEM fuel cell to power the system is evaluated as 1.085 g/s. For an on-board hydrogen production, the system requires 260 m^2 of PV cells and two Darrieus wind turbines with 20 m height and 3 m width. The energy harnessed from wind and solar is used to generate hydrogen via PEM electrolysis unit. The freshwater required for the electrolysis process is produced from seawater by a single-stage desalination unit. The required thermal energy for the desalination unit is evaluated as 28 kW, which is provided by the heat occurring during the operation of the 71-kW fuel cell stack with 98 cells. The fuel cell stack is also capable of providing the required heating load of 4 kW. The required cooling load (7.8 kW) is generated by employing a heat pump using the sea as heat sink. With the power consumption of 1.615 kW in its compressor, the coefficient performance of the heat pump is evaluated as 5.87. The performance of the proposed system evaluated energetically and exergetically through thermodynamic approaches. According to this the system's energy and exergy efficiencies are calculated as

26.75% and 18.20%, respectively. The system performance is further evaluated with parametric studies conducted on the primary design and operational parameters. Figure 2 presents the results of the parametric study investigating the impact of wind speed on the hydrogen production and overall system efficiency. As it can be seen from the figure, the increase in wind speed impacts the performance of the system in a positive manner. Figure 2 shows the results of another parametric study where the impact of solar irradiance on the system's energy and exergy efficiencies is evaluated. It can be seen that, increase in the solar energy input overwhelms the useful outputs from the system; thus, both energy and exergy efficiencies slightly decrease with increasing solar irradiance.

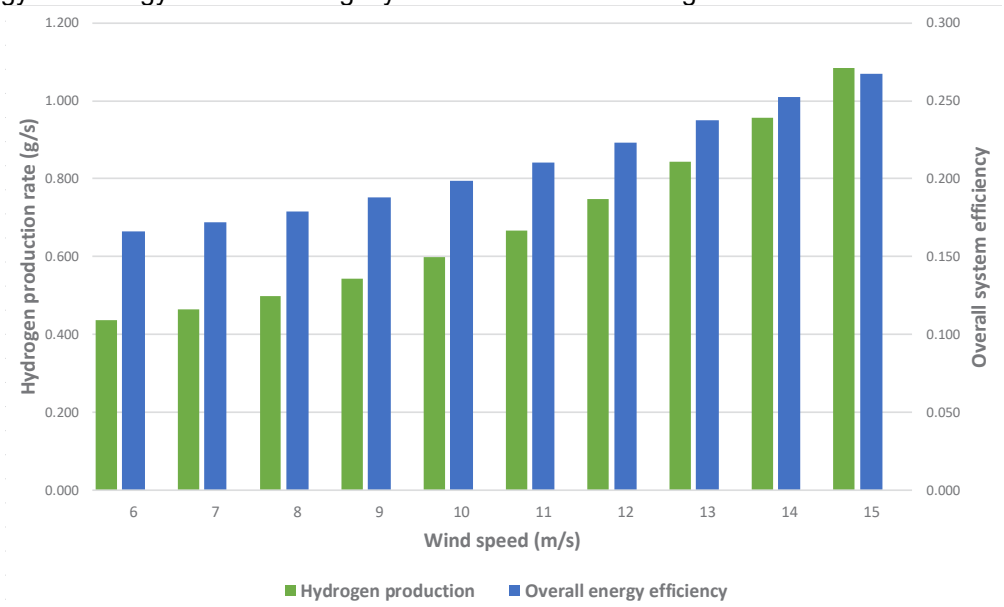

Figure 2. Impact of wind speed on the integrated system performance.

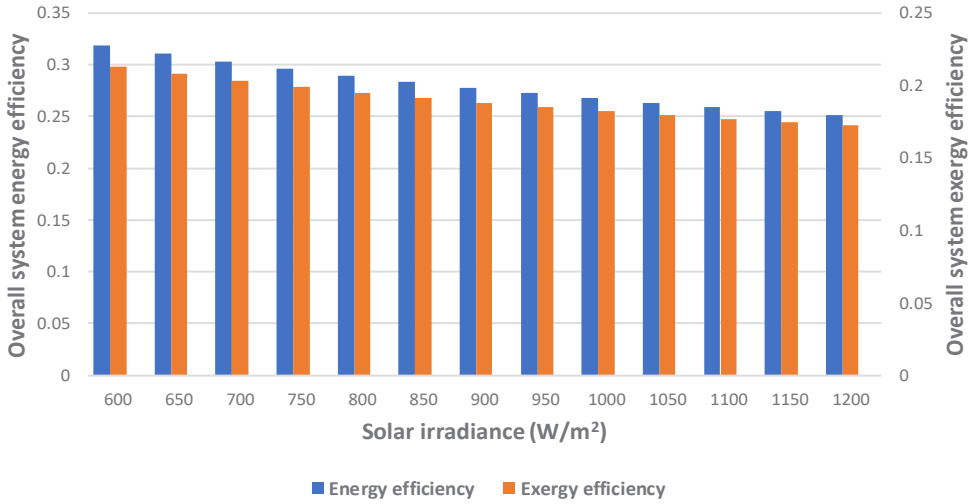

Figure 3. Impact of solar irradiance on the system performance.

CONCLUSIONS

In the current study, a new wind and solar driven integrated power system is investigated for self-sufficient ferry applications. The harnessed renewable energy is used to generate hydrogen on-board to fuel the ship. Electricity, heating, cooling, freshwater and green hydrogen are the useful outputs that the system provides. The system performance is evaluated through energy and exergy approaches as well as various parametric studies. According to the results, the system operates with an energy efficiency of 26.75% and exergy efficiency of 18.20%. The conducted parametric studies show that eventhough the hydrogen production rate increases increase in the solar irradiance, the overall system energy and exergy efficiencies decrease since the input energy becomes much greater than the useful output.

THE ULTRA-EFFICIENT FC-ICE HYBRID CYCLE WITH THERMOCHEMICAL RECOVERY OF THE WASTE HEAT - FINITE-TIME AND FINITE-SPEED THERMODYNAMICS ANALYSIS

[1] *David Diskin,* [2]* *Leonid Tartakovsky*
[1,2]Technion – Israel Institute of Technology, Mechanical Engineering, Technion City, Haifa, Israel

*Corresponding author e-mail: tartak@technion.ac.il

ABSTRACT

Efficiency and power of the hybrid cycle combining fuel cell (FC) and internal combustion engine (ICE) was analyzed using finite-time and finite-speed thermodynamics (FTT and FST). The study shows that at high efficiencies beyond 70% the hybrid cycle has the potential of a significant power gain (up to 35%) over FC or ICE operation alone. Power-efficiency maps of the hybrid cycle are obtained for various conditions and properties of the selected FC and ICE. Thermochemical recuperation (TCR) was suggested for heat recovery from the FC & ICE, and onboard hydrogen production. TCR is found to be the favorite choice for waste heat recovery in the hybrid cycle. Vehicle weight, size and the travel range are functions of the specific power and the efficiency of the propulsion system. Hence, the results of the reported study are of high importance for transportation.

Keywords: Electrochemical reaction, Combustion, Finite-time thermodynamics, Finite-speed thermodynamics, Fuel cell

INTRODUCTION

Fuel cells (FCs) produce electrical work by electrochemical reaction between fuel and oxygen. FC operation produces heat, as irreversible processes occur in the electrochemical reaction. Hybrid cycles that consist of FC and heat engine aim at using the waste heat to produce additional work, and by that to increase efficiency. Hybrid cycles with this configuration have been studied since 1990s [1]. Lately, internal combustion engines (ICEs) gained attention as the bottoming heat cycle, enabling the re-use of the FC anode off-gas on the one hand, and on the other hand enabling parallel work extraction by independent combustion cycle. Chuahy and Kokjohn [2] performed detailed analysis of a hybrid powertrain with a solid-oxide fuel cell (SOFC) and ICE and reported a 70% thermal efficiency of the system. Both SOFC and ICE can use the same fuel, and fuel reforming using thermochemical recuperation (TCR) can be employed as the waste heat recovery method from both FC and ICE.

Efficiency has a mutual relationship with power output due to their both dependency on the cycle driving forces. Therefore, power-efficiency analysis is of high importance and it is in the focus of this work. The analysis of heat engines that undergo irreversible interactions with its reservoirs was performed for the first time by Novikov in 1957 [3] and later by Curzon-Ahlborn in 1975 [4]. They were able to express the efficiency at maximum power of a heat engine. Petrescu et al. [5] developed a method called Finite-Speed Thermodynamics (FST) to evaluate the internal irreversible processes of the cycle. Sayyaadi et al. [6] applied the FST approach to ICEs. In [7,8], we have developed analytical expressions for efficiency at maximum power of the hybrid FC-ICE cycle. In the current study, we perform a detailed analysis of the hybrid cycle, using FTT and FST models for FC and ICE. An effect of TCR integration for waste heat recovery is analyzed also, and power-efficiency relationship of the cycle at various conditions and for various configurations is discussed.

MODEL

The hybrid system is composed of a FC, an ICE and a fuel reformer as shown in Fig 1. The system is fed with air and fuel. FC produces electrical work by an electrochemical reaction and the ICE produces mechanical work by gas expansion. FC waste heat is recovered by expansion of the hot FC exhaust gases in the ICE, and/or by thermochemical recuperation (TCR) in the reformer. Solid-oxide fuel cell (SOFC) was chosen due to its high working temperatures, and its power-efficiency characteristics were analyzed by a zero-dimensional model, with the following assumptions: 1. Uniform temperature across the whole fuel cell at steady state 2. Zero-dimensional channel representation 3. No bypass side reactions occur, and no crossover reactions occur 4. Negligible cells connection effects.

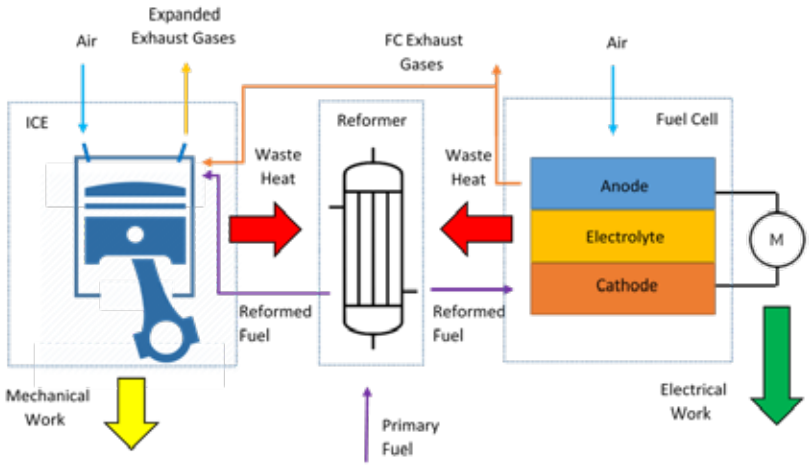

Figure 1. Hybrid ICE-FC scheme with TCR.

ICE model is built using the FST and FTT principles, which enable evaluation of the power-efficiency relation of a piston engine. ICE efficiency depends on the cycle duration and cylinder dimensions through several parameters. Piston speed has effect on pressure losses due to pressure gradient in the cylinder, throttling losses, and friction losses. The temperature after combustion is a function of the waste heat expelled from the FC (Eqs. 1,2).

Without TCR:

$$T_{cycle,\max} = T_{comp} + \frac{c_{v,23}\dot{m}_{ICE,parralel}\cdot(T_{\max} - T_{comp}) + c_{v_{FC,exhaust}}\dot{m}_{FC,series}\cdot(T_{FC} - T_{comp})}{c_{v,23}\dot{m}_{ICE,parralel} + c_{v_{FC,exhaust}}\dot{m}_{FC,series}} \quad (1)$$

With TCR:

$$T_{cycle,\max} = T_{comp} + \frac{c_{v,23}\dot{m}_{ICE,reformate,mix}\cdot(T_{\max,reformate} - T_{comp}) + c_{v_{FC,exhaust}}\dot{m}_{FC,series}\cdot(T_{FC} - T_{comp})}{c_{v,23}\dot{m}_{ICE,reformate,mix} + c_{v_{FC,exhaust}}\dot{m}_{FC,series}} \quad (2)$$

where T_{comp}, $T_{\max}$ and T_{FC} are the temperatures after compression, after combustion and FC working temperature respectively. $\dot{m}$ and c_v are the corresponding mass flow rates and heat capacities. $T_{\max,reformate}$ is the combustion temperature of the reformed fuel.

RESULTS AND DISCUSSION

Fig. 2 shows a power-efficiency map (Left) and power-efficiency curves (Right) of the hybrid cycle. The ICE-FC maximal power-to-weight ratio was set to 2, the compression ratio of the ICE is 15 and the working temperature of the FC is 850^{O}C. Methanol was selected as the primary fuel due to the compatibility for SOFC and ICE and its low-temperature reforming process. Two reforming methods were examined: Methanol Decomposition (MD) and Methanol Steam Reforming (MSR). It can be seen that the Hybrid cycle has a clear power-to-weight ratio advantage over the FC operation for a range of efficiencies, however, ICE operation alone is superior in terms of specific power. Without TCR, FC is superior for high efficiencies over 60%. Waste heat recovery through TCR is beneficial and provides the widest range of power gain in the efficiency axis, and efficiency over 70% can be achieved with a significant power gain (approx. 20%) compared to FC. The benefit of TCR waste heat recovery is because it is restricted only by the amount of waste heat and is not limited by the energy conversion efficiency of isentropic expansion.

An additional analysis of power-efficiency relation was performed in the study for different compression ratios, FC working temperatures and for different power-to-weight ratios of FC and ICE. The latter factor was discovered as a key parameter affecting the hybrid cycle performance.

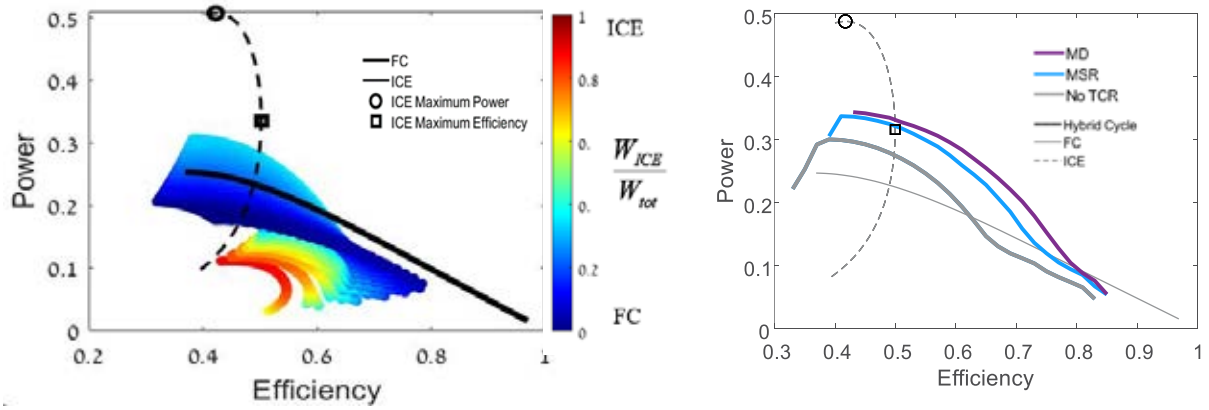

Figure 2. Power-efficiency relation of the hybrid ICE-FC cycle compared to the power and efficiency of the SOFC and ICE alone. Left: power-efficiency map without TCR, Right: power-efficiency curves with TCR.

CONCLUSIONS

Hybrid FC-ICE cycle performance was examined. Power-efficiency relation was analyzed for different FC and ICE properties and cycle configurations. It was found that the hybrid cycle is inferior in terms of maximum power compared to the ICE operation alone for almost all conditions - as our prior works suggest. However, for higher efficiency levels that cannot be achieved with ICE operating alone, the hybrid cycle performance is superior, and there is a range of efficiencies where a power gain is obtained compared to the FC. TCR was suggested for waste heat recovery from both the FC and the ICE, and power-efficiency relationship of a hybrid cycle with TCR was obtained and analyzed. The analysis shows that TCR is the beneficial method of waste heat recovery from the FC and ICE, and power gain is obtained for a wider range of efficiencies. Notably, the efficiency levels above 70% can be reached in the hybrid cycle with a significant power gain.

THE ROLE OF HYDROGEN FOR THE DEFOSSILISATION OF THE GERMAN CHEMICAL INDUSTRY

[1*] *Felix Kullmann,* [1] *Peter Markewitz,* [1] *Leander Kotzur,* [1,2] *Detlef Stolten*
[1] Institute of Techno-Economic Systems Analysis (IEK-3), Forschungszentrum Jülich GmbH, Wilhelm-Johnen-Str., 52428 Jülich, Germany

ABSTRACT

Within the European Green Deal, the European industry is summoned to transform towards a green and circular economy in order to reduce CO_2-emisisons and reach climate goals. Special focus is on the chemical industry to boost recycling processes for plastics, exploit resource efficiency potentials, and switch to a completely renewable feedstock (defossilisation). Despite common understanding that drastic changes have to take place it is yet unknown how the industrial transformation should be accomplished. How does a cost-optimal defossilisation of the chemical industry in the context of national greenhouse gas (GHG) mitigation strategies look like? The central part of this investigation is based on a national energy system model to optimize the future energy system design of Germany. A replacement of fossil-based feedstocks by renewable feedstocks leads to a significant increase in hydrogen demand by +40% compared to a reference scenario. Without the import of hydrogen-based energy carriers, the entire hydrogen demand, including the demand for renewable raw materials, must be produced domestically. This leads to cumulative additional costs of the transformation that are 72% higher than those of the reference scenario. Fischer-Tropsch synthesis and the methanol-to-olefins route can be identified as key technologies for the defossilisation of the chemical industry.

Keywords: Energy systems analysis, Defossilisation, Industrial transformation, Chemical industry, Climate targets

INTRODUCTION

The central concept of this work deals with non-energetic demand. This demand describes energy carriers that are not used as fuels or for conversion into other energy carriers, but as raw material inputs in processes [1]. The largest share of German non-energetic consumption is accounted for by mineral oil derivatives and natural gas which are used in basic chemicals, e.g., to produce methanol, ammonia, or plastics. Initially, no direct emissions are emitted through non-energetic demand. However, energy-related emissions can arise from the use of electricity or fuel for the manufacturing processes, as well as process-related emissions from the conversion of the non-energetic sources into end products. Worldwide, non-energetic consumption is responsible for about 15% of industrial CO_2-emissions [2]; the exact share of German CO_2-emissions is not recorded statistically. Since 1990, non-energetic consumption has remained constant at between 250 and 310 TWh [3]. Even though a slight drop in demand has been observed in the last three years, the chemical industry expects demand to increase in the future [4]. In recent national energy scenarios for Germany (e.g. [5-7]), showing possible transformation paths towards a low-carbon energy system in 2050, defossilisation is not at all or insufficiently considered. An assessment of the extent to which defossilisation measures are part of cost-optimal and efficient greenhouse gas reduction strategies and what effects their absence implies for the German energy system as a whole has not yet been made [8].

MODELLING

The *National Energy System model with SecTor coupling* (NESTOR) covers all system-relevant technologies of the German energy system, which are described by nodes and edges and set up a large interacting network [9]. The nodes describe all energy and material sources, conversion technologies, energy and material storage, and energy and material sinks, whereas the edges describe energy and material flows between the nodes. The energy system model analyses the future energy system design of Germany. Under greenhouse gas reduction restrictions, the model derives the energy system design and the transformation pathway based on cost-optimality. The cost comparison of the transformation is carried out on the basis of a reference scenario. This ensures that, among other things, autonomous developments of the energy system can also be taken into account. The model maps the German industrial final energy demand on a detailed process level. This allows processes for defossilisation of the chemical industry to be analysed and evaluated based on cost-efficiency and effectiveness.

A reference scenario is created (*REF95*), in which CO_2 emissions are reduced by 95% by 2050 compared to 1990 levels. Apart from the phase-out of coal and nuclear power generation, no other limitation is placed on the model. Recycling rates are fixed at today's levels in the individual industrial sectors until 2050. Novel recycling processes (e.g., chemical recycling of plastic waste) are only available from 2040. Otherwise, no further restrictions are

applied. Another scenario is calculated to analyze the effects of a switch in the chemical industry from a fossil-based to a fully renewable use of raw materials (*GreenCheem*).

RESULTS AND DISCUSSION

Fig. 1 shows the development of primary energy consumption of the *GreenChem* scenario and the change compared to the reference scenario *REF95.* In 2050, no major absolute change in primary energy consumption can be seen; additional 80 TWh primary energy are required in the *GreenChem* scenario, and it can be observed that non-energetic crude oil and natural gas are completely substituted by hydrogen.

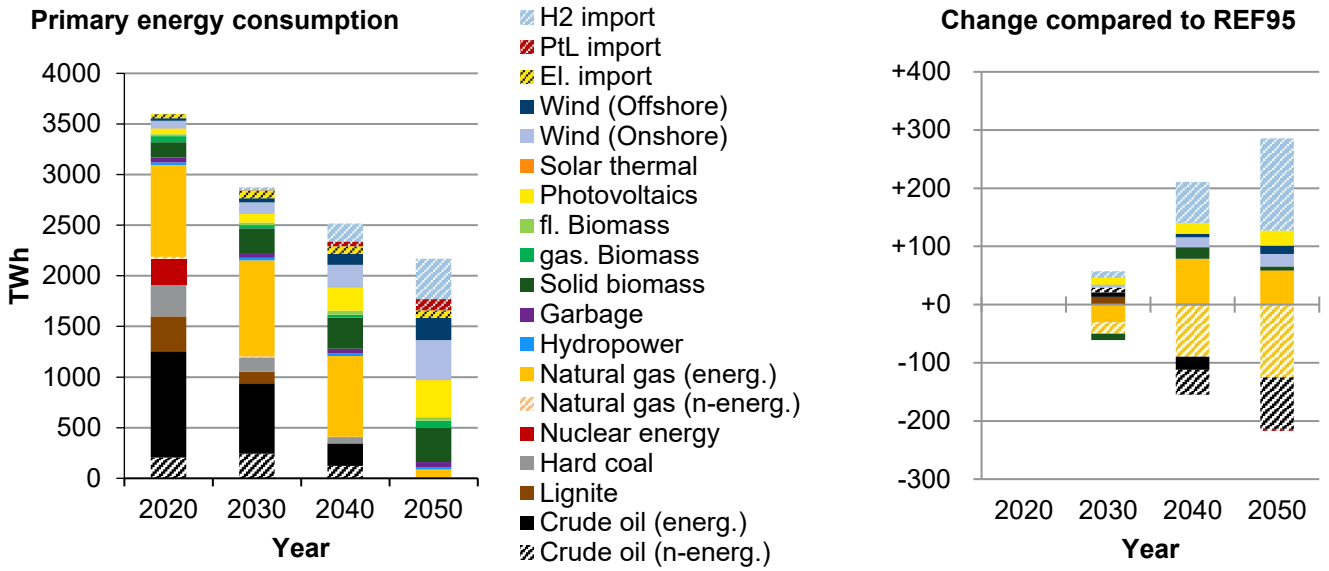

Fig. 1 Development of the primary energy demand of the *GreenChem* scenario until 2050 (left) and the change compared to reference scenario *REF95* in TWh (right)

In 2050, about 160 TWh hydrogen is needed more compared to the reference scenario, substituting 91 TWh crude oil and 125 TWh natural gas, resulting in a total demand of 560 TWh hydrogen for the whole energy system. In addition, there is a small additional consumption of natural gas used for electricity generation (59 TWh). This can be explained by the released CO_2 budget in the chemical industry. By forcing the chemical processes to switch to renewable raw materials, fewer CO_2-emissions are generated in this sector, which can be emitted more in other sectors, e.g., power generation, and still meet the overall GHG-reduction target.

A deeper dive in the model results of the chemical industry reveals that of the 16.5 Mt of plastics produced in 2050, 50% will be supplied via the methanol-to-olefins route and the other half via the use of green naphtha in steam crackers. This feedstock switch also implies a change in naphtha production. In 2050, about 10 Mt of naphtha will be produced. Of this, more than 3 Mt (30%) is based on pyrolysis oil from chemical recycling and about 7 Mt from Fischer-Tropsch synthesis. Compared to *REF95,* the introduction of Fischer-Tropsch synthesis in this way replaces the entire crude oil input for naphtha production in 2050. For the energy demand for naphtha production, this results in an additional demand of 94 TWh hydrogen in 2050 compared to *REF95* (Fig. 2). Together with methanol production (+89 TWh), these two areas are mainly responsible for the increase in hydrogen demand in the industrial sector. The chemical industry uses more than 250 TWh hydrogen in 2050.

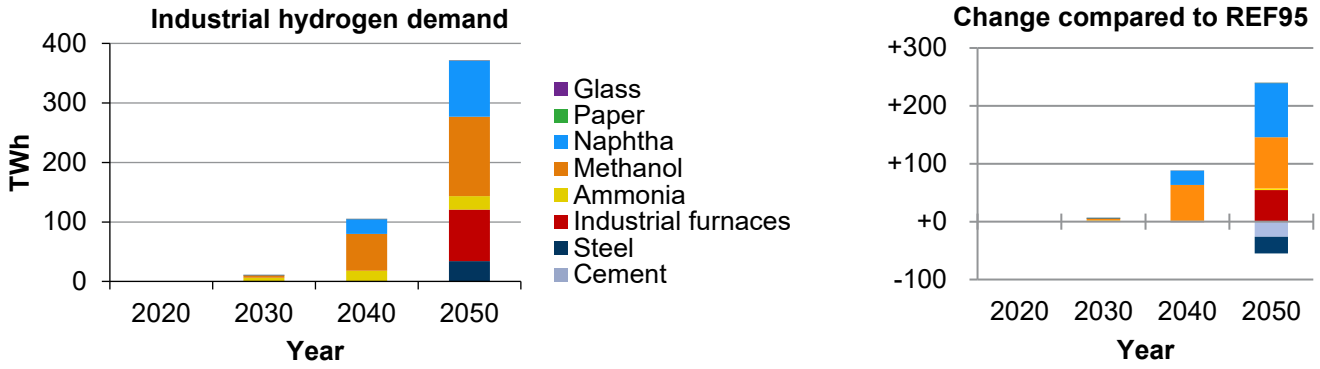

Fig. 2 Industrial hydrogen demand of the *GreenChem* scenario (left) and the change compared to scenario *REF95* (right).

CONCLUSIONS

Through the implementation of new and innovative industrial processes, it is now possible to evaluate the effects of defossilisation on the German energy system design. This also includes the analysis of suitable defossilisation strategies. The following results can be stressed:

- Defossilisation is an additional stringent constraint in addition to GHG mitigation itself.
- There is a significant impact on the overall energy system.
- The majority of non-energetic demand is replaced by hydrogen and its derivatives (green hydrogen is essential).
- Chemical recycling and the methanol-to-olefins route can be identified as critical technologies.
- Methanol production in 2050 will require additional 89 TWh hydrogen compared to a reference scenario, in which only GHG emissions are reduced. 19 Mt methanol is used for the production of highly refined chemicals.
- The industrial hydrogen demand is more than 185 TWh above that of the reference scenario. Overall, the hydrogen demand of the total energy system increases by 160 TWh.

A 95% reduction in CO_2 emissions in 2050 with additional defossilisation of the chemical industry leads to increased additional costs. In contrast to the reference case, the cumulative costs of the transformation increase by an additional 32%, or €212 billion. This additional cost is mainly due to the increased hydrogen import. In the course of a holistic consideration of the transformation of the energy system, the defossilisation of the chemical industry should be taken into account. In particular, the future supply of hydrogen is decisive for the associated additional costs.

ABSTRACT

This study proposes a draft system design for a solar photovoltaic (PV)-based energy community as an example of "Tsukuba Green Holonism Town" in Japan, as described in the previous report, "Building A Carbon-Neutral Community," and examines a preliminary energy demand-supply outlook in 2030. The energy outlook includes an allocation plan of zero-emission energy sources in the Ibaraki Prefecture and a set of residential electricity and heat demands estimated in winter, summer, and the other seasons. Japan decided to increase renewable energy sources (RES) from 18% in 2019 to 36%-38% energy mix in 2030, thus we are urged to deploy a considerable amount of RES in each region. The preliminary outlook identifies a particular problem in the PV-based energy community in Japan. Furthermore, an example of solving this problem is also suggested.

Keywords: Energy community, Renewable energy resource, Solar photovoltaic, Power-to-hydrogen and fuel cell

INTRODUCTION

Japan fixed the sixth strategic energy plan on October 22, 2021, and decided to increase renewable energy sources (RES) from 18% in 2019 to 36%-38% energy mix in 2030 [1], therefore we are urged to install a considerable amount of RES in each region. Since 2013, the Tsukuba 3E Forum's workgroup has been discussing a low-carbon community in Tsukuba City [2] and developing a concept called "Tsukuba Green Holonism Town," which aims to implement a carbon-neutral community in harmony with its residents and workers by 2030 [3]. This study proposes a draft system design of an example of Tsukuba Green Holonism Town in Japan, which is a solar photovoltaic (PV)-based energy community, and examines the community's preliminary energy outlook for 2030. The preliminary outlook identifies a specific problem that PV dominant systems in Japan have, and a rational solution to this problem.

PV–BASED ENERGY COMMUNITY

This is an example of Tsukuba Green Holonism Town. A draft system design of this community, an allocation plan of zero-emission energy sources near and in the community, and a preliminary energy supply and demand outlook in 2030, including discussion are described below.

A Draft System Design

Fig. 1 shows a draft system design for a PV-based energy community. The energy community is expected to be equipped in an existing city area, in Tsukuba City, Ibaraki Prefecture, with about a hundred households. It consists of community facilities that are powered by PV plants and a nuclear power plant, common facilities which are installed in public buildings near the community, vehicle-to-microgrid integration (VmGI) facilities that are charging and discharging stations for electric vehicles (EV) and fuel cell vehicles (FCV), household demand-installed fuel cells (FC) and PVs, and household demand with only appliances.

An Allocation Plan of Energy Sources

Excluding hydroelectric generation, PV accounts for over 90% of RES capacity as of 2019 in Japan, and will account for over 50% in 2030. In 2030, the Ibaraki Prefecture will have two types of zero-emission energy sources: utility PV plants with a generation capacity of 399 kW for the energy community and a generated energy of 1192 kWh per day which is simulated based on solar insolation in the Tsukuba City for a year, and a nuclear power plant, Tokai No.2 Power Station with a capacity of 46 kW and generated electricity of 628 kWh per day based on its capacity factor 56.9%.

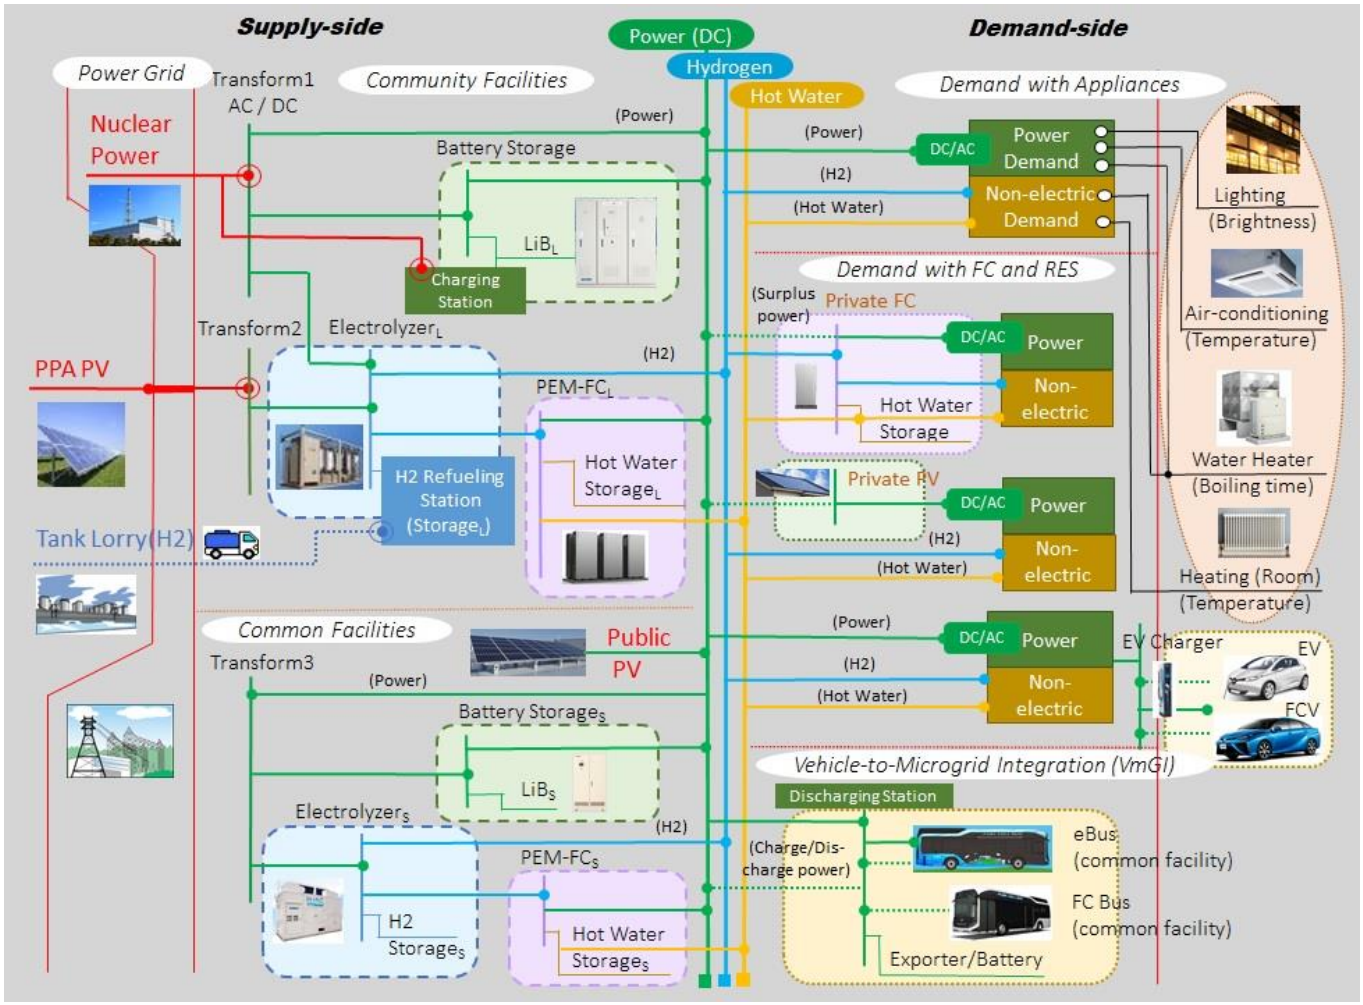

Fig. 1. System design for a PV–based energy community as an example of Tsukuba Green Holonism Town (draft)

A Preliminary Energy Outlook

According to reference [4], a set of residential electricity and heat demands in the Ibaraki Prefecture is designed in winter, summer, and other seasons. The residential demand is consistent with the electricity demand in 2010 in the Tokyo area, therefore it is necessary to consider the effects of energy efficiency and conservation (EE) in 2030. In comparison to the final energy consumption in 2013, Japan forecasts two types of EE in 2030: 10.2% and 22.9% of EE in the fifth and sixth strategic energy plans respectively [1]. In 2030, two types of EE in 2030 will lead the efficient demand, saving 10.2% and 22.9% of energy, respectively. The allocation plan and two types of energy demand, including energy-saving, indicate a preliminary energy outlook in 2030 in the PV-based energy community. Fig. 2 shows the preliminary energy outlook, which includes a preliminary energy supply from PV plants and nuclear power plants, and two types of energy demand with 10.2% and 22.9% of EE, and solar insolation in Tsukuba City in the terms of every three months. Notably, this energy outlook excludes conversion losses of AC-DC converters, power-to-hydrogen, and hydrogen-to-power, storage loss of batteries and hot water tanks, transmission loss of energy networks, and auxiliary power of the community facilities.

Discussion

Based on the allocation plan, PV accounts for over two-thirds of the energy supply, therefore solar insolation affects the amount of electric power supply in the energy community. Fig. 2 shows that energy supply varies by plus or minus 20% seasonally compared to the annual average, energy demand with 22.9% of EE varies from -15% in spring and autumn to +40% in winter compared to the annual average, and a demand-supply rate is calculated as 1.45 in winter, 0.59 in spring, 0.69 in summer, and 0.86 in the autumn.

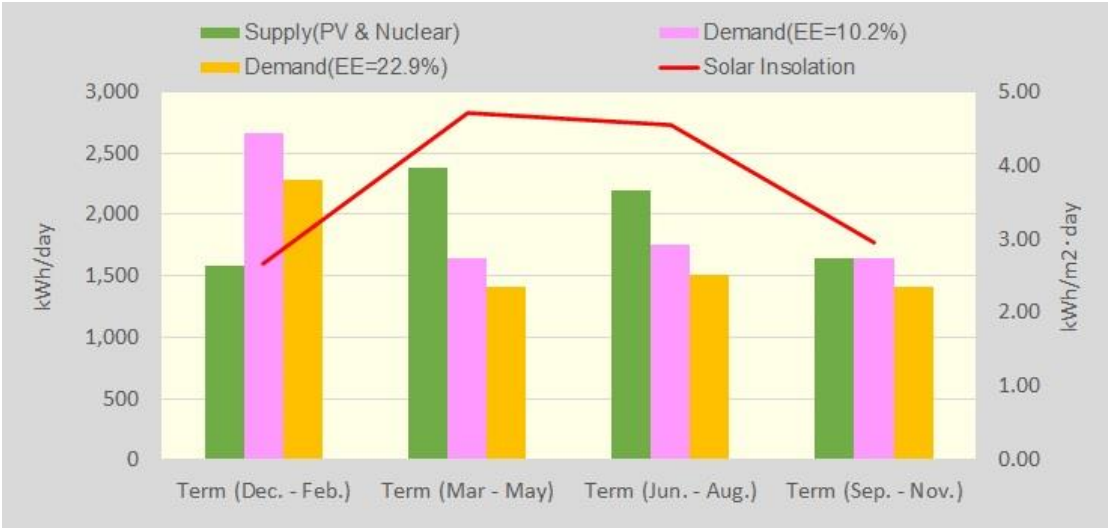

Fig. 2. Energy outlook of the PV–based energy community from December to November (preliminary)

The seasonal energy gap between supply and demand in winter is remarkably different from the other seasons in the PV-based energy community in Japan. These results show that the draft system combined with a demand response (DR) can balance energy in the spring, summer, and autumn if capacities of the facilities are fixed properly, but an additional system and backup mechanism is essential for the winter. An example of solving the winter energy gap is suggested, such as FCVs dispatching power at charging stations to the electric network as the VmGI facilities and an adaptive hydrogen distribution for hydrogen refueling stations (HRS), and FC cogeneration plants supplied by HRSs as the community facilities in the winter.

CONCLUSIONS

This paper proposed a draft system design of a PV-based energy community as an example of Tsukuba Green Holonism Town, and examined a community's preliminary energy demand-supply outlook for 2030. The outlook suggests that a hybrid hydrogen-battery storage and energy network mechanism combined with DR is expected to apply to the energy community effectively in the spring, summer, and autumn. As a gateway to solve the seasonal energy gap in Japan, an additional system such as FCVs for power dispatching to the community and FCs supplied by HRSs, and a backup mechanism, such as flexible hydrogen distribution for HRSs, are necessary for the winter.

ABSTRACT

This study illustrates a concept of “Tsukuba Green Holonism Town” in Japan, comprising three basic policies: achieving carbon neutrality in the community, balancing the energy demand and supply, and changing the lifestyle, work style, and mobility style of residents and workers. Furthermore, this community is constituted of five functional categories: community facilities with nearby renewable energy sources (RES), energy dispatching station and energy networks, common facilities equipped with fuel cells (FC), vehicle-to-microgrid integration facilities, household demand installed RES or FC, household demand with both controllable and uncontrollable appliances. Japan and other OECD countries are taking on the considerable challenge of reducing greenhouse gas emissions to zero by 2050, thus we must push for more robust green policies and decarbonization breakthroughs immediately. The workgroup of Tsukuba 3E Forum has been developing the concept of Tsukuba Green Holonism Town, which implements a carbon-neutral community using demand response methods in harmony with residents, workers, household FCs, and electric vehicles. An example of cooperative scenarios among the functional categories for a rainy week is also described.

Keywords: Carbon-neutral community, Balancing the energy demand and supply, Hydrogen and demand response

INTRODUCTION

Japan decided on October 26, 2020, to achieve a decarbonized society by 2050, and to reduce its greenhouse gas (GHG) emissions by 46% in 2030 compared to 2013 levels [1], therefore we should push for more robust green policies and lower-carbon breakthroughs. The Tsukuba 3E Forum’s workgroup has been discussing a low-carbon community in Tsukuba city [2] and is developing a concept of “Tsukuba Green Holonism Town,” which aims to implement a carbon-neutral community in harmony with its residents and workers by 2030 [3]. This study illustrates the community concept, which consists of three basic policies and five functional categories. An example of cooperative scenarios among the functional categories for a rainy period is also described.

TSUKUBA GREEN HOLONISM TOWN

This is a community concept based on three basic policies with five functional categories according to the capacity of available renewable energy sources (RES), household quantity, population, and energy demand in the community. The basic policies, functional categories, and an example of cooperative scenarios are described below. Fig. 1 shows a concept image of Tsukuba Green Holonism Town.

Basic Policies

The concept comprises three basic policies: environmental, energy demand and supply, and energy consumption behavior policies as follows.

- Achieving carbon neutrality in the community.

As shown in Fig. 1, the community attains and maintains net-zero carbon dioxide (CO_2) using RES, nuclear power, energy conversion, and CO_2 recycling technologies, such as solar photovoltaic (PV), power-to-hydrogen, hydrogen storage and transport, and fuel cells (FC).

- Balancing the energy demand and supply in the community.

The community supplies clean and variable energy depending on the weather through PV power plants located in and near the community. According to the demand response (DR), the energy demand meets the community supply.

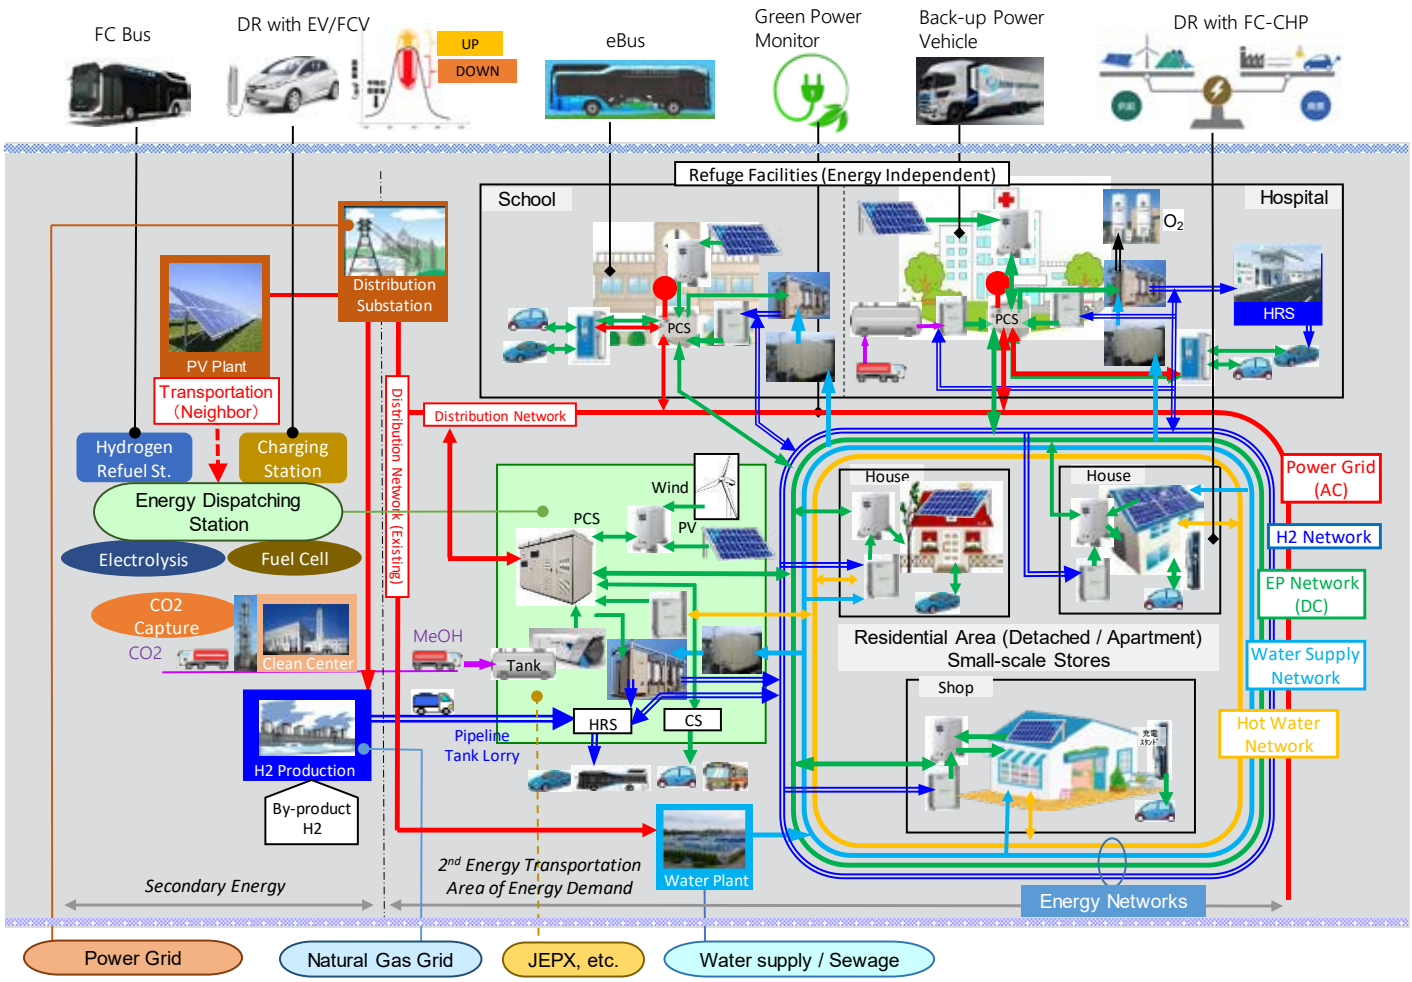

Fig. 1. A Concept Image of Tsukuba Green Holonism Town

The DR applications are, for example, water electrolysis and FC, and electric vehicle (EV) charge and discharge in Fig. 1.

- Changing lifestyle, work style, and mobility style of the community residents and workers.

The residents and workers in the community change their lifestyles, work styles, and their mobility styles in accordance with the energy production forecast, such as daylight savings time and remote work.

Functional Categories

The basic policy, carbon neutrality by 2030, means that zero-emission energy sources (e.g., PV, nuclear power) near the community should be introduced into the grid, and the generation capacity for the community should be shared rationally. The policy, balancing the energy demand and supply, means that the supply is estimated based on the weather in a given period, and the demand should meet the energy supplied to the community through water electrolysis, hydrogen storage, and network transport, FC regeneration, and vehicle-to-microgrid integration (VmGI). The changing lifestyle, work style, and mobility style means that the demand curve ought to be reshaped and fit to the energy supply by increasing the power generation of household FCs, discharging power from household EVs, and reducing the energy consumption of household appliances automatically or manually. Community facilities, common facilities, VmGI facilities, household demand with FC or RES, and household demand with appliances are the five functional categories that constitute the community. Table 1 shows the Tsukuba Green Holonism Town's functional categories and system configuration.

Table 1. Functional Categories and System Configuration in Tsukuba Green Holonism Town

Functional categories	System Configuration	
	Supply side	Conversion and Demand side
Community Facilities	Neighboring RES (PPA*2)	Energy Dispatching Station, including Electrolyzer, Fuel Cell, and Storage Tank Hydrogen Refueling Station and FCV, Charging or Discharging Station and EV
	Neighboring Nuclear Power (PPA*2)	
	Energy Networks (Power, Hydrogen, and Hot water)	
Common Facilities	RES deployed in the community	Conversion and Storage Equipment deployed in the community
VmGI*1 Facilities	Charging or Discharging Station, EV, FCV	Energy Network (Power)
Household Demand with FC or RES	Household FC and RES	Household FC and EV. Appliances (Controllable / Uncontrollable)
Household Demand with Appliances		Appliances (Controllable / Uncontrollable)

(*1) VmGI: Vehicle-to-Microgrid Integration (*2) PPA: Power Purchase Agreement

An Example of Cooperated Scenarios

Assuming that the neighboring RES power supply of the community facilities is primarily PV, power generation is dependent on solar insolation and weather-related temperature. If the weather forecast predicts rain for a week, this means the power supply will be drastically reduced for a week, then FCs both in the community facilities and in the household demand, and EVs in the VmGI facilities will generate and supply electric power to the community systematically for a week. Synchronously, energy consumption in the household demand will be curtailed by changing the lifestyle (e.g., disuse of vehicles), and the work style (e.g., remote work).

CONCLUSIONS

This study proposed a community concept of the Tsukuba Green Holonism Town, including three basic policies and five functional categories. A distinctive feature of this community is that the demand in collaboration with its residents, workers, and EVs meets the energy supply and varies based on weather conditions. Furthermore, it described an example of cooperative scenarios between common facilities and household demand against a dark period.

ABSTRACT

Hydrogen (H_2) is widely used in many industries because it can be used as a chemical raw material with its high mass-energy density and can be converted back into electricity via fuel cells. H_2 energy systems seem to be one of the most effective solutions for providing a better environment and sustainability. Green H_2, produced by renewable energy-assisted electrolysis without greenhouse gas emissions, has been of great importance in recent years. In this study, a hybrid energy system including Photovoltaic (PV), Wind Turbine (WT), Proton Exchange Membrane Fuel Cell (PEMFC), and electrolyzer is compared for grid-connected and off-grid operating conditions. In the grid-connected system, electricity generated from PV and WT is used directly to meet electricity demand, while excess electricity is used for green H_2 production. In the off-grid connected system, electricity generated from PV and WT was used for H_2 production. Produced H_2 and O_2 were used to generate electricity by PEMFC. While 20186 kWh energy & 3273 m^3 H_2 were generated in an on-grid connected system, 95145 kWh energy & 17942 m^3 H_2 and 83511 kWh energy & 14370 m^3 H_2 were generated in two different configurations in the off-grid connected system. The Levelized Cost of Energy (LCOE) for the on-grid connected system and the off-grid system for two different designs were determined as 0.307 $/kWh, 0.341 $/kWh and 0.349 $/kWh**,** respectively. The hybrid system design was simulated using MATLAB software and it was examined which hybrid energy system configuration would be the most economical to meet the load.

Keywords: Green hydrogen, Hydrogen production, Hybrid energy system, Renewable energy

INTRODUCTION

Nowadays, besides the fossil fuels, such as oil and natural gas, that are endangered, renewable energy sources (solar, tidal, geothermal, etc.) are alternative for those because of suitable for use and are everywhere [1]. Renewable energy means that never-ending energy sources or self-renewing and found in nature such as solar, wind, H_2, etc. All renewable energy sources, solar and wind energy have been widely used. Nevertheless, weather conditions, daily solar cycle, and seasonal variations affect the undesirable performance of PV and WT systems [2]. In addition, the storage of electricity is more difficult progress than its production. H_2 could be produced and stored by electrolysis with the generated electricity from renewable energy sources [3]. Thus, either all of the produced electricity or the excess electricity after use is stored as H_2. In this study, to meet the 25kWh electricity demand, on-grid and off-grid renewable hybrid energy systems were designed. The cost analysis was made and compared by calculating how many PV panels and WT were used and the power of electrolyzer and PEMFC.

MATERIALS AND METHODS

By obtaining hourly solar radiation, ambient temperature, and wind speed data from Atilim University Meteorology Station, hybrid energy systems were designed to supply 25 kWh energy connected as on-grid and off-grid applications.

Proposed On-grid and Off-grid Hybrid Systems

Fig. 1. (a) shows the on-grid hybrid energy system design. In this system electricity produced from PV panels and WT is fed to the grid and sent to the consumer. When the consumption is less than production; the excess of electricity is sent to the electrolyzer to produce H_2 and O_2. Produced H_2 and O_2 are stored in tanks with the help of compressors. Thus, excess electricity is not stored in batteries, but as H_2 and O_2.

Fig.1. (b) shows the off-grid hybrid energy system design. In this system, the electricity produced from PV panels and WT operates the electrolyzer to produce H_2 and O_2. Produced H_2 and O_2 are stored in tanks and fed to the PEMFC that generates electricity to meet the 25 kWh energy need of the system.

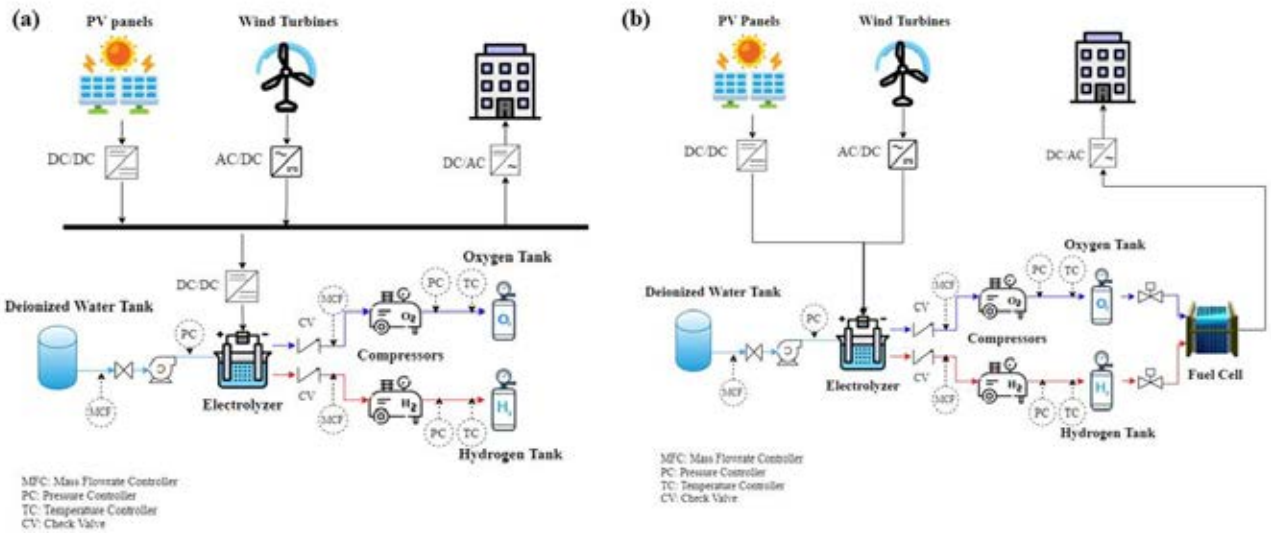

Fig. 1. (a) On-grid connected hybrid energy system design, (b) Off-grid connected hybrid energy system design

Optimal Design Strategy of the Proposed On-grid and Off-grid Hybrid System

On-grid hybrid system: Firstly, the number of PV panels and WT that meet the 25 kWh energy need is calculated. By using solar radiation, ambient temperature and wind speed data, the total energy produced from PV panels and WT are calculated. If the produced energy does not meet the entire consumed energy, energy need is met by using produced energy from PV panels and WT and grid. In case the produced energy is greater than the consumed energy, it is checked whether the excess energy is sufficient to operate the designed electrolyzer or not. When it is sufficient, excess energy is fed into the grid; in the other case, the electrolyzer is operated by using excess energy, H_2 and O_2 are produced and stored.

Off-grid hybrid system: The H_2 requirement of the PEMFC, which operates at 5 kW power for 5 hours, has been determined. According to the H_2 requirement, the power of the electrolyzer to be used to meet it, the number of PV panels and WT that will produce the energy for operating the electrolyzer are calculated. By using solar radiation, ambient temperature and wind speed data, the total energy produced from PV panels and WT are calculated. The produced energy is sent to the electrolyzer, then H_2 and O_2 are produced and stored. The stored H_2 and O_2 are sent to the PEMFC to produce electricity and the 25-kWh electricity need of the system is met.

RESULTS AND DISCUSSION

Table 1. Comparison of the grid-connected and off-grid hybrid system by annual produced energy stored H_2 and LCOE

Components		On-grid	Off-grid	
			Design 1	Design 2
PV	Number of Panels	30	140	105
	Installed Power (kW)	11.1	51.8	38.85
WT	Number of Turbines	1	1	1
	Installed Power (kW)	4	4	10
Electrolyzer	Number of Electrolyzer	1	1	1
	Power of Electrolyzer (kW)	7	20	20
PEMFC	Number of PEMFC	-	1	1
	Power of PEMFC (kW)	-	5	5
H_2 Tank	Temperature of Tank (°C)	25	25	25
	Pressure of Tank (bar)	150	150	150
Annual Produced Energy (kWh)		20186	95145	83511
Annual Stored H_2 (m^3)		3273	17942	14370
LCOE ($/kWh)		0.307	0.341	0.349

Table 1 illustrates the components of the on-grid and off-grid connected hybrid systems. Figure 2 shows the amount of the produced and stored H_2 of on-grid and off-grid systems. The levelized cost of energy for the grid-connected system and the off-grid system for design 1 and design 2 was determined as 0.307 $/kWh, 0.341 $/kWh and 0.349 $/kWh, respectively.

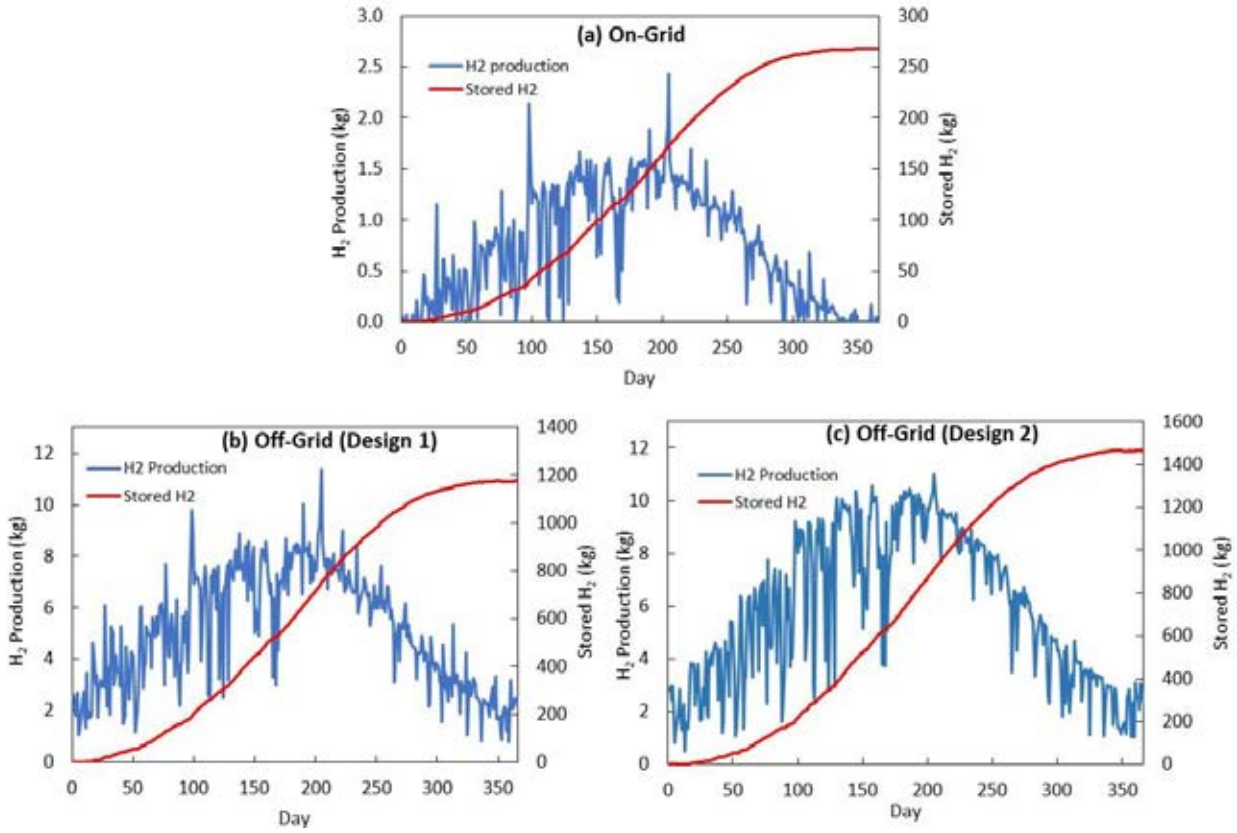

Fig. 2. The amount of produced and stored H_2 in (a) on-grid system, (b) off-grid system (Design 1) and c) off-grid system (Design 2)

CONCLUSIONS

In this study, renewable energy systems based on-grid and off-grid connected hybrid systems were examined. According to solar irradiation, ambient temperature, and wind speed, the number of PV panels and WT's, the power of electrolyzer, and PEMFC were calculated to meet the 25-kWh energy requirement. When the LCOE is examined, although the most suitable system seems to be the on-grid system, there is not much difference between it and other designs. This makes the idea that the entire system to be installed will consist of a renewable energy system more attractive.

ABSTRACT

In an electric power system consisting solely of non-fossil power sources, the capacity of storage batteries and hydrogen production facilities that should be attached to renewable energy power plants depends on the cost of these facilities and the cost of connecting them to the grid. In this study, assuming that a large amount of renewable energy will be introduced into the Japanese power system in 2050, the capacity and annual operation of storage batteries, water electrolysis equipment, hydrogen tanks, and transmission facilities that minimize costs were investigated. The results showed that solar photovoltaic (PV) plants require more variability mitigation equipment than wind farms. At a transmission cost of 1.2 JPY/kW/h, the optimal Li-ion battery capacity and transmission capacity for PV are 9.1 times and 0.18 times that for wind farms, respectively, and only PV is equipped with a 5 MW hydrogen production unit and 15 kNm^3 of hydrogen storage.

Keywords: Renewable energy, Hydrogen, Carbon neutrality, Sector coupling, Linear programming

INTRODUCTION

The decarbonization of energy supply is being promoted worldwide. One of the major challenges in increasing the introduction of renewable energy in Japan is that there are few suitable locations for renewable energy, and they are far from demand areas. Large-scale introduction of offshore wind power plants is expected, but the power grid needs to be significantly strengthened in order to transmit electricity to the demand areas.

Storage batteries and hydrogen production facilities attached to renewable energy site can be expected to reduce the capacity of power transmission facilities by shaving off the peak of renewable energy, and to improve the average unit price of electricity sold through time shifting. As a previous study on the optimization of storage batteries and hydrogen production facilities attached to renewable energy site, the cost of hydrogen supply by water electrolysis equipment (WE) attached to photovoltaic power generation systems has been analyzed in combination with and suppression of storage batteries [1]. Yamamoto et al. have shown that electricity supply costs can be reduced by an energy storage system that optimally combines storage batteries and hydrogen storage while also optimally combining photovoltaic and wind power generation [2]. However, since these models cannot represent electricity supply and demand on a nationwide scale, it is not possible to properly evaluate the effects of time shifting to control the timing of transmission. Therefore, in this study, we developed a model to determine the optimal configuration of ancillary facilities for local renewable energy power plants based on the optimized energy supply and demand in Japan in 2050, when renewable energy has been introduced.

MODELING

In this study, the equipment configuration shown in Figure 1 is investigated. The grid node (G-node) is a huge grid that covers the whole country, and the additional renewables node (AR-node) is a single power plant with 100 MW of photovoltaic (PV) or wind power. Each node is equipped with Li-ion batteries (LIB), water electrolyzer (WE), hydrogen combined-cycle plant (H2CC), and hydrogen tank. AR-node is connected to G-node by the transmission line. The configuration that minimizes the total cost is obtained by linear programming. In order to reduce the amount of computation, the solution is divided into the following two steps. In both steps, the optimal capacity and the hourly energy flow (power flow and hydrogen flow) that gives the minimum total cost are determined by linear programming.

- Step 1: Optimize G-node without AR-node.
- Step 2: Fix the capacity of facilities in G-node and optimize the entire model including the transmission system.

This model can consider the start-up and shutdown costs and partial load efficiency of the H2CC. It can simultaneously optimize 8760 hours of operation because it does not include integer variables and can be calculated quickly. This is particularly effective when considering long-term storage technologies such as hydrogen. The analysis period was one year, and the time resolution was set to one hour. GAMS was used as the calculation tool and CPLEX as the solver.

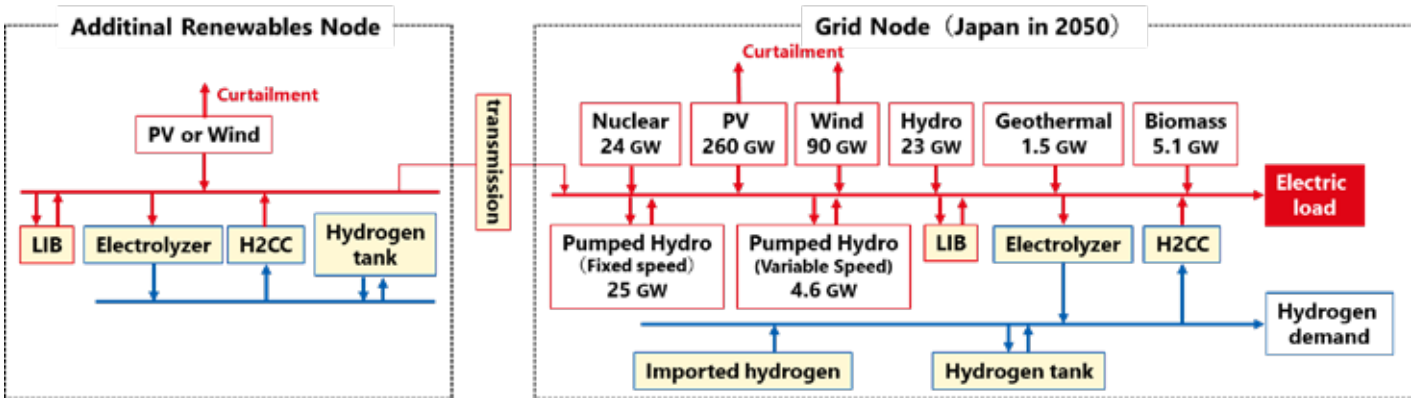

Fig. 1. Electricity-Hydrogen Model. The capacities of the facilities with yellow backgrounds were optimized.

Objective Function and constraints

The objective function *obj* to be minimized is shown in Eq. (1). It represents the sum of the equipment cost for each facility and the imported hydrogen cost.

$$\text{minimize: } obj = \sum_{node}\sum_{j} FC_{node,j} \cdot x_{node,j} + FC_{\text{tie}} \cdot x_{\text{tie}} + \sum_{i} HP \cdot u_{\text{imp},i} \quad (1)$$

The model includes constraints such as simultaneous equalization (electricity and hydrogen), supply and demand adjustment power, reserve power, output upper and lower limits, and storage upper and lower limits.

Exogenous variables

Electricity demand and generation curves were set based on the actual values in Japan in 2020. Hydrogen demand is assumed to be 16.7 million tons per year. Imported hydrogen was assumed to be available at 30 JPY/Nm^3 per hour in any quantity. The specifications of each power source and energy storage facility were set as shown in Table 1. It was assumed that no additional compression power is needed during storage since hydrogen is stored at low pressure.

Table 1. The specifications of each power source and energy storage facility.

Facility	Capital cost	kWh/kW ratio	Roundtrip efficiency
Pumped water	-	8	70 %
LIB	43,000 JPY/kWh	2	88 %
H2CC	161,000 JPY/kW	-	57 %
Water Electrolyzer (WE)	50,000 JPY/kW	-	79 %
Hydrogen tank	4,700 JPY/Nm^3	-	100 %

CASE STUDY

Parameters

In order to investigate the impact of transmission costs on the optimal installed capacity, the unit cost of power transmission (including cost of installation and maintenance of transmission and transformation facilities and power lines) between AR-node and G-node was set in the range of 0.3-1.8 JPY/kW/h for the case study.

Results and discussion

The optimization of G-node in step 1 resulted in the installation of 34 GW of WE and 55 GW of LIB. The capacity utilization of WE are 16 %, and domestic hydrogen production is mainly done when surplus electricity is generated. Out of the total PV and wind power generation of 557 TWh, 531 TWh that is not curtailed cover 62 % of the electricity demand.

In Step 2, AR-node was optimized. Figure 2 (a) and (b) shows the results of the optimal installed capacity in AR-node when the transmission unit price is changed. In the case of PV, even when the transmission unit price is 0.3 JPY/kW/h, the output is leveled by LIB. In the case of PV, output equalization by LIB is performed even when the

transmission unit price is 0.3 JPY/kW/h, but in the case of wind, it is not performed until 1.2 JPY/kW/h. In addition to the fact that PV has a smaller capacity utilization ratio than wind power, it also has a strong cannibalization effect, which lowers the value of electricity transmitted to the national grid when it is generated, because the generation period is concentrated in the daytime nationwide. Therefore, the effect of time shifting and transmission leveling to improve the utilization rate of transmission facilities can be considered to have been more significant.

Figure 2 (c) shows the supply and demand profile within AR-node from July 11 to 13 in the case where the transmission cost is 1.2 JPY/kW/y and the additional renewables is 100 MW of PV. In this case, the optimal transmission capacity is only 17 MW, and most of the power generate by PV is charged by 66 MW of LIB and discharged in the evening (time-shifting). Hydrogen production using surplus electricity will also be implemented by 5 MW of WE. The stored hydrogen in 15 kNm^3 of hydrogen tank will be used to generate electricity when renewable energy is in short supply nationwide. The optimal capacity of a hydrogen tank is 15 hours of rated hydrogen production for WE, which is used for longer term energy storage than LIB, so that LIB and hydrogen storage are introduced in coexistence. The optimal utilization rate of WE at renewables node is only 20.1%.

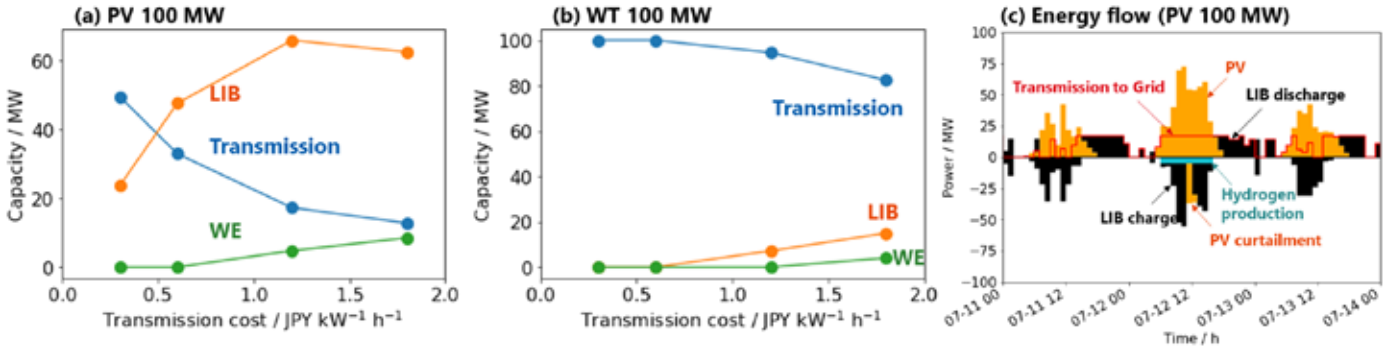

Fig. 2. (a) (b) Optimal installed capacity in AR-node when the transmission unit price is changed when the additional renewables is (a) PV or (b) wind. (c) The supply and demand profile within AR-node from July 11 to 13 in the case where the transmission cost is 1.2 JPY/kW/y and the additional renewable energy is 100 MW of PV.

CONCLUSIONS

In this study, the optimal configuration of ancillary facilities for renewable energy power plant was discussed in Japan in 2050, assuming a configuration that does not use fossil fuels, and the following suggestions were obtained.

- For the same transmission unit price, more electricity storage and hydrogen storage facilities will be required for PV than for wind power on the renewable energy side. This is due to the low utilization rate of PV facilities and the high value of time-shifting due to the strong cannibalization effect.
- In the market environment around the year 2050, for example, when the transmission unit cost is 1.2 JPY/kW/h, the optimal configuration with a 100 MW PV power plant is 66 MW, 132 MWh of LIB and 4.8 MW of WE.

NOMENCLATURE

node	Node (Grid / Additional Renewables)
j	Type of facility to be optimized (LIB, WE, H2CC, hydrogen tank)
i	time ($1 \leq i \leq 8760$)
FC_j	Fixed cost unit price of facility j, JPY/MW/y (JPY/Nm^3/y when j = tank)
x_j	Installed capacity of facility j, MW (kNm^3 when j = tank)
HP	Price of imported hydrogen, JPY/Nm^3
$u_{imp,i}$	hydrogen import volume at time i , Nm^3/h

ABSTRACT

Germany's transition to greenhouse gas-neutrality by 2045 requires a dynamic change in all sectors of its energy system. Despite several studies already depicting possible pathways for this transformation, the role of hydrogen in this process remains unclear. In this study we utilize a combination of energy system models to examine the usage and production of hydrogen during this transition in detail. Our results show that 412 TWh of hydrogen are needed in the year 2045, mostly in the industry and transport sector. Particularly, the use of hydrogen in industry is essential as there are no cost-effective alternatives for achieving greenhouse gas neutrality. Furthermore, we illustrate that domestic hydrogen production through electrolysis provides 53% of the needed hydrogen in 2045 and the remaining share is imported from other European countries or Northern Africa via pipelines or ships. Additionally, seasonal storage of hydrogen and hydrogen gas turbines play an important role in balancing the intermittent nature of variable renewable energy sources. In summary, hydrogen usage and production are crucial for a greenhouse gas-neutral Germany and should be integral part of the transformation strategy.

Keywords: Energy system modeling, Greenhouse gas-neutrality, Germany, Hydrogen demand, Hydrogen imports

INTRODUCTION

In 2021 Germany adapted its Federal Climate Change Act [1] and committed itself to become greenhouse gas-neutral by 2045. Furthermore, greenhouse gas emissions shall be reduced by at least 65 percent by the year 2030 compared to 1990 levels. Thus, a rapid transformation of the entire German energy system is necessary. Besides a large expansion of renewable energy sources like wind energy and photovoltaics, energy efficiency measures and a direct electrification in the end use sectors, hydrogen can play an important role in a greenhouse gas-neutral energy system.

However, recently conducted studies show a wide range for the expected German hydrogen demand in 2045. Moreover, the share of hydrogen imports differs significantly in the various scenarios. Prognos et al. [2] expect a hydrogen demand of 265 TWh in 2045, which is mostly used for electricity and heat production. Additionally, they state that 64% of the hydrogen is imported, but without mentioning of the import countries and costs. In contrast, the German energy agency [3] predicts a higher demand of 458 TWh hydrogen in 2045, where the largest consumption originates from the industry sector. Furthermore, they forecast that only 13% of the hydrogen is produced domestically and most of the hydrogen is imported from other European countries, North Africa, Russia, or Turkey. The scenarios conducted by the Fraunhofer Institute for Solar Energy Systems [4] show a range of 120 to 330 TWh hydrogen demand in 2045, but do, in contrast to other studies, not include the usage of hydrogen as a feedstock in industry. Depending on the investigated scenario most of the hydrogen demand stems either from the transport or the industry sector. In the Ariadne-Report [5] a wide range for the hydrogen demand from 100 to 600 TWh in 2045 is given, as different scenarios are investigated, and different energy system models are utilised. While the largest hydrogen demand is consistently based in the industry sector, the hydrogen demand in all sectors varies significantly between the scenarios and models. Moreover, the import share of hydrogen greatly differs between the scenarios and models, but import countries and costs are not given.

This study provides a holistic analysis of the hydrogen demand, production, and imports in a greenhouse gas-neutral Germany. We apply an integrated energy system model which includes all energy demand sectors and the demand for hydrogen as a feedstock. Furthermore, we discuss in detail sources and costs for hydrogen imports to Germany. Additionally, we show the role of long-term hydrogen storage for providing supply security in periods with low energy supply by wind energy and photovoltaics. While the previously mentioned studies investigate some of these aspects as well, to the best of our knowledge no study for a greenhouse gas-neutral Germany by 2045 discusses all aspects in detail and provides a complete view of the future role of hydrogen.

MODELING

In this study we use the model family ETHOS (Energy Transformation Pathway Optimization Suite), which was developed at the Institute for Techno-economic System Analysis (IEK-3) of the Forschungszentrum Jülich [6]. This model suite consists of models which represent energy systems in a high temporal and spatial resolution. The center of this analysis is the optimisation model FINE-NESTOR [7], which depicts the German energy system and analyses cost optimal transformation pathways to greenhouse gas-neutrality. This integrated energy system model represents the sectors energy, industry, buildings, and transport in detail through an hourly resolved network of energy sources, transformation processes, storages and energy demands. The central boundary condition for this analysis are the emission reduction targets from the Federal Climate Change Act, which must be met by the optimisation model. Hydrogen import sources and costs are determined with the simulation model InfH2 [8], which models worldwide energy supply chains. It includes the entire value chain for hydrogen imports from electricity production, electrolyzers and ship transport to Germany. The resulting cost-quantity curve is then passed to the FINE-NESTOR model, which decides if it is cheaper to produce hydrogen in Germany or import it.

RESULTS AND DISCUSSION

Our results show that hydrogen plays an important role for a greenhouse gas-neutral Germany. Fig. 1 displays that already in the year 2030 104 TWh of hydrogen are used. This demand increases by 2045 to 412 TWh. Thereby, the industry sector is with 267 TWh the main consumer of hydrogen. A main demand arises from the usage of hydrogen as a feedstock in the chemical industry, where 112 TWh of hydrogen are used to produce methanol. This methanol in turn is converted to high-value chemicals, which are used in the plastics production. Moreover, 86 TWh of hydrogen are used in the steel industry to produce iron via direct reduction of iron ore. Sensitivity analyses show that the industrial hydrogen demand is robust, as there are no cost-effective alternatives to the usage of hydrogen in this sector.

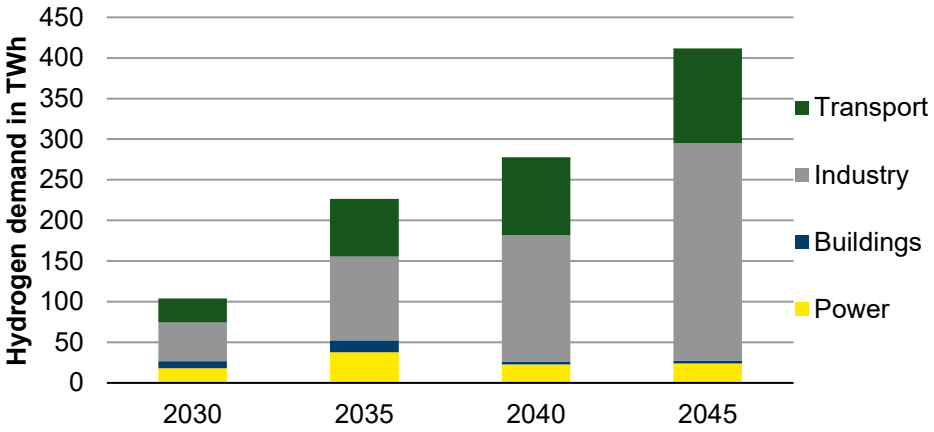

Fig. 1. Hydrogen demand by sectors in the transition to greenhouse gas-neutrality

In the transport sector 117 TWh of hydrogen are used, mainly for heavy trucks with fuel cells. Furthermore, hydrogen is used in the power sector to produce electricity in hydrogen gas turbines. This is especially important during dark doldrums, which describe periods with little energy generation from wind and solar power. In this study we consider a dark doldrum of two weeks in January, where only 10% of the capacity of wind energy turbines and photovoltaic plants is available for electricity production. To overcome this, period controllable power plants like hydrogen gas turbines or biomass power plants are used for meeting the electricity demand. Therefore, about 35.4 TWh of long-term hydrogen storage is needed to supply the hydrogen for the gas turbines and compensate for the seasonal variation of energy production from renewable sources. For this hydrogen storage salt caverns are used, which can mostly be created by conversion of existing natural gas storages.

Another source of flexibility for the energy system are the installed electrolyzers with a production capacity of 71 GW in the year 2045. They adjust their hydrogen production based on the available electricity produced by renewable sources and thereby help to balance the electricity production and demand. In the course of the transition, the full-load hours of centrally installed electrolyzers increase from about 2000 h in the year 2030 to about 2800 h in the year 2045. Fig. 2 shows that in the year 2045 electrolyzers produce 219 TWh of green hydrogen, the remaining 47% of hydrogen is imported from other European countries or Northern Africa via pipeline or ship. It must be noted, that in the year 2030 still about 26 TWh of hydrogen are produced by steam reforming, which is not depicted in Fig. 2.

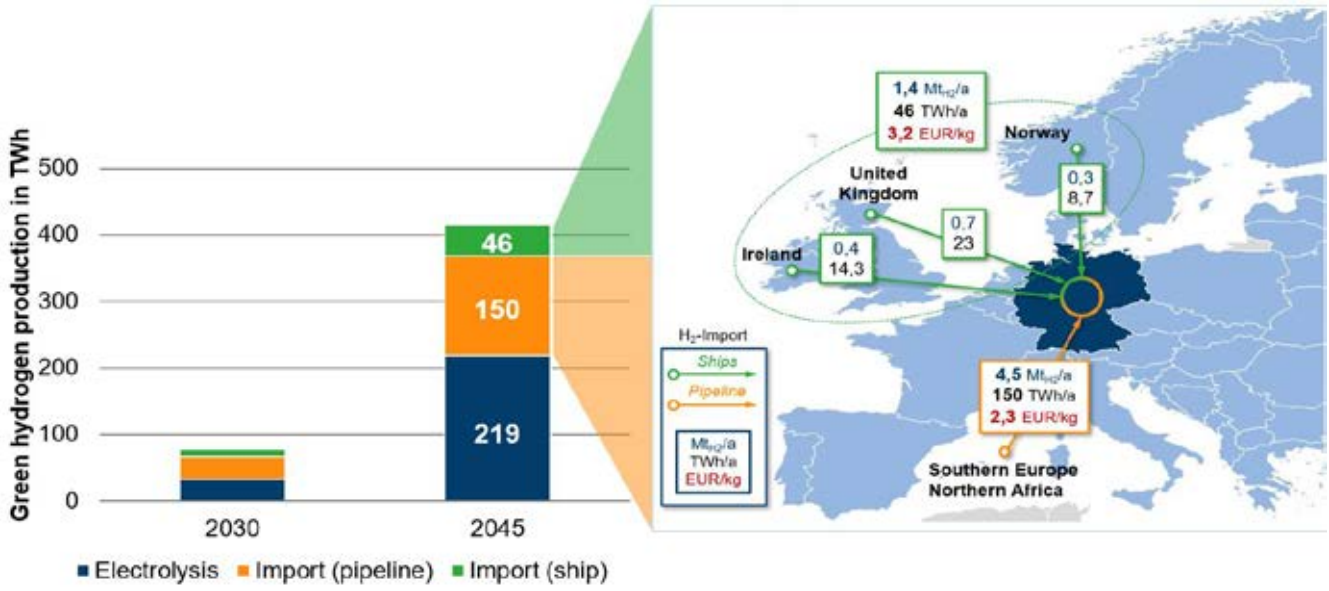

Fig. 2. Green hydrogen production and imports into a greenhouse gas-neutral Germany in the year 2045

With 150 TWh most of the hydrogen is imported via pipelines from Southern Europe or Northern Africa using mainly converted natural gas pipelines. Thus, the import costs of 2.3 €/kg are significantly lower than the average import costs of 3.2 €/kg for hydrogen imports from Northern Europe. This cost difference is mainly caused by the assumption that hydrogen from Northern Europe must be liquefied, transported by ship and then regasified in German harbors. If pipelines could be used to transport the hydrogen to Germany, the price difference would be smaller and more hydrogen could be imported.

CONCLUSIONS

Our study demonstrates that hydrogen is a central aspect of Germany's transition to greenhouse gas neutrality. Hydrogen is mainly used in the industry and transport sector, but also helps to balance the intermittent nature of photovoltaics and wind energy through long-term storage and flexible hydrogen gas turbines. Furthermore, this study shows that the target of the new German Federal Government of 10 GW electrolyzer capacity in 2030 [9] is not sufficient for the transformation, as according to our model results about 15 GW of electrolyzer capacity are needed in 2030. Thus, additional efforts must be made to meet 71 GW electrolyzer capacity in 2045, which is needed to produce 53% of the hydrogen domestically.

INTEGRATION OF A RENEWABLE METHANOL PRODUCTION PROCESS WITH A LOW CO_2 EMISSIONS CRGT POWER PLANT

[1*] *Vittorio Tola*, [1] *Francesco Lonis*
[1]University of Cagliari, Department of Mechanical Chemical and of Materials Engineering, Via Marengo 2, Cagliari, Sardinia, Italy

ABSTRACT

Power-to-liquids (PtL) technologies are an interesting way for storing the excess of renewable electricity into liquid fuels. Methanol is well-known as hydrogen carrier and energy feedstock, since it can be stored, transported and used more easily than hydrogen. The renewable methanol produced in PtL processes through the CO_2 hydrogenation process can feed a chemically recuperated gas turbine (CRGT) where the exhaust heat recovery boosts the plant performance. The hydrogen required for PtL is produced in an alkaline electrolyser, while the CO_2 is captured from the CRGT exhausts

Keywords: Methanol, CO_2 hydrogenation, Alkaline electrolysis, Chemically recuperated gas turbine, CO_2 capture

INTRODUCTION

One of the most interesting options to boost the performance of a gas turbine relies on exhaust heat recovery trough thermochemical recuperation (chemically recuperated gas turbine, CRGT). Many CRGT solutions are based on methane steam reforming, characterised by significant drawbacks, due to its high reforming temperature (600–800 °C), higher than the exhaust temperature of commercial gas turbines. On the contrary, methanol can be more suitable for CRGT plants owing to its lower reforming temperature (250–300 °C) [1]. Moreover, methanol can be easily stored, transported and used without significant changes in the existing infrastructure [2]. Typically, methanol is produced from fossil fuels, but renewable methanol can be produced via the application of power-to-X technologies [3], such as the catalytic conversion of hydrogen, from the excess of renewable energy sources (RES), and recycled CO_2 [4].

In this paper a performance assessment of an integrated plant based on a power-to-liquids system and a CRGT fuelled by methanol is presented. Methanol is produced in a synthesis section (MSS) via catalytic CO_2 hydrogenation, it is stored and reused by producing electricity via the CRGT to level out peak demand. The required H_2 is produced in an alkaline electrolyser (AEL) fed by excess of electricity from RES, whereas the CO_2 is captured from the CRGT exhausts. Heat recovery and thermal integration of the overall system are performed to obtain optimal operating conditions and energy savings in each section. Performance energy indexes were also defined for the single sections and the overall system. Functional schemes and dedicated simulation models were implemented using the Aspen Plus commercial software.

SYSTEM CONFIGURATION

Figure 1 shows the functional scheme of both the overall system and the CRGT.

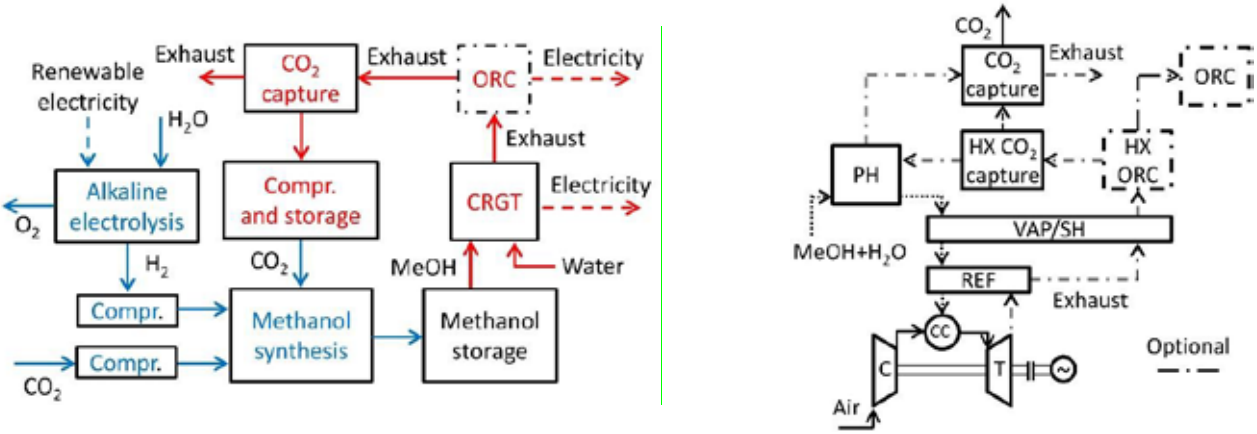

Fig. 1. Functional scheme of the overall system (left) and of the CRGT (right)

In case of excess electricity from RES, an AEL produces hydrogen, that is compressed and feeds, together with CO_2, a synthesis section to produce methanol in a catalytic reactor (charge phase). Methanol is stored at ambient conditions for feeding the CRGT in case of higher electricity demand (discharge phase). The CRGT exhaust firstly feeds the reforming section (vaporization, superheating and reforming of the mixture water-methanol), then is used to regenerate the MEA in the CO_2 removal section and finally, it is absorbed by the water-methanol preheating. To better exploit the residual heat released by the CRGT, the integration between the overall system and an organic Rankine cycle (ORC) was also studied.

The overall system was sized with reference to a 3.2 MW commercial AEL, leading to a H_2 production of 800 Nm^3/h and generating 350 kg/h of methanol in the MSS (about half of the only existing commercial renewable methanol plant [5]). Assuming the same duration for the charge and discharge phases, a power production of about 750 kW was calculated.

Alkaline electrolyzer

The chosen AEL is characterized by a H_2 production of 800 Nm^3/h (about 72 kg/h), requiring a water flowrate of about 640 kg/h. The electrolysis process is performed at a pressure of 5 bar and 65 °C, since under these conditions the efficiency reaches the highest value. The model of the AEL was adapted from the electrochemical model developed by Ursua and Sanchis [6] for simulating commercial water AELs. A specific energy consumption of about 4 kWh/Nm^3_{H2} was found [6].

Methanol synthesis section

CO_2 catalytic hydrogenation takes place in an adiabatic reactor operating at 65 bar and 210 °C [7]. H_2 and CO_2 are compressed and preheated to the reactor inlet temperature. Due to the exothermicity of the CO_2 hydrogenation a reactor outlet temperature of about 290 °C is obtained. Thermal energy from the reactor exhaust cooling is used to preheat the reactor feeding and the crude methanol upstream of the distillation column. Unreacted gases are separated and recycled back to the reactor. Assuming the stoichiometric conditions, a H_2 production of 72 kg/h requires about 520 kg/h of CO_2 to produce 350 kg/h of methanol. An extensive description of the MSS can be found in Lonis et al. [8].

Chemically recuperated gas turbine

The CRGT power plants is based on a small-size gas turbine characterized by a maximum temperature of 1100 °C and a pressure ratio equal to 8. The CRGT is fuelled by the reformed gas, which composition (mainly hydrogen, water and CO_2) strictly depends on the water-to-methanol molar ratio “n” entering the reforming section. The CRGT is integrated with a post-combustion CO_2 removal section based on a mixture of water and monoethanolammine (MEA) (30%wt). Assuming a CO_2 removal efficiency equal to 90%, a thermal power of about 425 kW is required for the regeneration of the MEA.

ORC section

An ORC plant was considered to increase the power output of the system by exploiting the residual heat of the CRGT exhausts. Benzene was chosen as working fluid and the regenerated ORC operates between 0.218 and 46.5 bar, and between 25 and 290 °C. The ORC shows a global efficiency equal to 0.26.

Performance indexes

Several performance indexes were defined to establish the performance of the subsystems and of the overall plant. The electrolysis efficiency is defined as the ratio between the chemical power of the hydrogen $\dot{m}_{H_2} \cdot LHV_{H_2}$ and the electric power consumed in the electrolysis process including auxiliaries $P_{AEL} + P_{BOP,AEL}$, as shown in Eq. (1):

$$\eta_{AEL} = \frac{\dot{m}_{H_2} \cdot LHV_{H_2}}{P_{AEL} + P_{BOP,AEL}} \quad (1)$$

From the methanol chemical power. an actual overall efficiency η_{MSS} and a chemical energy conversion efficiency $\eta_{MSS,C}$ of the MSS can be defined as reported in Eq. (2), considering or not the MSS auxiliaries $P_{BOP,MSS}$ contribution:

$$\eta_{MSS} = \frac{\dot{m}_{MeOH} \cdot LHV_{MeOH}}{\dot{m}_{H_2} \cdot LHV_{H_2} + P_{BOP,MSS}} \; ; \; \eta_{MSS,C} = \frac{\dot{m}_{MeOH} \cdot LHV_{MeOH}}{\dot{m}_{H_2} \cdot LHV_{H_2}} \quad (2)$$

WHEC-2022
23rd World Hydrogen Energy Conference
June 26-30, 2022 - Istanbul

An efficiency of the power-to-liquids process η_{PtL}, is obtained considering the efficiency chain of the electrolysis and MSS (Eq. (3)), where φ_{AEL} represents the fraction of power entering the AEL with respect to the total power (Eq. (4)):

$$\eta_{PtL} = \frac{\dot{m}_{MeOH} \cdot H_{i,MeOH}}{P_{AEL}+P_{BOP,AEL}+P_{BOP,MSS}} = \eta_{AEL} \cdot \varphi_{AEL} \cdot \eta_{MSS,C} \quad (3) \; ; \quad \varphi_{AEL} = \frac{P_{AEL}+P_{BOP,AEL}}{P_{AEL}+P_{BOP,AEL}+P_{BOP,MSS}} \quad (4)$$

The efficiency of the electricity production, defined as the ratio between the net power and the methanol chemical power, taking into account or not the ORC, is shown in Eq. (5):

$$\eta_{CRGT} = \frac{P_{CRGT}-P_{BOP,CRGT}}{\dot{m}_{MeOH} \cdot LHV_{MeOH}} \; ; \; \eta_{CRGT+ORC} = \frac{P_{CRGT}+P_{ORC}-P_{BOP,CRGT}-P_{BOP,ORC}}{\dot{m}_{MeOH} \cdot LHV_{MeOH}} \quad (5)$$

Globally, the power-to-power efficiency of the overall system η_g can be defined as the ratio between the net power produced and the total power entering the overall system, as shown in Eq. (6):

$$\eta_g = \frac{P_{CRGT}-P_{BOP,CRGT}}{P_{AEL}+P_{BOP,AEL}+P_{BOP,MSS}} = \eta_{PtL} \cdot \eta_{CRGT} \; ; \; \eta_g = \frac{P_{CRGT}+P_{ORC}-P_{BOP,CRGT}-P_{BOP,ORC}}{P_{AEL}+P_{BOP,AEL}+P_{BOP,MSS}} = \eta_{PtL} \cdot \eta_{CRGT+ORC} \quad (6)$$

RESULTS AND DISCUSSION

The proposed power-to-liquids system is characterized by an efficiency η_{PtL} slightly lower than 0.57, due to an electrolysis efficiency η_{AEL} of about 0.72 and an actual efficiency of the methanol synthesis section η_{MSS} of about 0.765.

Different sizes for the ORC were considered, varying the thermal power available from the CRGT exhaust. An increase of the ORC thermal input reduces the heat available in the reformer, leading to a lower value of “n”. A reference value of 300 kW was set, leading to a n value higher enough to avoid carbon formation. The introduction of the ORC causes a reduction of the CRGT efficiency, due to the lower flowrate in the gas turbine, while boosting the efficiency of the electricity production from 0.366 to 0.372. Globally, an overall power-to-power efficiency η_g slightly lower than 0.22 can be obtained. Tables 1 and 2 summarize the main results of the proposed system in terms of performance indexes and net power of the electricity production sections.

Table 1. Performance indexes of the AEL and MSS

Performance index	Value
η_{AEL}	0.722
φ_{AEL}	0.934
η_{MSS}	0.766
$\eta_{MSS,C}$	0.841
η_{PtL}	0.567

Table 2. Parameters of the CRGT and ORC sections

Parameter	CRGT	CRGT+ORC
P_{CRGT}	703.3 kW	656.9 kW
P_{ORC}	-	56.6 kW
η_{CRGT}	0.3662	0.3420
$\eta_{CRGT+ORC}$	0.3662	0.3716
η_g	0.2149	0.2180

Finally, a parametric analysis of the CRGT in function of the maximum temperature and pressure ratio was carried out.

CONCLUSIONS

A power-to-methanol energy storage system based on an AEL, a methanol synthesis section and a CRGT power plant was analysed, with and without the integration with an ORC. CRGT systems can be an interesting option to use the methanol produced through a CO_2 hydrogenation process, especially if integrated with an ORC and a CO_2 removal section. Indeed, despite an overall power-to-power efficiency slightly higher than 0.21, the proposed system can store renewable energy surplus and then producing electricity with very low CO_2 emissions. The introduction of the ORC allows a better use of the heat released by the CRGT, improving the global efficiency by 0.3 ppts, from 0.215 to 0.218.

ABSTRACT

The introduction of transformative pedagogy provides for active learning in the incentivized, faculty-led, study abroad programs focused on green hydrogen projects. These study abroad programs utilize Purdue's Hydrogen Learning HUB, which is comprised of the Vertically Integrated Projects, Collaborative Online International Learning, Hub of Intercultural Learning, and Strategic Doing educational programs. Two faculty-led study abroad programs have been developed, one in Peru during Spring Break and one in Europe during a 4-week summer term. The Peruvian program is focused on two open-pit mines, the Falchani Lithium and the Quellaveco Copper projects, for green hydrogen technology integration into the mining operations. American Lithium Corporation is developing the Falchani mine located in the Andes Mountains. The Falchani mine is the world's sixth-largest hard rock lithium deposit. The Quellaveco mine, which is being developed by Anglo American Perú, in partnership with the Mitsubishi Corporation, is one of the world's largest copper deposits. The summer study abroad focuses on remote island communities, such as the Orkney Islands, as an ideal candidate for evaluation of green hydrogen technology integration into remote communities on islands. Currently, the community-based renewable energy systems on the Orkney Islands generate more than 130% of the electric energy consumed.

Keywords: Green hydrogen, Transformative pedagogy, Vertically integrated projects

INTRODUCTION

The Hydrogen Insights 2021 report [1] published by the Hydrogen Council [2-4] in collaboration with McKinsey & Company notes that, with the scaling up of hydrogen projects and the falling renewable energy costs, the Total Cost of Ownership (TCO) of green hydrogen could be the most competitive solution in more than 20 applications by 2030, including heavy-duty mining trucks. Purdue University introduced a Green Hydrogen Study Abroad program targeting the earliest breakeven Total Cost of Ownership (TCO) of Fuel Cell Electric Vehicles (FCEV) in the transport sector, i.e. heavy-duty, haul trucks in open-pit, surface mining operations [5]. Purdue University introduced a second Green Hydrogen Study Abroad program targeting remote [6], small-island communities as early net-zero winners in the Race-to-Zero, such as the Orkney Islands. The first Study Abroad program focuses on two open-pit mines, the Falchani Lithium and the Quellaveco Copper projects, for green hydrogen technology integration into the mining operations. American Lithium Corporation is developing the Falchani mine located in the Andes Mountains. The Falchani mine is the world's sixth-largest hard rock lithium deposit. The Quellaveco mine, which is being developed by Anglo American Perú in partnership with the Mitsubishi Corporation, is one of the world's largest copper deposits. The second study abroad focuses on remote island communities, such as the Orkney Islands, as an ideal candidate for evaluation of green hydrogen technology integration into remote communities on islands. Currently, the community-based renewable energy systems on the Orkney Islands generate more than 130% of the electric energy consumed.

First introduced by Georgia Tech, the Vertically Integrated Projects (VIP) [7] program provides a transformative mindset to enhance educational outcomes by engaging undergraduate and graduate students in ambitious, long-term, global, interdisciplinary project teams that are led by faculty. VIP programs are now active in over 40 universities across the globe. The VIP program extends project-based learning with the inclusion of innovative study abroad programs. These Purdue University study abroad programs [8] utilize a Hydrogen Learning HUB, which is comprised of the VIP, Collaborative Online International Learning (COIL), Hub of Intercultural Learning (HubICL), and Strategic Doing [9] educational programs.

The Green Hydrogen Study Abroad program focused on mining trucks at two open-pit mines in Peru as ideal candidates for evaluation of green hydrogen technology integration into the mining operation. The mining projects are known as the Falchani Lithium Project and the Quellaveco Copper Project. The first surface mine is being developed by American Lithium Corporation and is known as the Falchani Lithium Project and located on the

Macusani Plateau in the Andes Mountains of the south-eastern part of Peru. It is estimated that the Falchani Lithium deposit to be the world's sixth-largest hard rock lithium deposit. The Falchani Lithium Project incorporates many green initiatives, including the recycling of up to 90% of process water, a self-sufficient, high-efficiency green energy on-site acid plant, and goals of adding future "green energy" initiatives. The second surface mine is the Quellaveco Copper Project and is being developed by Anglo American Perú, in partnership with the Mitsubishi Corporation near Moquegua in southern Peru, as one of the world's biggest undeveloped single porphyry copper deposits with a reserve base of more than 1.3 billion tonnes. ENGIE Energía Perú and Anglo American Perú signed an agreement to convert the total electricity supply for the Quellaveco mines (187 MW) to 100% green energy. ENGIE Energía Perú will source the renewable energy from its Punta Lomitas wind power plant, an in-development wind farm with a joint nominal capacity of 260 MW located in Ocucaje-Ica and a 60 km transmission line connecting the plant with the National Interconnected Electric System. Figure 1 illustrates a solar PV microgrid for the Falchani Lithium mine utilizing a hybrid battery/hydrogen energy storage system to provide both electricity and hydrogen for the fleet of fuel cell, electric-drive mining trucks equipped with trolley assist.

Fig. 1. Solar PV Microgrid integration into the Falchani Lithium Mining Operation

A four-week summer study abroad program focuses on remote island communities, known as the Orkney Islands, was selected as an ideal candidate for evaluation of green hydrogen technology integration into remote communities on islands. Orkney is an archipelago in the Northern Isles of Scotland. Orkney has about 70 islands, of which 20 are inhabited with a total population about 22,000. Since the Orkney Islands have an abundance of wind, waves and tides energy resources, they have become a green hydrogen hub for R&D projects demonstrating the use of hydrogen to decarbonize electric power, heat and transport applications. Currently, these community-based renewable energy systems generate more than 130% of the electric energy consumed on the islands, even with the growing number of plug-in cars on the islands. The largest of these green hydrogen projects is the Flotta Hydrogen Hub powered by offshore wind turbines.

TRANSFORMATIVE PEDAGOGY

Transformative pedagogy provides for active learning through incentivized, faculty-led, study abroad programs. It is imperative that faculty members in a faculty-led program [1] focus on learning outcomes and the assessment of those outcomes. Example of Transformative pedagogy at Purdue include (a) Team Project-Based Learning [10], (b) Global and Cultural Immersions, and (c) Innovative Teaching Methods. *Team Project-Based Learning* allows for learning through the lens of a project, along with exposure to real-world team dynamics, problem-solving and deadlines, which prepares graduates for success. *Global and Cultural Immersions* allows students to gain insights into cultures other than their own, broadening their perspectives and becoming more marketable to employers. *Innovative Teaching Methods* allows for a shift away from lectures to active-learning such as faculty-led study abroad programs.

CONCLUSIONS

Using Transformative Pedagogy in the VIP faculty-led study abroad programs in green hydrogen provides for active and engaged learning. The faculty-led study abroad program relies on creating a student-centered learning environment where innovative skills such as applying new green hydrogen technologies to the greening of mining fleets and integrating hydrogen energy systems for net zero communities are learned. The world economy and energy needs are in the throes of transformation, Transformative Pedagogy in a faculty-led study abroad program provides a high-impact approach for the application of green hydrogen energy systems.

ABSTRACT

Remote Piloted Vehicles are in the aim of the experts because of its wide usability. The main disadvantage of battery based technologies are their low endurance operation time due to high energy demand coming from propulsion system. This paper proposes a way to overcome this problem by means of a fuel cell (FC) and batteries hybrid system. The hybrid system designed consists in a 500W fuel cell and a 3S-3P battery in active configuration to deliver enough energy to feed the different loads onboard during at least 7h mission. The final target system increase of the total mission time and reliability of the whole system.

Keywords: Hybrid system, Fuel cell, Batteries, Hydrogen, Stack

INTRODUCTION

Unmanned vehicles begin to gain attention as they can be used in a wide range applications as repetitive or unpleasant tasks, those tasks that involve danger to an operator, between others. Electric propulsion systems become a good option due to their high performance and low emissions compared to internal combustion engines. Despite of achieve power requirements, only battery-based systems present disadvantages as short life cycle and long charging periods, etc. [3-5] a Fuel cell (FC) and batteries hybrid systems are intended to combine advantages of both technologies. Such as increase the operating range of the vehicle, reliability, life cycle and performance. There are two possible configurations for the interaction between fuel cells and batteries, which depend on the energy regulation, namely, passive or active configuration. Passive configuration uses passive electronics like diodes to couple the devices, it is a higher specific (W kg^{-1}) power powerplant which means simplicity in the end, but require to match voltages between FC and batteries which is not possible sometimes. Active configuration regulates the energy flows with energy electronics like DC/DC converters to adapt the operation point to optimize the efficiency, although it does not require the voltage matching between batteries and FC, but control electronics become more complex as additional sensors and actuators must be used [6].

This paper details the development and testing of a hybrid power plant, designed to be integrated in an unmanned surface vehicle (USV) for environmental monitoring. Systems such as hydrogen storage, electricity production by means of a FC and Li-ion batteries, monitoring system, navigability, positioning and propulsion subsystems will be onboard. Energy system will work in an active configuration, i.e., a DC/DC converter will fix the optimal operating point of the FC to achieve the energy demand. Nevertheless, usability of the whole platform will be extensive and will depend on the payloads onboard.

MATERIALS AND METHODS

The hybrid system will be mounted in the hull of a ship, and it is designed specifically for this purpose depending on the power requirements of the platform. The whole system can be divided in four well differentiated parts, and they will interact between each other:

Hydrogen subsystem

This system includes hydrogen piping from the gas storage tank until consumption point at FC. It also includes devices such a pressure regulator at 0.5bar, security devices (press release device PRD) and solenoid valves to control gas inlet and venting in the stack. A DC/DC converter fixes the best performance of the system depending on the energy demand. And finally, the proper hydrogen storage tank, which depending on its size, the operating time will be rise or decreased.

Battery subsystem

A battery bank is mounted as main power supply for the whole vehicle. Additionally, battery bank act as an energy buffer so the different system will simultaneously input and draw the energy. The initial conception of the system is

that batteries will assume high peak consumptions during short periods while hydrogen system supply energy to cover average demand as well as charging the battery bank. A battery bank consists in a number of cells in series (S) and a number of arrays in parallel (P). The association in series set the working voltage level and the number of parallel arrays set the capacity and the maximum instant demand from the rest of the platform. This way, as propulsion system admits up to 3 cells in series (3S), probably, the battery bank would be 3S and at least 3P. Parallel number is only limited by the maximum affordable weight of the ship.

Energy monitoring and management system (EMMS)

As a part of the above systems, the ship will be equipped with an Energy Monitoring and Management System (EMMS). EMMS consist of voltage, current, temperature and pressure sensors which allows the user to know the energy status of the platform. Those measurements let us to know where the energy is coming from and where it is spent. In addition, EMMS can decide to switch off a power source (FC or the whole system) when some maximum admissible limits are reached such as low battery, low voltage of the stack, low pressure at gas storage, etc. This is possible thanks to electronic switches (MOSFETS, transistors, etc) driven by the microcontroller in the EMMS. In active configurations, EMMS plays a special role due to it is in charge to control the DC/DC converter to couple FC to the rest of the power supply system.

Navigation and propulsion subsystem

This subsystem is responsible for moving, maneuvering and positioning the ship. By means of a flight controller board based on Ardupilot and Mission Planner software, the vessel will be able to control directional surfaces (rudder), the main motor, GPS communication for positioning as well as IMU communication for knowing the situation of the ship. Final user would schedule a trajectory to execute autonomously or would follow the route manually by means of a Radio Control (RC) transmitter. The device will increase complexity of the whole system as it needs sensors, the knowledge of the software, there are a lot of parameters to configure, etc. However, a lot of functionalities will be added, and it allow extra safety and reliability to the platform. Some of those functionalities are the return to home in case of failure, path planning, real time telemetry, payload control, video streaming, between others.

An electronic speed controller will manage the energy for the brushless three-phase motor wide used in RC field and RC servos ensure enough power to keep steering over the vessel during the whole mission.

Figure 1 shows a diagram of the whole system and the interaction between subsystems above explained.

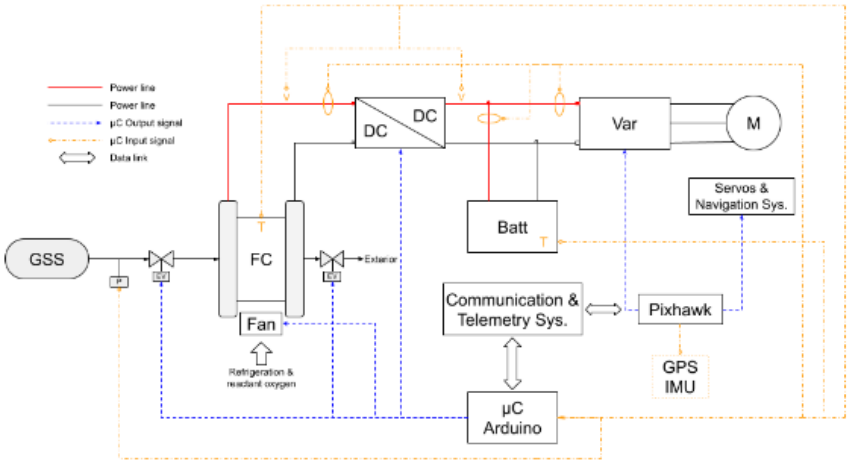

Fig. 1. Block diagram

RESULTS AND DISCUSSION

To analyze feasibility of the installation of the hybrid system, the first test consists in measuring the energy consumptions of the vehicle in a target mission, in this case the monitoring of physical, chemical and biological parameters in a lake. During this test, the vehicle was equipped with a 30A Electronic Speed Controller (ESC) and a brushless motor as a propulsion system, a Pixhawk with standard M8n GPS device as onboard computer and the very early version of the energy monitoring and management system to serve as a data-logger. The vessel was

tested at 2 knots of constant speed in a swell under 0.3 m in height. These real data serve to obtain different load profiles, which are used in test benches to evaluate the hybrid power systems configuration.

Although the power system has been designed for a higher demanding applications, for this particular mission and application of the USV, which no high speed nor sudden movements are required, the consumption is around 300 W. Energy strategy to be pursued will be that the fuel cell will cover the average consumption while battery will supply energy during power peaks in the demand due to proper fluctuations over it. In this case, the proposed hybrid system includes a 500W fuel cell, 4.7 L and 300 bar hydrogen tank and 3S-3P, 27Ah LiPo Battery. It is important to mention that the fuel cell is intended to cover a higher demand than required for this application if it means necessary.

Considering the performance of the fuel cell and converter and power density of the hydrogen at 300 bar –45 and 96% respectively and 0.7 kWh/l– available energy will be 1.37 kWh. The battery voltage and current meet ESC and motor specifications given by manufacturers. Preliminary characterization of the main components of the systems is done, and the results of the testing of the hybrid power system will be presented at the conference.

CONCLUSIONS

After several tests carried over a prototype of the USV platform, a profile of the energy demand has been obtained, and a hybrid system has been proposed to extend its operating time. The prototype vessel, powered currently by batteries would operate for 3 h in the best conditions and an average 300 W load. The hybrid system proposed will allow to increase the operating time up to 7 h, depending on the features of the hydrogen storage system, weather conditions, etc. In terms of energy density, if the vessel works with the same weight in batteries, it will reach 258 Wh/kg. By means of the hybrid system, the energy density decreases to 205 Wh/kg. Despite of its lower energy density, dead time due to recharge the system will be significantly reduced as refueling the hydrogen system only last for a few minutes. Now, tasks to integrate hybrid FC and batteries energy system in a specific test bench, in order to subject the system to a load profile similar to the one obtained previously under real conditions. Once carried a successfully test at the test bench, the hybrid system will be mounted in the real platform to assess it in a real operation.

ABSTRACT

The miniaturization movement in the recent years motivated the development of micro-combustion-based power generators. The micro-thermophotovoltaic (MTPV) relies on converting the heated micro-combustor radiation into electricity using PV cells. Enhancement of heat transfer and wall temperature distribution in a MTPV combustor is strongly influenced by the combustor structure. In this regard, a novel planar micro-combustor geometrical configuration based on creating a stable recirculation zone near the chamber wall using trapezoidal rib, is proposed. This work numerically investigated the flow and flame behavior in the proposed micro-combustor. It also studied the effect of hydrogen to air mixing ratio and the inlet velocity on the wall temperature distribution. The results shows that the wall temperature is increased by 3.4% to 9.24% with the increase of the inlet velocity and decreases for lean and rich hydrogen/air mixture by 0.33% to 3.92%. The average outer wall temperature is higher than that without ribs. The chemical reaction products locked in the recirculation zones formed around the ribs that acts just like an igniter and the flame is more stable and continuous. The proposed structure is found to have a better performance in terms of the thermal parameters of mean weighted average and non-uniformity index.

Keywords: Micro-combustion, Heat transfer enhancement, Hydrogen, Temperature distribution.

INTRODUCTION

The miniaturization movement in the recent years motivated the development of a variety of Micro Electro Mechanical Systems (MEMS) devices. Meanwhile, the conventional power supplies sources met their limits [1]. Proceeding from the urgent need, a revolutionizing alternative combustion-based micropower generator system was proposed by Epstein and Santuria in 1997 [2]. The trigger is to get advantage of the higher power density per unit of weight offered by the hydrogen combustion. In this regard, numerous of systems that vary in geometrical configuration have been developed. Such as the micro thermoelectric generator (MTEG) and the micro thermophotovoltaic (MTPV) system [3]. However, the Micro Thermophotovoltaic (MTPV) relies on converting the heated micro-combustor radiation into electricity using PV cells. Therefore, the effectiveness of the MTPV system passes basically through the improvement of the combustion efficiency and the combustor thermal performance. Which is strongly influenced by the combustor structure. So far, several experimental and numerical studies have been conducted by different researchers in order to analyse and optimize the geometrical configuration effects. Different approaches are extensively being proposed and employed. For example, Saad Akhtar et al. [4] has discussed the impact of different cross-section backward facing step on the flow and flame behavior. The results shows that the trapezoidal and triangular cross-sections are found to have the better performance. Aikun Tang et al. [5] developed a micro-combustor with a multi-mode heat transfer passages in the combustion channel. The numerical study proves the enhancement of heat transfer and the effect of the plates number and length on the uniformity of the external wall temperature distribution. Siliang Ni et al. [6] studied the effect of different rib shapes based on the mean temperature as a parameter to measure the thermal performance. It found that the two ribs perform generally better than that with a single rib and the round shape to be the optimum shape. Besides, Xiao Yang et al. [7] numerically investigated the thermal performance on proposed converging diverging combustor configuration. Results show the increase of the wall temperature by 82.39 K and the emitter efficiency by 6.59 %. Hai Chen et al. [8] proposed an improvement to the micro-combustor with wall cavity by adding a rectangular rib. The configuration is investigated under various operating conditions. Results prove that the enlargement of recirculation zone enhances the energy conversion. On this basis, this study proposed an improved micro-combustor with a backward facing step and 4 trapezoidal shaped ribs. Different operating conditions were investigated numerically using Ansys Fluent software. The mean wall temperature, the wall temperature difference and the non-uniformity of wall temperature are used as parameters of gage.

MODELIING

Physical Model

In contrary to previous studies, we introduce 4 ribs instead of single rib. The ribs have a novel shape which consist of a trapezoidal cross-section; the micro planar combustor dimensions are detailed in the Fig. 1.

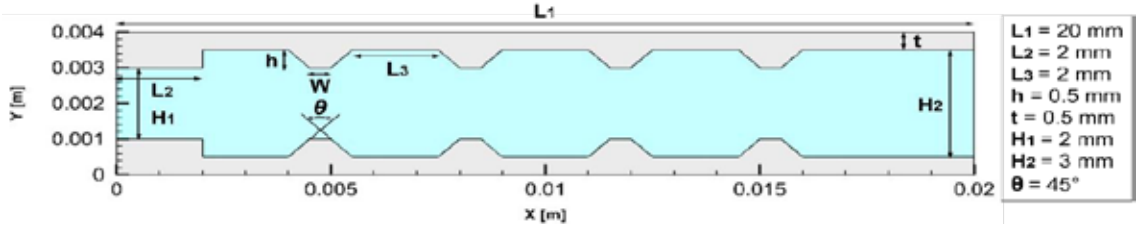

Fig 1. Schematic diagram of the proposed micro-combustor general configuration

Mathematical Model

The steady-state conservation equation of mass, momentum, energy, and species in the fluid zone can be written as:

$$\nabla \cdot (\rho \vec{v}) = 0 \quad (1)$$

$$\rho(\vec{v}.\overrightarrow{\nabla v}) = -\nabla p + \nabla \cdot (\mu[(\nabla \vec{v} + \vec{v}^T) - \frac{2}{3}\nabla \cdot \vec{v} I] \quad (2)$$

$$\nabla \cdot \vec{v}(p + \rho E_f) = \nabla \cdot \left[k_{eff}\nabla T - \left(\sum_i h_i \vec{J_i}\right)\right] + S_h \quad (3)$$

$$\nabla(\rho \vec{u} Y_i) = -\nabla \vec{J_i} + R_i \quad (4)$$

The heat along the solid zone transport purely by steady-state conduction following the Fourier's law, expressed as:

$$\nabla \cdot (k_w \cdot \nabla T) = 0 \quad (5)$$

RESULTS AND DISCUSSION

Validation of model and effect of the geometry

The results of the numerical model and the experimental data measured by Aikun Tang et al. [9] were compared as shown in Fig. 2(a). It is indicated that there is some disagreement at the inlet from 0 to 2 mm. Beyond that the maximum relative error is only around 1.06% and 1.78%. This confirms the reasonable accuracy and the model is applicable. The effects of introducing the novel ribs appears clearly by the increases of the overall outer wall temperature profile in comparison to the combustor without ribs, as shown in Fig. 2(b). We note that the introducing of ribs results an important increase of outer wall average temperature (T_{ave}) by 3.46%. Besides, temperature difference (ΔT) and non-uniformity index (Y) of the temperature distribution decreases by 15.27% and 26.86%, respectively.

Effect of inlet velocity and equivalence ratio

Fig. 2(b) show the significant effect of inlet velocity for 5 different velocities. These values were chosen based on the limitations of flash back and acoustic emission. The results show the parallel increment of temperature with the inlet velocity. The results show the increment of the average temperature with the velocity. While, decrement of temperature difference and non-uniformity up to 10 m/s and then rise again. Besides, Fig. 2(c) show the effect of 5 different H_2/air mixing ratio varies from 0.8 to 1.2, as the inlet velocity is set to 6 m/s. It can be seen that the temperature profiles decrease from 0.8 to 1.0, then slightly overlap for 1.0 and 1.1, and decrease again for 1.2. While, the non-uniformity decreases from 0.8 to 1.0 then balance.

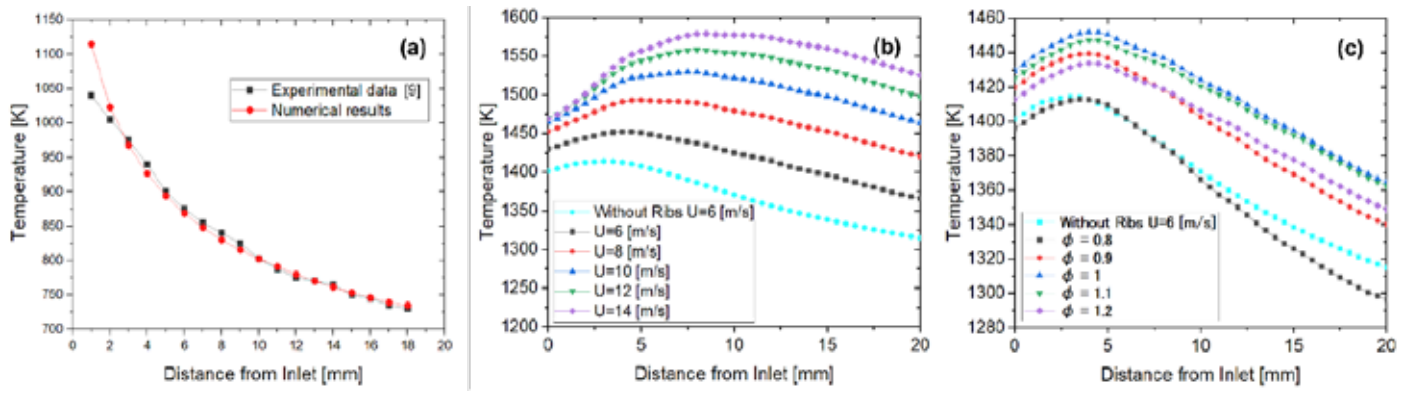

Fig. 2 The outer wall temperature distribution profiles, (a) Validation of model, (b) Effect of the ribs and the inlet velocity (c) Effect of the ribs and the equivalence ratio Φ

CONCLUSION

Compared to the micro-combustor without ribs, micro-combustor with trapezoidal ribs owns higher and more uniform outer wall temperature. Results an important increase of outer wall average temperature by 3.46% and ***decreases temperature difference and non-uniformity by 15.27% and 26.86%, respectively***. In a second step, we deduced that the wall temperature is increased by 3.4% to 9.24% with the increase of the inlet velocity and decreases for lean mixture by 0.33% to 3.92%. The temperature profile increment for inlet velocity is more uniform and the highest in magnitude. This reflects the important enhancement of heat transfer due essentially to the stable recirculation zones formed by the trapezoidal ribs. Furthermore, the equivalence ratio is found to have a slightly better performance only for rich mixture.

ABSTRACT

Storage devices play a very important role in the efficient utilization of renewable supply, since energy can be flexible scheduled by storage in time horizon and thus improve the energy utilization efficiency. It is important to plan, schedule, and coordinate storage devices together with other energy devices in energy systems. This paper proposes a bi-level planning and operation optimization problem of hydrogen-based integrated energy systems. The optimal combination and capacities of storage devices can be obtained at the upper-level. The optimal scheduling strategy of the system is obtained at the lower-level, and a scenario tree-based algorithm is used to solve the lower-level problem with the system uncertainty. The effectiveness of the developed method is demonstrated using numerical case studies. It is also found that the combination of hydrogen and water tanks is most efficient in saving cost.

Keywords: Hydrogen-based integrated energy system, Storage devices, Bi-level programming problem

INTRODUCTION

Hydrogen is well known as the ultimately conventional energy media in the 21st century due to its cleanness and sustainability [1]. Since hydrogen can be produced by the renewable supply and stored into hydrogen tanks, and then converted to electrical and thermal energy through fuel cells, hydrogen coordinated with the renewable supply is considered as a potential way to improve the utilization efficiency of renewable supply [2]. And it has attracted a lot of attention. Li et al. [3] developed an operation optimization method for coordinating the hydrogen and heating energy generated from the renewable energy sources with district heating networks to meet the demand loads. Liu et al. [4] optimized the planning of a distributed hydrogen-based energy system under several cases with different characteristics of renewable supply and demand. Dong et al. [2] studied the coordination of a hydrogen-based integrated energy system (HIES), and the utilization efficiency of renewable supply was improved through the coordinated scheduling of the HIES.

Although the above innovative results lay the foundation for the application of hydrogen coordinated with the renewable supply, the impact and performance of energy storage devices is rarely analyzed in the HIES. Storage devices play a very important role in the efficient utilization of renewable supply, since energy can be flexible scheduled by storage in time horizon and thus improve the energy utilization efficiency. However, there are many types of storage devices, how to select the appropriate storage devices is very important for maximizing the utilization efficiency of renewable supply based on quantitative performance analysis and comparison. In this paper, we focus on planning, scheduling, and coordinating different storage devices together with other energy devices in a HIES. A bi-level optimization problem for the integrated planning and scheduling of the HIES is thus presented. With the proposed formulation, the best combination and optimal capacities of storage devices can be obtained at the upper-level. The optimal scheduling strategy of the HIES can be obtained at the lower-level. And a scenario tree-based algorithm is used to address the uncertainty in both the renewable supply and demand profiles.

MATERIALS AND METHODS

Problem Statement

The focus of this paper is to study the performance analysis of different energy storage devices by investigating the integrated planning-and-scheduling problem with other devices in the HIES. The problem is formulated as a bi-level mixed integer programming problem. The investment decisions of the storage devices are determined by the upper-level problem, and it will affect the scheduling strategy in the lower-level problem. And the scheduling strategy of the HIES is determined by the low-level problem by minimizing the operation cost, and it will affect the investment decisions in the upper-level problem. As shown in Fig. 1, the HIES consists of the distributed power grid, hydrogen market, renewable energy sources such as photovoltaic (PV) panels and solar thermal collectors (STC), electrolyzer, compressor, fuel cell CHP unit, absorption chiller, heat pump, battery, hydrogen tank, and water tanks. The objective function is to minimize the annual overall planning cost of the storage devices and operation cost of the HIES over the

scheduling horizon with the time of use (TOU) electricity price. While satisfying the electrical, heating and cooling demand. A set of scenarios of renewable supply and demand profiles is used to describe the system uncertainties.

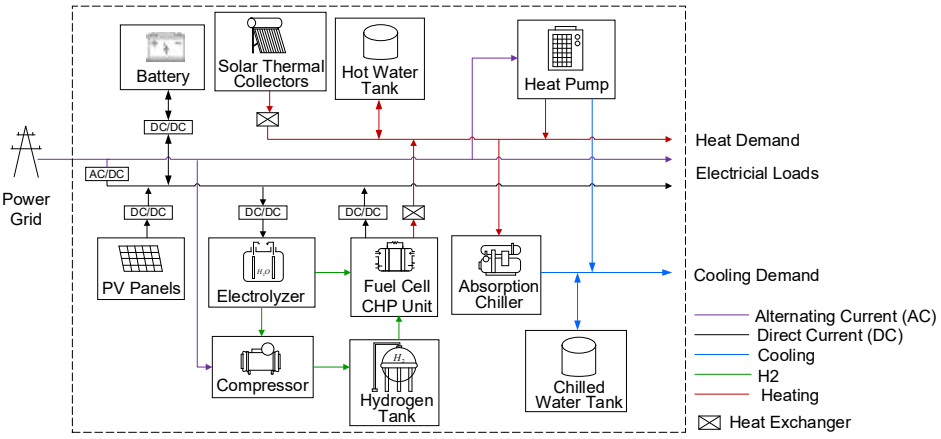

Fig. 1. Hydrogen-based integrated energy system (HIES)

Problem Formulation

At the upper-level, the objective function of the problem is to minimize the annual investment cost of energy storage devices (CPEX) and the annual operation cost of the HIES as following:

$$\min J = CRF^{ct} \cdot Q^{ct} \cdot c^{ct} + CRF^{wt} \cdot G^{wt} \cdot c^{wt} + CRF^{ht} \cdot M^{ht} \cdot c^{ht} + CRF^{bat} \cdot E^{bat} \cdot c^{bat} + OPEX \tag{1}$$

where CRF is the capital recovery factor [4]. Capacity decision variables are $Q^{ct}, G^{wt}, M^{ht}, E^{bat}$. c is unit investment cost. Upper indexes ct, wt, ht, bat represent the chilled water tank, hot water tank, hydrogen tank and battery, respectively. $OPEX$ is the annual operation cost of the HIES.

At the lower-level, considering the uncertainty of renewable energy and demand profile, a stochastic optimization problem is constructed to minimize the average operation cost of all scenarios in the scheduling horizon. Therefore, we have the following objective function:

$$\min OPEX = \sum_{i}^{I} \pi_i \sum_{j}^{J} \pi_j \sum_{t=1}^{T} \left[\lambda^{G}_{i,j,t} p^{G}_{i,j,t} \cdot \tau + \lambda^{B} m^{B}_{i,j,t} \right] \tag{2}$$

where i, j are the scenario index of the demand profile and solar radiation, respectively. t is the time period index. π is the scenario probability. λ is the price. p is power. m is mass of hydrogen. τ is the period span. Upper indices G, B represent the electricity purchased from power grid and hydrogen purchased from hydrogen market respectively. Note that the subscripts i, j indicating the scenario indices are omitted in following constraints for simplicity.

$$e^{io}_{t+1} = e^{io}_{t} + p^{bat}_{t}, x_0 = x_T, \underline{x} \cdot E^{bat} \le e^{io}_{t} \le \bar{x} \cdot E^{bat}, z^{in}_{t} + z^{out}_{t} \le 1, z^{in}_{t} \cdot \underline{p}_{bi} - z^{out}_{t} \cdot \bar{p}_{bo} \le p^{bat}_{t} \le z^{in}_{t} \cdot \bar{p}_{bi} - z^{out}_{t} \cdot \underline{p}_{bo} \tag{3}$$

$$m^{io}_{t+1} = m^{io}_{t} + m^{in}_{t} - m^{out}_{t}, m^{io}_{t} + m^{in}_{t} \le M^{ht}, z^{in}_{t} + z^{out}_{t} \le 1, 0 \le m^{out}_{t} \le z^{out}_{t} \cdot M^{ht}, 0 \le m^{in}_{t} \le z^{in}_{t} \cdot M^{ht} \tag{4}$$

$$g^{io}_{t+1} = g^{io}_{t} + g^{in}_{t} - g^{out}_{t} - g^{loss}_{t}, g^{io}_{t} + g^{in}_{t} \le G^{wt}, q^{io}_{t+1} = q^{io}_{t} + q^{in}_{t} - q^{out}_{t} - q^{loss}_{t}, q^{io}_{t} + q^{in}_{t} \le Q^{ct} \tag{5}$$

where e is electrical energy in the battery. Upper indices $io, in, out, loss$ represent the remaining, input, output and loss energy of the storage devices, respectively. Upper index bat represent the battery. x is the state of charge of battery. z is the binary variable. Subscripts bi and bo represent charge and discharge of the battery respectively. g is the heating energy. q is the cooling energy. Eqs. (3)-(5) represent the dynamics and operating constraints of battery, hydrogen tank and water tank respectively, as similar to our previous work [2], [5]. The constraints of energy balance and operating constraints of other energy devices such as the fuel cell, absorption chiller are excluded in this paper, which are similar to our previous work [2].

In this paper, a particle swarm optimization algorithm [6] is used to iteratively solve the bi-level problem, and thus obtain the optimal investment decisions of the energy storage devices. In addition, a scenario tree-based algorithm [2] is used to address the system uncertainty in the lower-level problem.

RESULTS AND DISCUSSION

The bi-level problem is tested based on an office building with 3000 m^2 at Beijing, Yinchuan, Shanghai, Guangzhou and Chongqing, China. The developed HIES includes a fuel cell CHP unit (with a rated power of 250 kW), an absorption chiller (with a rated power of 500 kW), an electrolyzer (with a rated power of 500 kW), a compressor (with

a rated power of 100 kW), a heat pump (with a rated power of 50 kW), PV panels (laying area of 1000 m^2) and solar thermal collectors (laying area of 500 m^2). The unit investment cost of battery, hydrogen tank (HT) and water tanks (WT) are assumed to be 1600 RMB/kWh, 3600 RMB/kWh and 35 RMB/kWh, respectively [4].

The optimal combination and capacities of storage devices of different locations are shown in Fig. 2. The results show that the optimal capacities of storage devices vary with locations due to the demand and solar radiation. The performances of different combinations of storage devices are tested, and the results are shown in Table 1. The results show that the combination of hydrogen and water tanks can save the overall cost by 42.6%, which is the most significant among all combinations. A winter day in Yinchuan is used as an example to demonstrate the characteristics of scheduling strategies, and the result are show in Fig. 3. It can be seen that there is a mismatch between renewable energy supply and demand. However, with the hydrogen tank, hydrogen can be converted from the renewable supply and stored into the hydrogen tank, such hydrogen can be converted to electrical and heating energy to meet the demand at other periods. Thus, the utilization efficiency of the renewable supply can be improved. During the off-peak periods (1:00-7:00), a large amount of electricity can be purchased to produce hydrogen and stored in the hydrogen tank. A part of hydrogen is consumed to produce heating energy and stored in hot water tanks. During the peak periods, the fuel cell consumes the hydrogen, which stored in the hydrogen tank, to produce heating and coordinating with the hot water tank to jointly meet the heating demand. It is beneficial to achieve the energy balance and improve the energy utilization efficiency.

Table 1. Overall cost with different combinations of storage devices in Yinchuan

Cost (RMB)	Include all devices	Without storage	Battery	HT	WT	Battery + HT	Battery + WT	HT + WT
CPEX	14411	0	7391	22733	4167	22366	4167	14411
OPEX	45114	103764	89976	46903	59500	47131	59500	45114
CPEX+OPEX	59525	103764	97367	69636	63667	69497	63667	59525

CONCLUSIONS

In this paper, we study the performance analysis and comparison of different storage devices in the HIES. A bi-level decision problem for planning and scheduling is established. In the lower-level, a stochastic optimization problem is proposed to minimize the operation cost of the HIES and solved by the scenario tree-based algorithm. In the upper-level, the optimal combination and capacities of storage devices are obtained to minimize the annual investment cost of storage devices with the annual operation cost of the HIES. The numerical results show that the developed method can effectively select the optimal combination and capacities of energy storage devices, and obtain the optimal

scheduling strategy of the HIES, as well as improving the utilization efficiency of the renewable supply. It is also found that the combination of hydrogen and water tanks is most efficient in saving cost.

ABSTRACT

A wide range of studies have analyzed the transportation of liquid hydrogen (LH_2) over long distances. This study aims to investigate the role of LH_2 in the downstream process of a greenhouse gas neutral energy supply system. The high volumetric energy density and high level of purity are two features that distinguish LH_2 from gaseous pipeline transport. An integrated energy system model covering the sectors electricity, hydrogen, and methane for Germany in a carbon neutral scenario for 2045 has been enhanced by means of liquid hydrogen transportation via inland vessel, truck, and rail.

The results of the energy systems optimization highly depend on the amount and spatial distribution of the LH_2 demands: LH_2 demands can be either served by imports and the distribution by single means of transportation as well as combination of multiple means of transportation (intermodal) or even by the inland liquefaction of gaseous hydrogen (GH_2). The promising applications of LH_2 transportation in future energy systems are currently underrepresented in the discussion around options for hydrogen distribution.

Keywords: Liquid hydrogen, Hydrogen transportation, Integrated infrastructure analysis, transportation costs, Domestic hydrogen distribution

INTRODUCTION

For the first time, a comprehensive analysis of the LH_2 transportation options by inland vessels, truck and rail is carried out within this study. These means of transport are embedded in an integrated optimization model of a national energy system including grid-bound infrastructure for electricity, gas, hydrogen, and heat.

In the current state of the literature trucks are the LH_2 transportation option featured most often in the field of energy system analyses [1–6]. Vessels for the transportation of LH_2 are primarily analysed in the context of intercontinental transport [1, 4, 5, 7]. No studies could be identified that investigate inland vessels and only in one study LH_2 transportation by rail has been investigated [4].

This work aims to shine light on mostly underrepresented means and modes of hydrogen transportation as hydrogen is expected to play a significant role in future climate neutral energy systems. From this level of importance, the need to evaluate potential usecases and applications of LH_2 transportation is derived.

MATERIALS AND METHODS

The energy systems analysis in this paper is based on the ETHOS Framework developed by the Institute for Techno-Economic System Analyses of the Forschungszentrum Jülich. ETHOS incorporates an energy system optimization model with high spatial (80 regions) and temporal resolution (8760 timesteps per year). The sectors electricity, gas and GH_2 and its corresponding components for storage, transmission, conversion as well as sources and sinks of the respective energy carriers make up the optimization model. Key objective is the minimization of the total annual costs (TAC) to obtain the cost optimal energy system design and its operation. The methodology is applied to the energy system of Germany for a climate neutral scenario in 2045 as a case study.

For the year 2045, the optimization results to demands for electricity (727 TWh/a), natural gas (39 TWh/a) and GH_2 (378 TWh/a) based on a single-region model for Germany [8]. These demands are distributed among 80 regions for Germany (derived from Voronoi regions around the nodes of the national electricity transmission grid).

The current implementation of the hydrogen domain in ETHOS includes GH_2 and its import via locations in the west and southwest of Germany, its transmission via pipeline (newly built and converted), its storage (e.g., in salt caverns) and its demands (in the transportation, industry and building sector). This paper describes the modeling of the liquid hydrogen transportation. The key aspects supply, distribution, and demand are highlighted in the following.

Supply: LH_2 can either be produced within the energy system (liquefaction of GH_2) or be imported via oversea vessels. The harbors Wilhelmshaven, Stade, and Brunsbüttel in northern Germany which are currently considered as potential LNG terminals serve as import locations for LH_2 in this 2045 case study.

Demand: Four different scenarios of LH_2 demands (cp. figure 1) are considered to identify potential use cases and modes of transportation of LH_2.

Reference Scenario: LH_2 options for transportation are introduced in the model without introducing any dedicated LH_2 demand. This shall determine whether the transportation of LH_2 is an economical option to serve GH_2 demands.

Scenario Aviation: Additional 33 TWh/a of LH_2 are introduced as a kerosene replacement for emission-free air travel. This accounts to a third of the energy content of today´s kerosine consumption in aviation. The LH_2 is spatially distributed based on the location and the passenger volume of the 24 largest airports in Germany. In two other scenarios parts of the projected GH_2 demands for 2045 are assumed to be served by LH_2 of equivalent energy content instead.

Scenario Industry: 30 % of the projected GH_2 demands in the industry sector (predominantly in the chemical sector) are replaced with LH_2 demands. This results in LH_2 demands of 78 TWh/a that are distributed according to major ammonia and methanol production sites and their production volume.

Scenario Transportation: Due to the low temperature of LH_2, contaminating gases with higher liquefaction temperatures than hydrogen are separated during the liquefaction process. This results in high levels of hydrogen purity, which is required for fuel cell applications e.g., in vehicles. In this scenario the largest fueling stations for high duty vehicles are considered to receive LH_2 instead of GH_2 resulting in a total LH_2 demand of 62 TWh/a.

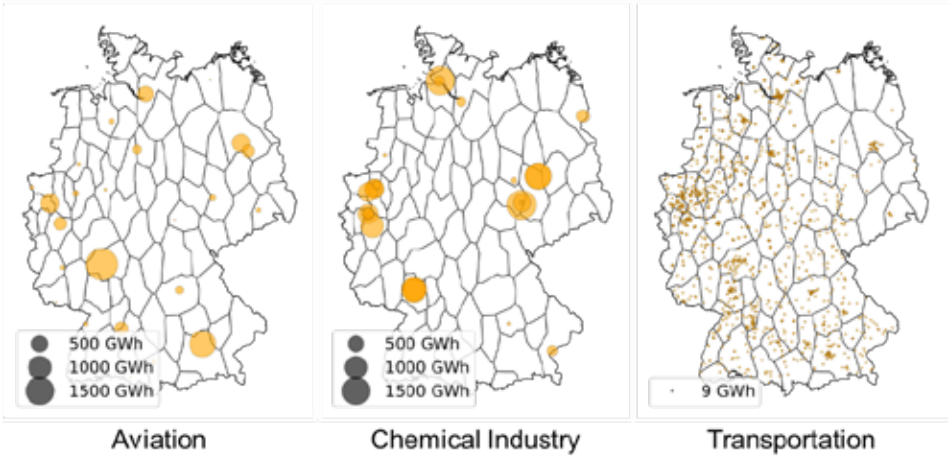

Figure 1: Amount and spatial distribution of LH_2 demands in the different scenarios.

Transportation: Rail, truck, and inland vessel are eligible candidates for LH_2 transportation as their applications in the past (rail and inland vessel transport for NASA space missions [9]) and present (truck and oversea vessels [10, 11]) demonstrate. Roads, railroads, and federal waterways serve as possible transport routes [12–15]. Using Dijkstra's algorithm, the shortest path between the region centroids is calculated for the different means of transportation [16]. Capital and operating costs are calculated á priori for each combination of regions as a function of distance and fed to the model. Due to the high rate of utilisation of the rail network and already congested route sections the transportation of LH_2 via rail is limited to two trains (each carrying 25 Waggons) per day that can be loaded and unloaded in every region. The techno-economic parameters for the three means of transportation are based on the studies [3, 7, 17].

RESULTS AND DISCUSSION

From the first results, four main observations can be made: **No LH_2 transmission is used to serve GH_2 demands when there are no LH_2 demands.** The import and distribution of GH_2 via pipeline in the reference scenario is economically more efficient than the import of LH_2 and the distribution via rail despite its higher energy density.

The ranking in terms of economic efficiency of LH_2 transportation options is rail, ship, truck. More expensive transportation option are drawn when cheaper options reach capacity limits. For railway transport, the limiting factor is the number of train deliveries per day. The limiting factor of inland vessels is the course of the waterways not connecting all regions. Regions that can not be reached by waterways are likely to be served by trucks.

A combination of transport technologies is carried out to bypass constrains of transportation options. This can be observed in the aviation scenario where the *import limit* for liquid hydrogen by rail is exceeded in the region of the Munich airport in southern Germany. For example, to overcome this limitation, LH_2 is transported to Munich neighboring region by rail then reloaded onto more expensive trucks for the last kilometers. Bypassing the *export limitation* can be observed in the transportation scenario. Only in two regions in northern Germany LH_2 can be obtained by oversea vessel imports. To extend the amount of LH_2 distributed by rail in this scenario, inland vessels are deployed to carry LH_2 to neighboring regions further inland. From there it is loaded to trains and distributed within the country.

Inland liquefaction of GH_2 can be preferred to the import and distribution of LH_2. This occurs in the industry and the transportation scenario in regions in the southwest and in the east of Germany. Reasons for preferring liquefaction over import and distribution of LH_2 lie in the high overall LH_2 demand in these scenarios and the capacity limits of rail transportation. The reasons why especially these regions rely on liquefaction can bee seen in the proximity to a GH_2 import location in the southwestern regions and the high availability of renewable energy sources in the eastern regions.

CONCLUSIONS

The results of the optimization show that LH_2 inland transportation represents a promising alternative to pipeline transportation. It can be a use case when high purity levels of hydrogen are required, when hydrogen is demanded in liquid form and when regions cannot be connected to the pipeline network. The lack of comprehensive studies on this topic shows that LH_2 transportation (especially the role of railways) is still underrepresented in the discussion of future hydrogen infrastructures.

ABSTRACT

The looming threat of global warming has elicited efforts to develop reliable sustainable energy resources. Hydrogen as a clean fuel is deemed an appealing solution to problem of the storage of power from renewable energy technologies. Among current thermochemical hydrogen generation methods, the thermochemical copper-chlorine (Cu-Cl) cycle is of high interest owing to lower temperature requirements. However, this method faces challenges such as scaling up. Therefore, it is crucial to improve the performance of the cycle in terms of designing more efficient heat exchangers to surmount such obstacles. Present study investigates a novel heat exchanger comprising a thermoelectric generator (TEG) within the Cu-Cl cycle. This configuration enables electric power production, which could be utilized in the electrolysis step of the cycle. There are several heat recovery spots within Cu-Cl cycle where conventional heat exchangers could be superseded by TEGs. The performance of the proposed heat exchanger is numerically examined using commercially available finite element software, COMSOL Multhiphysics. Impact of operational conditions on the performance of TEG has been assessed to provide insights for better understanding of the design. Results indicate that maximum generated power is 41.3 W at the matching current. Average deviation from anticipated friction factor and Nusselt number are 0.31% and 16.77%, respectively.

Keywords: Thermoelectric generator, Hydrogen, Thermolysis, Heat transfer, Copper-chlorine cycle.

INTRODUCTION

Global warming as an existential threat entails mitigation of greenhouse gas emissions resulting from the consumption of fossil fuels. Hydrogen, as a carbon free fuel, could play a pivotal role in our transition toward finding a more sustainable energy resource. Furthermore, excess energy of power plants as well as curtailed power, due to intermittent nature of most renewable and green energy sources, could be stored through hydrogen generation. Nevertheless, most of the existing methods for hydrogen production emit carbon dioxide themselves. Therefore, it is crucial to develop more sustainable hydrogen methods for substantial hydrogen generation at affordable costs [1]. Among hydrogen generation methods thermochemical cycles, especially copper-chlorine (Cu-Cl) cycle, have shown ample potential regarding zero carbon emission [2]. Cu-Cl cycle employs several reactions to split water into its constituent compounds, hydrogen and oxygen. In comparison with other thermochemical counterparts, Cu-Cl cycle possesses lower temperature requirements [1,3] although maintaining high temperature levels, near 530°C, is still inevitable for this cycle to some extent. The common 4-step Cu-Cl cycle consists of electrolysis, thermolysis, and hydrolysis reactors and emerged in response to the pressing need for surmounting concerns regarding exergoeconomic and exergoenvironmental concerns [4]. The decomposition of water into its constituent elements occurs through several intermediate stages and reactors. Previous studies aimed at investigating heat exchangers in five-step and four step Cu-Cl cycle in attempt to improve the cycle performance [3,5]. Results indicate that more effective heat exchangers would lead to better energy and exergy performances. Therefore, a shrewd approach would include design and use of efficient heat exchangers to improve the overall performance of the cycle.
TEGs, as direct energy conversion devices, produce electricity due to Seebeck effect [ref]. Key attributes such as low-cost, long life cycle, no emissions and absence of moving parts have turn them into decent low grid energy recovery devices [2, 6]. Several n-type and p-type semiconductor junctions, which are connected electrically in series and thermally in parallel form a thermoelectric module. Applying a temperature gradient to a TEG would lead to an electric current [7]. Employing TEGs alongside other energy systems, predominantly as heat exchangers and for heat recovery purposes, has been extensively studied [2, 6, 8, 9]. In the realm of hydrogen generation, TEG has been considered as a Rankine cycle condenser and the generated power has been transferred to PEM electrolyzer for hydrogen production. Results delineate that the integrated system could enhance the overall performance satisfactorily in terms of exergy efficiency and reducing total cost [2]. Thermal efficiency is usually determined using the widely accepted but rather simple approach non-dimensional figure of merit (ZT). ZT has been introduced to compare various thermoelectric materials since thermoelectric performance is highly dependent on material properties. For available TEGs in the market, ZT is approximately 1 leading to an energy conversion efficiency of around 5% [10]. Manufacturers mainly use bismuth telluride (Bi2Te3) for thermoelectric semiconductors, hence TEGs with same properties are adopted in the present study. The efficiency values of TEG based heat exchangers might seem very low; however, such devices harvest electric energy from waste heat increasing the system's overall

efficiency. Regardless of appealing aspects of Cu-Cl cycle, scaling up and improving the efficiency of the cycle remains as an inextricable challenge. Thus, methods to enhance the overall efficiency of the cycle are of high interest. There are various points in the Cu-Cl cycle where the TEG heat exchangers could be used such as steam and HCl separation unit, condenser after the dryer and/or the thermolysis. The overarching goal of the present work is to introduce a thermoelectric based heat exchanger to improve heat recovery from this cycle. Hence, a novel TEG heat exchanger within the Cu-Cl cycle is proposed and its power generation efficiency will be examined via a numerical approach. To maintain a temperature difference throughout the TEG module, the molten salt leaving the thermolysis is used to serve as the heat source while heat is dissipated from the other side of the TEG to water. In this study, a three-dimensional steady state compact model is proposed to model the thermoelectric module. Heat and electric fields for the TEG elements considered to be coupled and pertinent equations are solved numerically using COMSOL Multiphysics software. A cooling tube using water as the coolant is attached to the upper side of TEG. Another tubular chamber carrying molten Cu-Cl is attached to the lower side of TEG serving as the heat source. Boundary conditions will be applied regarding the existing data for the Cu-Cl cycle. In the quest of better understanding of the designed heat exchanger, both molten salt and water fluid fields are also modeled.

METHODOLOGY AND BASELINE CASE DESCRIPTION

TEG elements consist of two different semiconductor materials which are connected thermally in parallel. By applying a temperature gradient to the junctions, two electromotive forces will be formed, i.e., Thomson and Peltier. To gain higher levels of voltage, a series of semiconductor junctions connected electrically in series is required [11, 12]. The two main approaches to model thermoelectric devices comprise energy balance (zero-dimensional) model and heat transfer (differential form) model. In this research, a three-dimensional, steady state compact TEG model is considered to simulate the TEG unit. Owing to extreme reduction of the computational domain, this approach, i.e., compact model, reduces the computational costs substantially while maintaining acceptable error levels [12,13,14]. The fully coupled temperature and electric potential fields are solved using COMSOL Multiphysics software. Bismuth telluride-based semiconductors are considered as TEG materials. The melting temperature for bismuth telluride is about 585 ℃ [12]. In this study, working temperatures of the TEG block are kept below this value to ensure satisfactory performance of the TEG unit. The conservation of energy equations for the TEG, water circuit and molten salt circuit are solved in a steady state analysis. Moreover, conservation of mass and conservation of momentum equations have been employed to visualize fluid flow fields for both cold and hot fluids.
A schematic representation of the TEG unit and the propounded boundary conditions are depicted in Fig. 1. Top (cold) end of TEG block is attached to a tubular circuit for water flow as heat dissipating heat sink. TEG side boundaries are assumed to be adiabatic while bottom (hot) end of the unit is attached to another circuit containing molten salt. The results must be independent of number of employed grid. Thus, grid independence test is performed to examine the generated mesh for the heat exchanger. As an indispensable part of the analysis, the proposed computational model is compared with the reported results in the literature. The utilized thermoelectric model has been collated with the compact model introduced in [15]. Results demonstrate an agreement between the reported data in [15] and current investigation. Additionally, the adopted laminar fluid flow model for both molten salt and water circuits have been compared with existing results and experimentally validated formulation for such flows. Friction factor and Nusselt number are considered to verify the flow field and the thermal solutions, respectively. Average deviation of the present model results from anticipated friction factor is only 0.31% and 16.77% for the Nusselt number in laminar regime. One concern regarding the configuration of the heat exchanger is to prevent CuCl molten salt from solidification due to heat loss to the cold heat sink. Therefore, inflow Reynolds number of molten salt ought to be above 190 to ensure a continuous fluid flow.

RESULTS AND DISCUSSION

As demonstrated in Fig. 2, temperature and velocity flow fields for both circuits have been solved using a CFD analysis. Moreover, output power of the TEG unit over effective applied electric current is presented in Fig. 3. Identical to other electric generators, maximum produced power occurs at the matching electric resistance equal to internal electric resistance of the TEG itself and for the applied boundary conditions this value is about 41.3 W, at I=4.5 A. An assorted range of boundary conditions including various inlet velocities and temperatures for water and molten salt have been considered in the present work. It is expected that power generation fall behind maximum amount for higher hot inlet temperatures, owing to domination of conduction heat transfer. To compensate for conduction heat transfer due to higher temperatures, increasing the inlet velocity of water will facilitate the TEG element to have a better performance at higher temperatures, although the outlet temperature of water will decrease.

CONCLUSIONS

A TEG heat exchanger for heat recovery purpose within the copper-chloride cycle can generate electric power which can be used in other Cu-Cl reactors, namely the electrolysis reactor. This could increment the overall efficiency of the Cu-Cl cycle. This study aimed at investigating of the thermal performance of a TEG heat exchanger operating under Cu-Cl cycle working conditions. The focus of current study has been on modelling a novel thermoelectric heat exchanger numerically.

Results are within acceptable error levels comparing with existing data. Average deviation of present model results from anticipated friction factor and Nusselt number are 0.31% and 16.77%, respectively. The generated power shows a parabolic behavior with respect to the applied electric current. Maximum power occurs at the I_{max} corresponding to matching resistance. An exhaustive analysis of thermal and exergy performance of the hybrid heat exchanger could be subject of future works. Considering the exergy destruction in the heatsink is necessary to investigate the capability of the novel hybrid heat exchanger. Although applied temperatures in this study were below the melting point of TEG materials, these devices should not operate at such temperatures. Certain types of TEGs for high temperatures have been developed which could be used for empirical investigations. The model-based framework employed in the present paper could be translated to improve the design and performance of other heat exchangers for hydrogen production applications as well.

ABSTRACT

In this study, a novel system which generates cooling effect, heat, electricity, hot water and distilled water simultaneously for a green building is analyzed which operates based on solar and geothermal heat pump, proton exchange membrane (PEM) electrolysis, proton exchange membrane (PEM) fuel cell, photovoltaics, desalination system along with pressure exchanger. The results demonstrats that energy and exergy efficiencies in cooling mode are 13.27% and 32.44% respectively, and in heating mode are also 17.25% and 42.4%, respectively. The largest exergy destruction occurs in the photovoltaics and organic Rankine cycle. It is also worth noting that turbine and vaporizer have the highest portion in exergy losses of organic Rankine cycle. The unit exergy cost of cooling, and hot water, and the cost of produced distilled water and 84.5 $/GJ, 64 $/GJ and 67.63 c$/m^3, respectively.

Keywords: Zero energy building, CCHPW System, Geothermal energy, Solar energy, Exergy-economic analysis

INTRODUCTION

Solar energy and geothermal energy are two important sources of renewable energy that can be used for a variety of constructional applications, such as electricity generation, heating and cooling of buildings, and consuming water. Ezzat et al. [1] investigated the energy and exergy analysis of a new hybrid system powered by geothermal and solar energy. The results showed that total energy and exergy efficiencies are 69.9% and 42.8%, respectively. Ozturk et al. [2] studied thermodynamic analysis of a hybrid system based on solar energy, which produces electricity, heating, cooling, hot water, and hydrogen. They found that the exergy efficiency of total system is 57.35%, while it is 44.88%, 19.62%, 14.31% and 20.32%, respectively, for Rankine cycle, Rankine organic cycle, cooling/heating, and hydrogen production. Islam et al. [3] presented an analysis and evaluation on a hybrid system based on solar and geothermal energies for simultaneous production. Their results indicated that energy and exergy efficiencies are increased by the mass flow rate, while turbine inlet pressure has reverse effect on the efficiencies. Boyaghchi et al. [4] studied the optimization of a new combined cooling, thermal and power cycle containing water-CuO nanofluid based on geothermal and solar energies. The maximum daily thermal coefficient and minimum rate of price for R1234ze are 39.940% and $5819 per year, respectively.

In present study, we investigate a hybrid system with more comprehensive objectives than previously studied ones. In this combined system, photovoltaic system, Rankine cycle, heat pump, fuel cell, and water desalination system are integrated and used together for the first time to meet all energy and fresh water requirements of a residential building based on renewable energies. Economic exergy analysis of the system evaluates its implementation feasibility from the perspective of second law of thermodynamics, as well as its economic justification. Furthermore, the performance of the system is surveyed at different working conditions and the optimal values are obtained.

SYSTEM DESCRIPTION

Figure 1 depicts the flowchart of a hybrid system based on solar and geothermal renewable energies which supplies electricity, cooling and heating, hot water, and fresh water for a zero-energy building. The system includes an organic Rankine cycle, fuel cell, photovoltaic system (PV) with energy storage tank, heat pump with geothermal energy source, and reverse osmosis (RO) desalination system with energy recovery. The electrical power, heating and cooling loads, hot water consumption and fresh water demand in the residential building are 142 kW, 27.8 kW, 32.4 kW, 93.4 kW and 2.6 m^3/h, respectively.

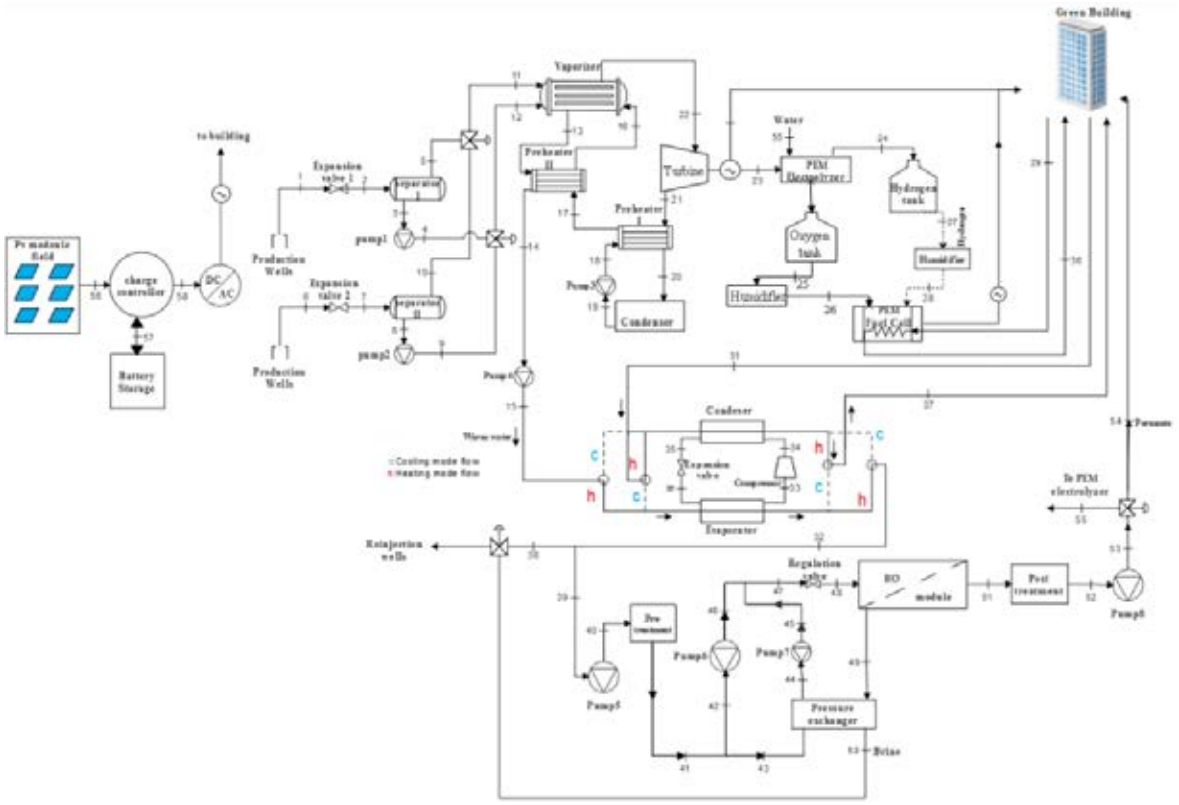

Fig. 1. Flow diagram of the simultaneous cooling, heating, electricity and water production system

ENERGY, EXERGY AND EXERGYECONOMIC ANALYSES

The governing equations for the analysis of intended cogeneration system include mass balance, energy balance, and exergy balance and cost balance. The exergy balance is written as follows [3,4]:

$$\dot{E}x_Q + \sum_{in} \dot{E}x_{in} = \sum_{out} \dot{E}x_{out} + \dot{E}x_W + \dot{E}x_{des} \quad (1)$$

The exergy destruction in the electrolyzer can be calculated using the following equation:

$$\dot{N}_{H_2O.in}\dot{E}x_{H_2O.in} + \dot{W}_{PEM} + \dot{E}x_{heat.PEM} = \dot{N}_{H_2}\dot{E}x_{H_2} + \dot{N}_{O_2}\dot{E}x_{O_2} + \dot{N}_{H_2O.out}\dot{E}x_{H_2O.out} + \dot{E}x_{des.PEM} \quad (2)$$

The PEM fuel cell voltage is consisting of ohmic, activation and concertation overpotentials and it is calculated as follows:

$$V_{cell} = E_{Nernst} - V_{act} - V_{ohm} - V_{cons} \quad (3)$$

The exergy of solar radiation is calculated as follows:

$$\dot{E}x_{solar} = I_s A\left(1 - \frac{4}{3}\left(\frac{T_0}{T_{solar}}\right) + \frac{1}{3}\left(\frac{T_0}{T_{solar}}\right)^4\right) \quad (4)$$

The energy and exergy efficiencies of the overall cycle are written as follows:

$$\eta_{en.total} = \frac{(\dot{m}_{37}h_{37} - \dot{m}_{31}h_{31}) + (\dot{m}_{30}h_{30} - \dot{m}_{29}h_{29}) + (\dot{m}_{60}h_{60} - \dot{m}_{59}h_{59}) + \dot{W}_{gen} - \dot{W}_{cons}}{\dot{m}_1 h_1 + \dot{m}_6 h_6 - \dot{m}_{RW}h_{RW} + \dot{Q}_{Solar}} \quad (5)$$

$$\psi_{ex.total} = \frac{(\dot{E}x_{37} - \dot{E}x_{31}) + (\dot{E}x_{30} - \dot{E}x_{29}) + (\dot{E}x_{60} - \dot{E}x_{59}) + \dot{W}_{gen} - \dot{W}_{cons}}{\dot{E}x_1 + \dot{E}x_6 - \dot{E}x_{RW} + \dot{E}x_{Solar}} \quad (6)$$

The cost balance equation for each component of the system is presented as:

$$\sum \dot{C}_{out.k} + \dot{C}_{w.k} = \sum \dot{C}_{in.k} + \dot{C}_{q.k} + \dot{Z}_k \quad (7)$$

Each component has it own cost equation that is used to estimate the investment cost. The main assumptions in the exergy-economic analysis are summarized in Table 1. The total cost rate includes investment, operation, maintenance, and exergy destruction costs. The cycle utilizes electrical energy storage therefore the operation hours is 7600 h.

Table 1. Summary of main assumptions

Parameter	Quantity
Annual interest rates, i_r	14 (%)
Lifetime (n)	15 (year)
Maintenance factor, ∅	1.06
Annual operation hours	7300 (h)
Hydrogen cost, c_{H_2}	10 ($/GJ)
Geothermal saline water cost, c_{GW}	1.3 ($/GJ)

RESULTS AND DISCUSSION

Herein, the results of thermodynamic analysis of the integrated system in cooling and heating modes are presented. Then, the results of exergy-economic assessment are discussed. Figure 2 shows the effect of current density on the exergy efficiency of the organic Rankine cycle in cooling and heating modes. increasing the current density, the amount of voltage and power required by the electrolyzer increase and the exergy efficiency of the Rankin organic cycle decreases. It is observed that increase of current density from 1000 A/m^2 to 5000 A/m^2 lead to almost 10% decrease in the exergy efficiency of the ORC.

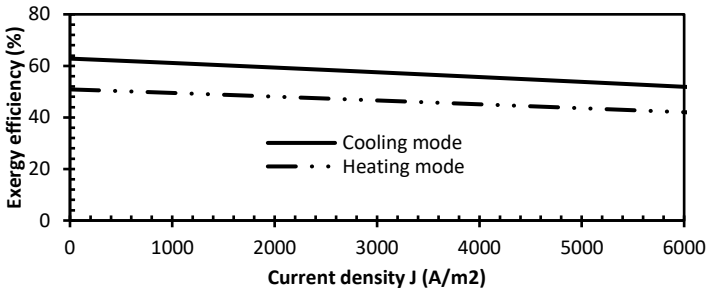

Fig. 2. The effect of electrolyzer current density on the exergy efficiency of the ORC

Figure 3 presents the effect of solar irradiation on energy and exergy efficiencies of the overall system in cooling mode. Increase of solar intensity from 200 to 800 W/m^2 cause 36% increase in the exergy efficiency. Increase of solar radiation intensity leads to higher input exergy of which large portion is wasted due to heat dissipation in different subsystems.

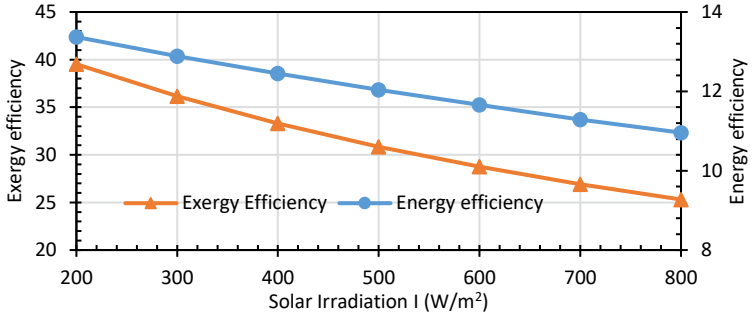

Fig. 3. Energy and exergy efficiency of the overall system in cooling mode versus solar intensity

Table 2 presents the unit exergy cost of system products. It is concluded that cooling has the highest cost per unit of exergy and electricity has the lowest cost per unit of exergy, i.e., 84.5 and 9.23 $/GJ, respectively. In this system, the fuel cell uses hydrogen (at a high exergy unit cost) as fuel for its operation; this causes a high cost per unit of exergy hot water.

Table 2. Exergy unit cost of output commodities in cooling mode

	Electric power	Cooling	Hot Water
Exergy unit cost ($/GJ)	9.23	84.5	64.06

CONCLUSIONS

- Energy and exergy efficiency of the overall system in cooling mode are 13.27% and 32.44%, respectively, and in heating mode are 17.24% and 42.4%.
- The photovoltaic panels and organic Rankine cycle cause the highest exergy destruction. Also in the ORC, the highest exergy loss take place in the turbine and steam generator.
- Increase of current density by 5 times leads to increase of exergy unit cost of the produced electricity by 11%.

ABSTRACT

This article identifies and evaluates large-scale hydrogen production processes - those capable of providing hydrogen for an eventual automotive hydrogen program in a community and along highways - to answer the following research question: which of the production processes of hydrogen is more attractive for an eventual automotive hydrogen program? To answer this question, the MACBETH method – Measuring Attractiveness by the Category-Based Assessment Technique Method and the computational code M-MACBETH 3.2.O are used. The MACBETH is a method to support complex decision making, which allows evaluating alternatives or options, taking into account multiple criteria. Thus, this work used the computational code M-MACBETH 3.2.0 to evaluate ten hydrogen production processes and build some Rankings of attractiveness of hydrogen production processes, considering the following criteria: economic (invested capital and production cost), technical (the purity of the hydrogen produced) and environmental (the amount of energy used to produce one kilogram of hydrogen and the CO2 emissions to produce one kilogram of hydrogen). In the end, MACBETH built three Rankings considering three scenarios, which allow to conclude that: a) the hydrogen production process from natural gas reforming with CCS is the most attractive alternative when economic and financial aspects prevail over environmental aspects and technicians; b) the hydrogen production process by the electrolysis process using photovoltaic solar energy becomes more attractive when the environmental aspects prevail over the economic and financial aspects; c) the process of producing hydrogen by the electrolysis process using photovoltaic solar energy is also the most attractive process when using balanced weights of economic, financial, technical and environmental aspects, in the analysis taken for decision making in relation to hydrogen.

Keywords: Hydrogen, Gasification, Steam Reforming, Electrolysis

INTRODUCTION

The hydrogen is the most abundant element in the universe; however, it is rarely found in its elemental form on Earth. So, it must be produced, which is made from some industrial processes using raw materials containing it, such as water, coal, biomass, natural gas and oil and its derivatives, using an energy source [1]. In this context, this article carried out a structured bibliographic research in order to identify the processes of large-scale hydrogen production - capable of producing quantities of hydrogen for a highway, a city, a state and even an entire nation - and at the end answers the following research question: Which of the hydrogen production processes is the most attractive for an eventual hydrogen program for the automotive transport sector, considering as criteria, the capital needed to produce, the cost of production, the purity of the hydrogen produced, the depletion in the energy matrix and in greenhouse gas emissions resulting from the production process? Thus, this work aims to evaluate the hydrogen production processes to select the most attractive process for an eventual hydrogen program for use in the automotive sector in conjunction with a cell, which has as an essential requirement the purity of the hydrogen that is supplied as fuel. The minimum hydrogen purity required is established by the International Organization for Standardization ISO 14687:2019 as 99.97%. In addition, the aforementioned standard specifies the limits for the presence of several other contaminants [2], as some of them are considered poison for a fuel cell.

There are several processes capable of producing hydrogen on large-scale for supporting a hydrogen program for the automotive sector of a city, a state and a nation. Among them, the following stand out: a) gasification; b) steam reforming; and c) the electrolysis of water.

In Gasification process, raw materials such as biomass and coal are transformed in gas in equipment called a gasifier, through a process that involves drying, pyrolysis, oxidation reduction, producing a gas composed of CO, CO_2, CH_4, H_2, H_2O. Furthermore, in the case where the raw material is coal, S, sulfur is produced. After the process of capturing CO2 and eliminating impurities, it turns synthesis gas (syngas) [3, 4].

The steam reforming process, consists of the reforming of liquid and gaseous fuels, such as ethanol and natural gas, which are transformed into hydrogen in an equipment called a steam reformer [1]. In the methane gas reformer, the CH_4 reacts with water steam. This process, after a series of reactions, produce a gas containing H_2, CO, CO_2 and ash (C) [3,4]. The ethanol reforming process, on the other hand, takes place in equipment called an ethanol reformer. This process begins when the C_2H_5OH reacts with steam water followed by a series of reactions that result in a gas composed from H_2, CO_2, CH_4, H_2O and ash (C) [3,4].

As can be seen, the synthesis gas produced by the gasification and steam reforming processes does not contain pure hydrogen and, therefore, needs to go through cleaning processes, which include the capture of contaminants and the capture of carbon compounds before storage as vehicle hydrogen, which here will be identified as CCS. There are several mature CCS processes, which make the gases produced acquire, in the end, the hydrogen content and purity necessary so that they can be burned in a fuel cell that drives a hydrogen vehicle [3,4].

In the electrolysis process, water molecules are split into hydrogen and oxygen by the electric current [3,4]. The research identified three electrolysis technologies: alkaline electrolysis, proton exchange membrane electrolysis, and solid oxide electrolysis, all of which use a reactor called an electrolyzer, which are respectively called an alkaline electrolyzer (AEC), proton exchange membrane (PEM or PEMEC) and the solid oxide electrolyzer (SOEC) [4].

MATERIALS AND METHODS

To answer this research question, the computational code M-MACBETH 3.2.0 is used, and it was developed based on the MACBETH method - Measuring Attractiveness by Categorical Based Evaluation Technique Method, which is a method to support complex decision making, which allows evaluating existing alternatives or options, taking into account multiple criteria, developed by two researchers in the 1990s [5,6]. At the end of the evaluation, MACBETH builds Rankings in descending order of attractiveness, and the alternative that presents the best score is considered the most attractive alternative.

The computational code M-MACBETH 3.2.0 was developed to be used as an interactive method to support complex decision-making and was mathematically modeled in four linear programs called Mc1, Mc2, Mc3 and Mc4. The Mc1 program analyzes the consistency of the data presented as a performance of the alternatives being analyzed. The Mc2 program suggests and builds a numerical scale of attractiveness of the alternatives, calculates the differences in attractiveness, interacts with the analyst doing the analysis and, in the end, generates reports and graphs. The Mc3 and Mc4 programs identify and reveal inconsistencies, interact with the analyst by accepting or rejecting judgments, validating or changing data [5, 6]. The MACBETH mathematical modeling will not be presented, in order not to lose the necessary objectivity in this work, however, it is very well detailed in [5,6].

The research identified several production processes, however, it was selected for analysis in this work, only those that are capable of producing hydrogen on a large scale, capable of supplying hydrogen to a city, a state or even a nation.

The selected processes were coded and registered in M-MACBETH 3.2.0 and are as follows: 1) Coal gasification without CCS **-** Primary gasification of coal producing hydrogen as synthesis gas without capture of CO_2 and without removal of impurities; 2) Coal gasification with CCS **-** Primary gasification of coal producing hydrogen as synthesis gas with capture of CO_2 and with removal of impurities; 3) Biomass Gasification without CCS - primary gasification of biomass producing hydrogen as synthesis gas without capture of CO_2 and without removal of impurities**;** 4) Biomass Gasification with CCS - primary gasification of biomass producing hydrogen as synthesis gas with capture of CO_2 and removal of impurities**;** 5) Natural Gas reforming without CCS- synthesis gas resulting from the steam reforming process of natural gas or Methane without capture of CO_2 and without removal of impurities; 6) Natural Gas reforming with CCS- synthesis gas resulting from the steam reforming process of natural gas or Methane with capture of CO_2 and with removal of impurities; 7) Ethanol reforming - synthesis gas resulting from the steam reforming of ethanol without capture of CO_2 and without removal of impurities; 8) On grid electrolysis - hydrogen gas product of electrolysis powered with energy from the electrical grid; 9) wind electrolysis - hydrogen gas product of electrolysis powered with electricity from wind generators off grid; and 10) Solar PV electrolysis - hydrogen gas product of electrolysis powered with electricity from photovoltaic generators off grid.

The research also identified several indicators that could be used as criteria in the evaluation of hydrogen production alternatives, however, it was selected and used only five criteria: 1) Purity (%) - considers the purity of the hydrogen produced measured in percentage of hydrogen contained in the gas that will be delivered to vehicle filling stations; 2) Depletion (Btu/kgH_2) - considers the amount of energy removed from the energy matrix in the form of raw material and energy; 3) Emissions (kgCO_2/kgH_2) - considers the amount of carbon dioxide that is emitted per kilogram of

hydrogen produced; 4) Costs (U$/kg$H_2$) - evaluates the cost of producing hydrogen for the alternative under analysis; and 5) Capital (US/kWH_2) - evaluates the capital needed to produce an equivalent kW of hydrogen. The performance indicators of the selected processes and object of this evaluation are shown in Table 1.

Table 1. Performance indicators

Options	Capital (U$/kg$H_2$)		Costs (U$/kg$H_2$)		Depletion (Btu/kgH_2)		Purity (%)		Emissions (kgCO_2/kgH_2)	
Coal gasification wo CCS	2,670	[8]	1.34	[3]	223,253	[7]	20	[1]	20.2	[8]

[*] Estimated by the authors; wo=without; w=with; CCS= CO_2 capture and storage.

The performance data presented in Table 1 were entered into M-MACBETH 3.2.0, which, after judgments and validation, generated several reports and graphs, including Rankings of attractiveness of hydrogen production processes. Three scenarios were considered and analyzed: scenario A considers that the decision maker has a preference for economic and financial criteria; scenario B considers that the decision maker has no preference for any of the criteria and scenario C considers that the decision maker has a preference for criteria that consider sustainability aspects. The results are shown in Figure 1 and analyzed below.

RESULTS AND DISCUSSION

Scenario A – focus on economic aspects

In this scenario, it was informed in the MACHBETH judgment matrix that the decision maker decides with a focus on economic and financial aspects. For this, they were assigned, with a weight of 30% being assigned to the capital criterion, 30% to the cost criterion, 10% for hydrogen purity, 15% for energy matrix depletion, and 15% for CO2 emission. The ranking for this scenario is shown in Figure 1, where it can be seen that the most attractive process is NG reform with CCS with a rating of 86.52 and that the second most attractive process is solar PV electrolysis with a rating of 85.54. This ranking also shows that the worst processes are those without CCS.

Scenario B – Balanced

In this scenario, it was informed in the MACHBETH judgment matrix that the decision maker has no preference for any of the criteria. For this, equal weights were assigned to each of the criteria. Thus, a weight of 20% was assigned to the capital criterion, 20% to the cost criterion, 20% to hydrogen purity, 20% to energy matrix depletion and 20% to CO2 emissions. The classification for this scenario is presented in Figure 1, where it can be seen that the most attractive process is photovoltaic solar electrolysis with a rating of 90.36. The second most attractive process is Wind Electrolysis with a rating of 90.06. This ranking shows that the worst hydrogen production processes are those without CCS.

Scenario C – Focus on sustainability

In this scenario, it was informed in the MACHBETH judgment matrix that the decision maker decides with a focus on sustainability. For this, they were assigned, with a weight of 30% being assigned to the CO2 emissions criterion, 30% to the energy matrix depletion criterion, 10% for hydrogen purity, 15% for capital, and 15% for costs. The ranking for this scenario is shown in Figure 1, where it can be seen that the most attractive process is solar PV electrolysis with a rating of 92.77. The second most attractive process is Wind Electrolysis with a rating of 92.54. This ranking also shows that the worst processes are those without CCS.

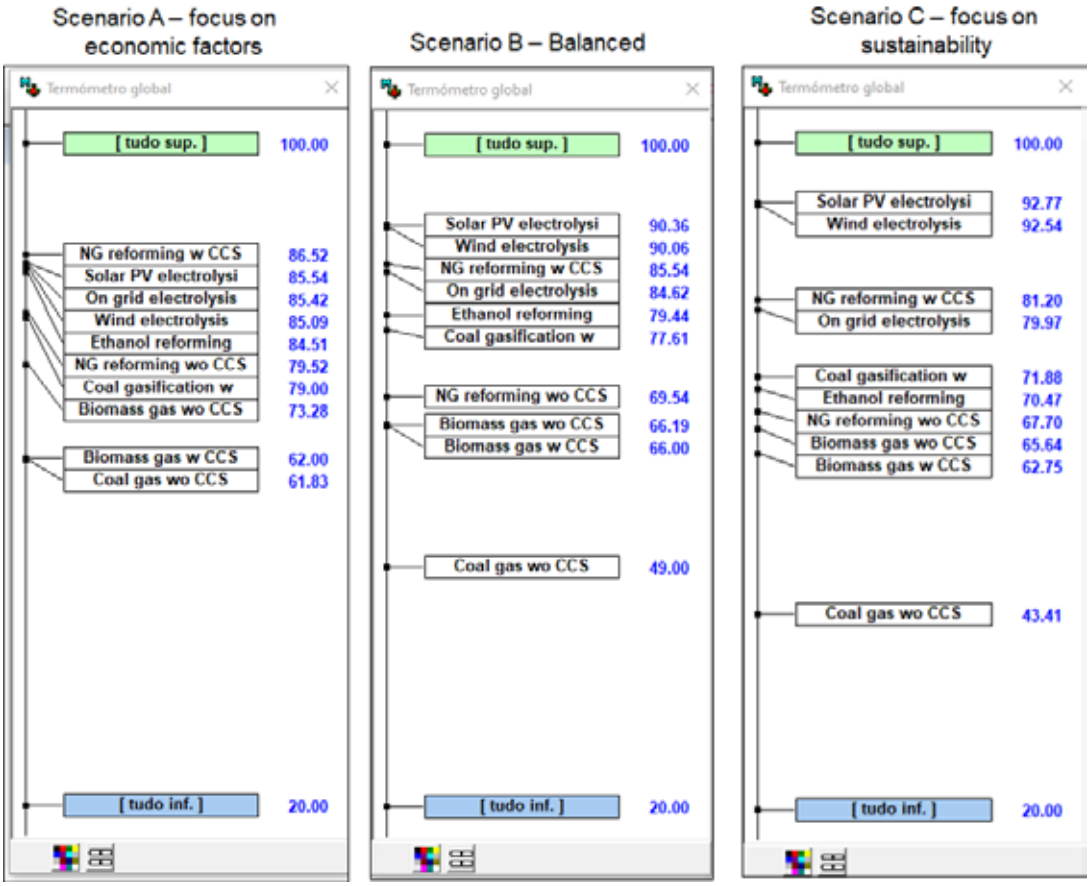

Fig. 1. Attractiveness rankings built by MACBETH

CONCLUSIONS

This work carried out a structured bibliographic research and identified ten processes capable of producing hydrogen on a large scale for an eventual hydrogen program for the transport sector. These ten processes were evaluated by the MACBETH method through the M-MACBETH 3.2.0 computational code considering economic, technical and environmental criteria. The MACBETH built three Rankings considering three scenarios, which allow us to conclude that: a) the process of producing hydrogen from the reform of natural gas with CCS is the most attractive alternative, when, in the decision-making, economic and financial aspects prevail over environmental and technical aspects; b) the hydrogen production process by Solar PV electrolysis becomes more attractive when, in decision-making, environmental aspects prevail over economic and financial aspects. This conclusion is completely in line with the current reality, since most of the hydrogen currently produced in the world is through the reform of natural gas, despite the fact that NG is a fossil fuel, finite, polluting and contributes to increase the greenhouse effect. Furthermore, this work is in line with scientists around the world, as they believe that hydrogen produced by electrolysis from renewable sources will be the energy solution of the future for the transport sector, when necessary capital and its costs come down.

THE ROLE OF RENEWABLE HYDROGEN-BASED SYSTEMS TO ACHIEVE LOW-CARBON STATIONARY POWER APPLICATIONS

[1] *Víctor Manuel Maestre,* [1*] *Alfredo Ortiz,* [1,] *Inmaculada Ortiz*

ABSTRACT

Increasing the contribution of renewable energy sources (RES) to the final energy consumed is fundamental to achieving a low-carbon economy. In this context, the use of hydrogen as an energy carrier offers a clean and versatile alternative to boost RES penetration and ensure an uninterrupted energy supply. Moreover, stationary applications account for almost 75% of greenhouse gases (GHG) emissions globally associated with power generation. This study thoroughly analyzes the state of the art and presents an overview of the evolution of renewable hydrogen-based systems (RHS) from simulated case studies to pilot plants and commercial systems for large power generation, industrial parks, buildings, and critical infrastructures. Relevant techno-economic parameters such as levelized cost of energy (LCOE), loss of power supply probability (LPSP), self-sufficiency ratio (SSR), hydrogen roundtrip efficiency (HRE), or renewable fraction (f_{RES}) are evaluated. Subsequently, the main techno-economic barriers and challenges for the deployment of RHS are identified and discussed. Finally, a pilot plant implemented in the north of Spain in the frame of the SUDOE ENERGY PUSH project is presented as a case study of the application of RHS in buildings.

Keywords: Renewable hydrogen, Stationary applications, Fuel cell, Technical feasibility, Cost-competitiveness.

INTRODUCTION

Governments, policymakers, private companies, and stakeholders are coordinating different measures to fight the unsustainable climate change situation and to ensure the required energy transition. In this context, more than 2,500 GW of RES capacity is already installed worldwide, with solar photovoltaic (PV) and wind energy predominating. However, a six-fold increase in the contribution of RES to the energy mix is required to comply with the Paris agreement [1]. To enable a higher RES penetration, hydrogen has emerged as a promising and feasible energy carrier. Accordingly, countries are focusing R&D activities on the generation of “green hydrogen” obtained through water electrolysis and renewable energy as an alternative to hydrogen produced by steam methane reforming that represents almost 95% of hydrogen generated globally [2]. Green hydrogen is an emissions-free and versatile solution that can be employed as a bulk energy storage system (ESS) or for small dispatchable backup power generation, with a fast response and long periods of full-load operation.

This study provides an in-depth overview of RHS and their deployment in the stationary sector, exploring the green hydrogen generation and power retrieval by different FC technologies. First, the different topologies and ways of integrating the components that make up each of the configurations are also evaluated. Furthermore, a global market status, trends, and main barriers beyond techno-economic ones are highlighted from a comprehensive perspective [3]. Finally, a case study of RHS pilot plant within the framework of the SUDOE ENERGY PUSH project is analyzed.

MATERIALS AND METHODS

Renewable hydrogen-based systems (RHS) are designed depending on the type of load to be supplied, the meteorological conditions of the location, the type of technologies to be used, or the budget available for the execution of the installation. Therefore, their evaluation requires a deep understanding of energy balances within the system, implemented control strategies, and load characteristics. Figure 1 depicts a general schematic diagram of an RHS that is divided into three main parts: 1) power generation, 2) energy storage and supply, and 3) load demand [4].

Renewable energies represent the primary power supply sources and their surpluses are then employed to charge the ESS (consisting of batteries, supercapacitors, etc.) and to run the electrolyzer. The generated hydrogen can be stored in vessels, pressurized tanks (needing an intermediate compressor), salt caverns, etc. The stored energy is released via direct electricity or hydrogen re-electrification in an FC system when RES is not enough to cover the demand. Besides, diesel generators and grid connections can be used as dispatchable backup energy sources to avoid power shortages, but they may imply CO_2 emissions. Microgrids with properly sized RHS and grid-tied converters may be remunerated for back feeding the power utility grid in compliance with the local legislation for self-consumption.

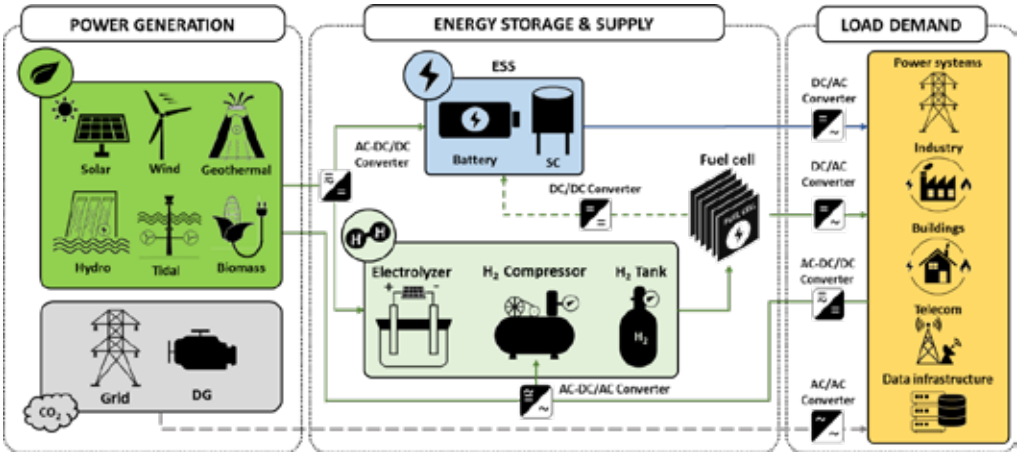

Fig. 1: Schematic diagram of an RHS including RES and fossil fuel-based power generation (through grid and DG), energy storage and supply (through hydrogen-based technologies and other ESS), and load demand (considering required power converters).

To evaluate the performance of RHS in a uniform and harmonized manner, the following techno-economic parameters are selected as the most reported ones in the literature: levelized cost of energy (LCOE), hydrogen roundtrip efficiency (HRE), loss of power supply probability (LPSP), self-sufficiency ratio (SSR), and renewable fraction (f_{RES}).

$$LCOE = C_{ann,tot} / E_{load} \quad (1)$$

$$HRE = \eta_{EL} \cdot \eta_{FC} \quad (2)$$

$$LPSP = \Sigma(E_{load}(t) - E_{gen}(t)) / \Sigma(E_{load}(t)) \quad (3)$$

$$SSR = 1 - E_{grid,imp} / E_{load} \quad (4)$$

$$f_{RES} = 1 - E_{non,RES} / E_{load} \quad (5)$$

Where $C_{ann,tot}$ is the total annualized cost of the system in US$, E_{load} is the total load consumption in kWh, η_{EL} and η_{FC} are the electrolyzer and FC efficiencies respectively, $E_{load}(t)$ and $E_{gen}(t)$ are the consumed and generated energy in every time step in kWh, $E_{grid,imp}$ is the total energy imported from the grid in kWh and $E_{non,RES}$ is the total non-renewable energy consumed in kWh.

RESULTS AND DISCUSSION

The literature reflects a predominance of PV as the main RES over wind turbines (WT) for buildings as roofs and facades can be exploited for PV energy harvesting. However, WT represent a good opportunity in remote areas without grid access and limited surface availability. The combination of PV panels and WT would reduce the energy storage needs. In addition, the reduction of loss of power supply probability (LPSP) and the increase of the renewable fraction (f_{RES}) and self-sufficiency ratio (SSR) enlarge the system size and investment needed. Reduced hydrogen roundtrip efficiencies have the same impact on the configuration dimensions and economics. Finally, despite the current high CAPEX of hydrogen-related technologies in comparison with fossil fuels, off-grid hybrid schemes may present a competitive levelized cost of energy (LCOE) in mid and long-term scenarios.

Concerning real implemented systems, large-scale pilot projects focus on the decarbonization of the utility grid and industrial applications using multi-MW fuel cells to get heat and power and benefiting from waste streams with high hydrogen content or biofuels. The waste heat produced can be used for district heating or within industrial processes. At lower scales, RHS schemes contribute to the decarbonization of micro-grids, residential communities, and other remote applications; while micro-cogeneration and stationary FC systems are the main alternatives for buildings due to the lower complexity and space requirements. These trends are also reflected in commercial devices that are paving the way towards carbon neutrality by 2050. However, different barriers apart from techno-economic boundaries arise to achieve broader deployment of hybrid systems. Thus, hybrid systems require focused, consistent and specific policies to establish a solid legal framework to create a robust hydrogen infrastructure.

CASE STUDY SUDOE ENERGY PUSH PROJECT

The SUDOE ENERGY PUSH project proposes an innovative solution for the overall management of social housing located in the regions of southwestern Europe as a reference to increase the energy efficiency of public buildings and improve the quality of life of disadvantaged citizens. Through the combination of passive renovation, RES, and

BIM methodology, it aims at reducing the consumption and emissions of buildings and at improving the comfort of the inhabitants, overcoming the risks of energy poverty [5]. In this context, a pilot plant combining RES and hydrogen technologies will be implemented in social housing in Cantabria (Spain) to demonstrate the feasibility and benefits of the system depicted in Figure 2. This demonstration is aimed at achieving energy self-sufficiency of the house without needing neither electricity from the grid nor fossil fuel-based ancillary gensets during the year. In addition, further RES surpluses that cannot be stored will be re-injected into the grid so that the inhabitants can obtain extra remuneration.

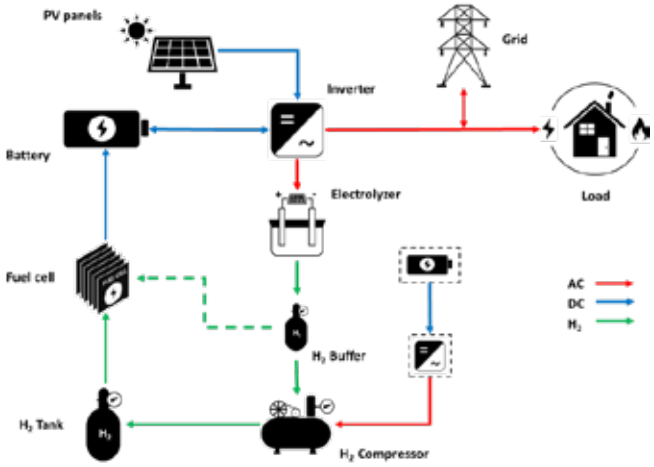

Fig. 2: Schematic diagram of the hybrid renewables hydrogen-based system in Cantabria (Spain)

CONCLUSIONS

The combination of RES and emerging hydrogen technologies is continuously evolving as a solution to achieve the required energy transition of the stationary sector. Both are well-known technologies, but their integration is in an early stage of development. Thus, several studies have been conducted, and a variety of pilot plants from few kW to multi-MW systems deployed to assess their potential. Despite the successfully implemented systems worldwide, there are still pending challenges to overcome for a broader deployment of RHS in the stationary sector. Apart from the lack of dedicated infrastructure, defining proper regulation, codes, and standards for safe hydrogen management combined with dialogue, education, and experience is crucial to encourage end-users awareness. Therefore, the SUDOE ENERGY PUSH project aims at improving energy efficiency management, combating energy poverty, and achieving greater social acceptance of hydrogen-based technologies among the most disadvantaged inhabitants by implementing a pilot plant.

CONTROL STRATEGIES FOR THERMAL COUPLING SYSTEM OF FUEL CELL AND METAL HYDRIDE TANK: A REVIEW

[1] Jiaxuan Liu, [1*] Fusheng Yang, [1] Zhen Wu, [1] Zaoxiao Zhang
[1]School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an, China

ABSTRACT

The utilization of hydrogen storage unit in distribute energy system (DES) attracts wide attentions, and storing hydrogen with metal hydrides (MH) have been explored as a promising way considering the high volumetric density and relative safety. To improve system efficiency and compactness, the thermal coupling of fuel cell (FC) and MH tank is proposed. However, the strong interactions in the system introduces challenges for meeting the power demand satisfactorily, thus various control strategies have been proposed. The aim of this study is to review the control strategies of thermal coupling system in multiple scenarios comprehensively. The literature survey illustrates that the traditional linear controller e.g. PID can realize a good tracking performance in some application, but the output may fluctuate with fast-changing signal, and nonlinear multi-input-multi-output (MIMO) controller is hence recommended in this case.

Keywords: Thermal coupling, Metal hydride, Fuel cell, Control strategies

INTRODUCTION

To integrate large amounts of renewable energy like solar and wind power, the distributed energy systems (DES) has gained a lot of interest in recent years [1]. However, the inherent randomness and intermittence of renewable energy source (RES) hampers the development of DES. On the other hand, the energy storage system (ESS) has been proven as a feasible solution to alleviate this problem and becomes a necessary component for DES [2].
Hydrogen is set to become a promising energy carrier for long-term energy storage due to high gravimetric energy density and convenient transportation [3]. Compared with the conventional hydrogen storage technologies e.g. compressed gas and liquefaction, storing hydrogen with metals hydride (MH) has seen rapid development in recent years due to its high volumetric density, relative safety and wide range of operating temperatures and pressures [4].
In MH storage tank, the mechanism of hydrogen absorption/desorption is reversible reactions between MH and hydrogen. However, large amounts of heat need to be removed or provided to maintain the desired reaction rate. For this sake, a variety of thermal management solutions have been proposed, as reviewed by Nguyen et. al [5]. On the other hand, the heat generated by FC system is also need to be dissipated to avoid overheating, thus the removed heat can be recovered by MH storage tank during desorption, and the feasibility of this thermal coupling system (TCS) has been first confirmed by Jiang et. al [6]. Although the TCS is projected to be of great benefit for system compactness and efficiency, the heat provided by FC will influence the desorption rate of MH significantly. In addition, the output of FC is often irregular due to the unpredicted power demand. Thus, a higher requirement for control strategy of TCS is put forward.
Actually, Lototskyy et. al [7] reviewed developments in hydrogen storage systems integrated with fuel cells. Particular emphasis was laid on the MH material selection and container design. Various control strategies for individual PEMFC subsystems were discussed by Wu et. al [8]. However, there is a lack of review associating with control strategies of TCS. This paper is dedicated to summarize the control strategies of TCS focusing on system structure and control method. The discussion starts with a brief introduction of thermal coupling approaches and then is followed by a critical review of control strategies distinguished by linear and nonlinear controller. Finally, several gaps and search directions are addressed.

THERMAL COUPLING APPROACHES

The thermal coupling approaches can be divided into passive and active types based on the controllability, as shown in Fig. 1. The passive approaches include direct contact heat transfer and heat pipes. Kang et al. [9] proposed a direct heat exchange method, and the FC in TCS shows a 31% increase in maximum power compared with single one. The feasibility of TCS utilizing heat pipes was proven by Tetuko et al. [10], and the simulation results showed the maximum hydrogen flow rate of each tank increases by additional heat significantly with low maintenance. In addition, the heat transfer effect can be adjusted based on the equilibrium pressure and boiling point of liquid in heat pipes.

The active types include air-cooled and liquid-cooled approaches. Zhu et al. [11] analyzed a mathematic model of air-cooled TCS considering the degradation of FC and MH, and the exhaust air from FC stack is blown to the external surfaces of the MH tank. The results demonstrated that for a stable operation of 1000 h, the voltage degradation of PEMFC is reduced from 6.8% to 4.5% by thermal coupling, and this kind of TCS has been proven to be effective for small size FC (< 2 kW) due to low convection heat transfer coefficient of the exhaust air and thermal conductivity of the MH tank [12,13]. Førde et al. [14] investigated a liquid-cooled TCS by experiment. The exhaust heat from FC was recovered through a U-tube heat exchanger embedded into the MH tank. The results indicated that the MH tank can supply the hydrogen demand for 3h at the maximum power of FC, and about 25% of total cooling load of the PEMFC is sufficient for MH desorption.

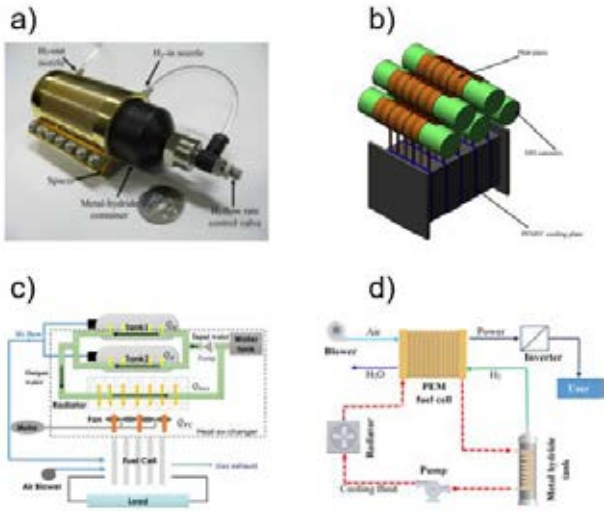

Fig. 1. Thermal coupling approaches; a) direct heat exchange [9]; b) heat pipes [10]; c) air-cooled [11]; d) liquid-cooled [14].

CONTROL STRATEGIES OF TCS

One of the major concerns of control strategies is controller design. Mostly, the linear controller is developed by approximate linearization, while nonlinear controller is integrated with intelligent algorithm. Table 1 summarizes part of the control strategies of TCS based on different controller and control variable. It can be seen that most of the control variables for TCS focused on the thermal management system, and mainly linear controller is adopted.

What's more, from the recent simulation research of TCSs, the lumped model is often adopted whose error between experiment is non-negligible for large-scale system. On the other hand, it's hard to analyze a TCS using the multi-dimensional model due to high computational expense. Thus, it is necessary to propose a novel analysis method with both acceptable accuracy and efficiency for TCS.

Table 1. Summary of control strategies of TCS.

Research method	Control variable	Controller	Ref
Simulation and experiment	Fan power	PID controller	[11]
Experiment	Water mass-flow rate	On/off-switching controller	[14]
Experiment	Gas mass-flow rate	NI-PXI control system	[15]
Experiment	Fan power	PID controller	[16]
Simulation	Water mass-flow rate and fan speed	Two PI controller	[17]
Simulation	Water mass-flow rate	Rule-based controller	[18]
Simulation	Water mass-flow rate	PI controller	[19]

CONCLUSIONS

The paper presented an extensive review on control strategies of TCS. One of the main technical challenges of system control are irregular power demand and nonlinearity of MH reaction. The thermal coupling approaches can be divided into passive and active types base on the controllability. The enhancement of convection heat transfer and thermal conductivity of the MH tank should be taken into account for the air-cooled method, whereas the liquid-cooled method is more compact in large-scale system. For system control, linear controller is often used in research whereas the output may fluctuate with rapid power change. Two separate controllers are adopted for better control effect but a coordination operation for controllers should be considered. Thus, a multivariable nonlinear controller is required.

Furthermore, an analysis method with both acceptable accuracy and efficiency for TCS remains an open issue to be addressed by future studies.

GREEN MILITARY SITE SUPPORTING PUBLIC HYDROGEN MOBILITY

[1] Mitja Mori, [1] Urban Ž. Baškovič, [1] Boštjan Drobnič, [2] Robert Šipec, [1*] Tomaž Katrašnik*

[1] University of Ljubljana, Faculty of Mechanical Engineering, Aškerčeva 6, Ljubljana, SI-1000, Slovenia

ABSTRACT

To support the energy transition in the defence sector, transport, and power generation sector at the local level simultaneously, a detailed virtual analysis was conducted with an aim to convert military sites from a conventional consumer of external energy vectors to an energy positive hub and at the same time ensure independent operation in case of emergency circumstances. This was achieved by coupling of green energy sources, where geographic conditions favour solar energy, and zero emission storage devices with the main energy storage being hydrogen, which is supported by the batteries. This approach enables multiple shifts of paradigms: a) development of a stand-alone green energy system for military sites, b) converting military sites to energy positive hub for powering military and civil vehicles with green energy vectors (cumulative on-site production of electricity and hydrogen exceeds the electricity consumption by over 50 %), c) achieving autonomous energy operation for several days or weeks depending on the sizing of the system and concept of operation (with normal energy consumption the site can be autonomous for 30 straight days during 60 % of the year and with some reduction in energy consumption 30 day autonomous operation can be achieved throughout the entire year), and d) achieving, on the yearly basis, low or in some cases net negative carbon footprint of military barracks including support of the mobility sector (carbon footprint can be reduced by as much as 70% with respect to grey H_2 production). Such an approach ensures higher robustness of energy supply and storage, construction of hydrogen mobility infrastructure, and the support of local communities through green hydrogen production.

Keywords: Green hydrogen, Military site, Mobility, Sector coupling, Carbon footprint

INTRODUCTION

Military site in the study represents an island energy system (energy hub), which is required to operate independently from external energy sources in emergency situations. For normal operation the system is also connected to the grid and can offer it's resources to community. Self-sufficient military sites are planned to form a network of energy hubs across Slovenia and EU forming Defence RESilience HUB Network in Europe [1]. This is important direction in the energy transition of the EU defence sector based on renewable energy sources (RES) with low carbon footprint (future decarbonization), energy storage systems (hydrogen, battery) and the possibility to act like a prosumer (producer and consumer) in the EU energy system. The basic topology of the energy hub (Fig. 1), in which solar panels, battery, PEM electrolyzer, hydrogen tanks, and PEM fuel cell are the main components, was designed based on the strict military energy requirements, considering the basic energy balance and the 3-, 10-, and 30- days autonomy and predictions of hydrogen mobility in military environment and local community. As a prosumer, energy hub transfers PV electricity to electricity grid and the hydrogen provided also for public mobility sector (sector coupling). The military energy hubs represent an important building block in the hydrogen road map of the EU in the transition to more sustainable energy sources [2].

METHODOLOGY

A numerical model of the observed energy system was developed to evaluate the operational characteristics of the system based on various input parameters, including onsite available RES, power consumption, and component's characteristics. Topology of the energy system allows to achieve predefined goals of the study, designed to fulfil military standards and to achieve high share of renewable energy within the energy system: (i) PV electricity production should be maximized and used to produce green hydrogen; (ii) Hydrogen is stored in storage tanks to enable off-grid operation of the site; (iii) Hydrogen is primary used for mobility, alternatively it is used in PEMFC during off-grid operation of the site; (iv) Battery should be utilized for day-night storage; (v) Electricity production on a yearly basis should be higher than electricity consumption; (vi) Hydrogen and electricity can be supplied from external source or grid.

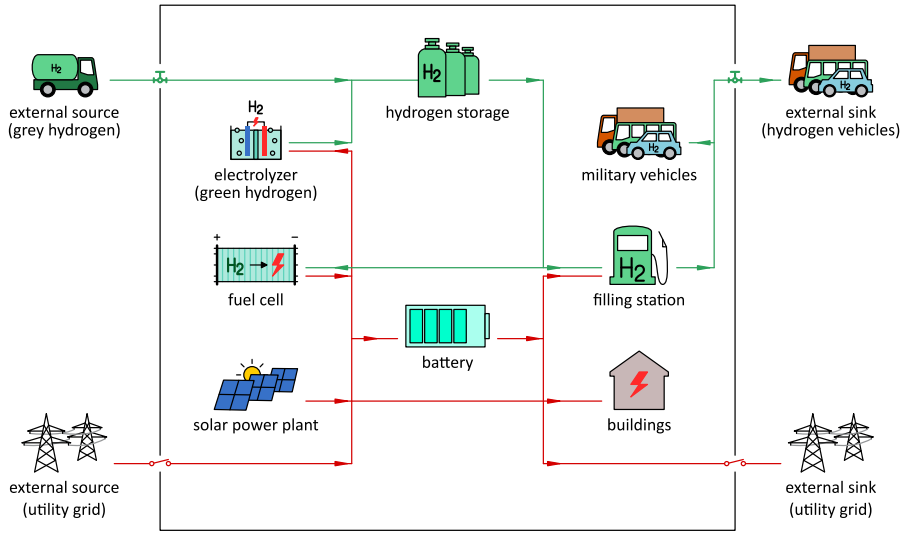

Fig. 1: Topology of the military energy hub for Peter Petrič barracks in Kranj, Slovenia.

The operation of the proposed system was evaluated monthly, considering electricity consumption profile of the barracks, the available RES (solar radiation), the required hydrogen consumption at the refuelling stations, and the characteristics of the power system components (efficiencies, performance, and capacity). Electricity consumption of the site is based on measured consumption over several years while estimations were made regarding hydrogen consumption and additional electricity consumption for hydrogen production, storage and further use. Availability of RES was estimated with respect to available data for typical meteorological year (TMY).

RESULTS AND DISCUSSION

Operating characteristics of the designed energy system are presented in Fig 2a, which summarizes integral values on a yearly basis, and in Fig. 2b, which summarizes results on a monthly basis. The thin columns represent electricity consumption, and the thick columns represent electricity generation or transfer from the grid.

a) b)

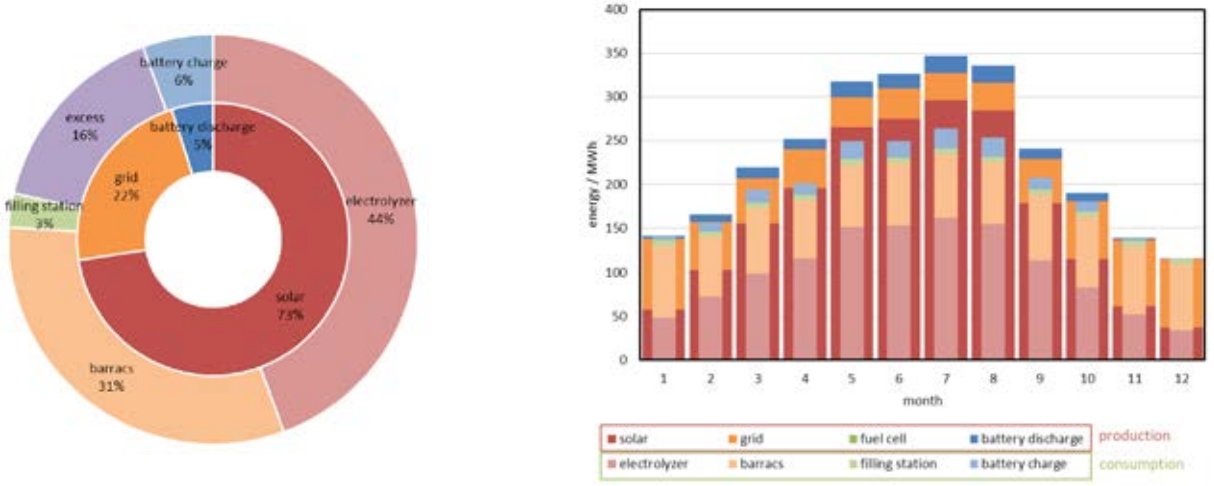

Fig. 2: Monthly (a) and yearly (b) generated and consumed electricity in Peter Petrič barracks in Kranj, Slovenia.

The largest consumer of electricity (44 %) is the electrolyzer, which produces hydrogen for the refuelling stations, and the second largest (31 %) are the barracks. The rest of the electricity is used to recharge batteries during the day and to power refuelling stations. About 16 % of the electricity produced by PV is transferred into the grid as green electricity, reducing the carbon footprint of the energy hub and generates avoided environmental impacts in the electricity grid of the region or country. On the production side, most electricity is generated by PV system (73 %), followed by the electricity grid (22 %). The military energy hub is not completely independent in baseline operational regime (no crisis, no natural disasters, etc.), since 6 % of the electricity still must be transferred from the grid. But when crisis occurs the military energy hub is capable of autonomous operation for a longer period relying just on

internal energy sources without being connected to the grid or outside hydrogen source. To further evaluate the operation of the energy hub monthly integral data are analysed in Fig. 2b. During the warmer months with higher solar radiation (May through August) PV electricity can power all the loads, providing complete independence. Nevertheless, a certain amount of electricity from the grid is needed for the operation, as the battery capacity is not sufficient for the night-time operation and on days with lower solar radiation intensity. During the summer the hydrogen storage state of charge (SOC) increases, so the energy system can operate into the fall without additional hydrogen from external sources. During the rest of the year, electricity consumption is higher than PV electricity generation resulting in the need for additional electricity from the grid even during the day.

In Fig. 3 three cases of the carbon footprint for the military energy hub are presented. "*H2 grey in*" is the case where all H_2 (grey) is distributed to the military energy hub from the outside distributor and "*H2 onsite*" is the case, where hydrogen is produced onsite with PEM electrolyser using electricity from the grid that is in the case of Slovenian Ministry of Defence low carbon electricity with 131 $gCO_2eq./kWh$. The *"model case"* carbon footprint consist of H_2 that is distributed to the military place from outside, the electricity that is provided from grid and the electricity for onsite H_2 production (mobility, PEMFC) and consumption which is generated with the PV system. However, the green electricity distributed to grid presents negative carbon footprint since it reduces the need for electricity from non-renewable sources, so the combined effect is much lower than in other two cases. Further, if in the "model case" the green H_2 would be distributed to the military energy hub the carbon footprint reduction would be even bigger, and we would approach near zero carbon footprint.

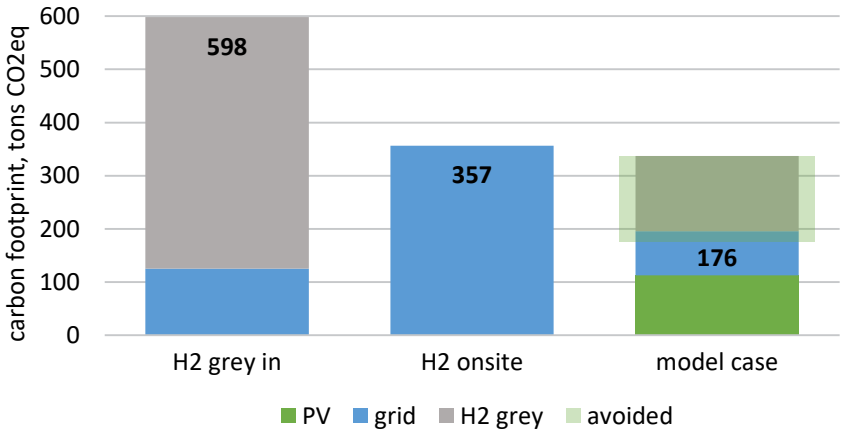

Fig. 3: Carbon footprint of the electricity generation and hydrogen for mobility.

Results show we can expect carbon footprint to be much lower in the "Model case" (-70.6 %) than in the case of distributing grey H_2 to the site or even producing H_2 onsite with low carbon electricity (-40.4 %). The main reason for that is the generation of green electricity that is transferred to the grid, therefore avoided impacts occur relative to the normal electricity production scenario in the grid. Although the need for electricity from the grid is necessary to operate the barracks, the proposed energy system has a significantly lower environmental footprint than the current energy system that relies solely on electricity from the grid, and most importantly, the proposed energy system allows to produce 17.2 tonnes of green hydrogen per year to support hydrogen mobility.

CONCLUSIONS

The designed system model provides the basis for transition to green technologies by coupling different sectors and could be further optimized in terms of component characteristics based on additional input parameters, including the requirements for autonomous operation of the military site and the change in energy performance of the buildings within the military site after optimizing their energy consumption. Further, if the energy hub is a part of a Defence RESilience HUB Network in Europe it can use the green hydrogen not only from its own production, but green hydrogen can be transported from other military energy hub to enable sustainable energy supply.

ABSTRACT

A data-driven simulation approach is proposed in this study to minimize the development process and efforts of hydrogen combustion-based energy systems. For this purpose, both reacting and non-reacting large-eddy simulation of a turbulent diffusion type burner is conducted to generate the data, which will be trained further using an artificial neural network that predicts the reacting field from a cold flow field. The training data consists of a non-reacting flow field as an input value, from which the neural network should predict the reacting flow, and a reacting flow field is treated as the true value. In the training phase, the prediction of the reacting flow from the former non-reacting flow is compared with the latter reacting flow. In addition, a governing equation is considered in the comparison.

Keywords: Hydrogen combustion, Large eddy simulation, Reacting flow, Non-reacting flow, Artificial intelligent

INTRODUCTION

Hydrogen combustion is considered the next-generation power source, which is carbon-free and energy-efficient. In addition, its utilization is also economically sustainable since the existing conventional combustion technologies can be applied to it. Currently, hydrogen-fueled combustion systems are in active development by many companies [1-3]. However, the development of hydrogen-combustion technologies requires more effort than conventional combustion because of its properties, such as the higher flame speed and temperature, resulting in a high-cost experiment or higher simulation effort.

The development of a combustion chamber requires an interactive optimization cycle starting from prototyping a combustion chamber, then a numerical investigation followed by experimental investigation, and finally a system validation [4]. If this optimization process can be achieved by utilizing a model-based numerical study, as it is done in the automobile industry, the development cost could be reduced drastically. Currently, the usage of combustion simulation in the industry is still not widely adopted, compared to a computational fluid dynamics or structural simulation. The non-reacting flow can be easily utilized to design the rough dimension of the chamber. However, this must always be validated through any experiment, which leads to a longer optimization cycle and higher cost.

A numerical simulation of hydrogen combustion is not widely performed because it consumes a very high calculation power than conventional fuels like methane because of its higher flame speed. In addition, compared to the reacting simulation of conventional fuel, the spatial and temporal resolution must be higher in order to get a valid result. Moreover, while it requires a calculation power of many-core processors in high-performance computers, they are often located in highly-advanced research facilities, in which the companies cannot run large numbers of simulations.

To overcome the problem of limited computational resources, a coupling of a reaction-free flow field and reacting combustion flow field by a physics-informed neural network is proposed. This work aims to use a small number of large-scale simulations to train a network, which will then emulate many numbers of reacting flow under different conditions. As a result, it can increase the number of numerical investigations instead of experiments, leading to a shorter development cycle and total cost.

NUMERICAL SETUP AND METHODS

Figure 1 shows the whole main concept developed in this research. In general, two main research steps are conducted, including combustion data generation and data training. In the former, a large-eddy simulation (LES) is conducted in this study to generate both reacting and non-reacting combustion data. The generated data is then validated using the experimental data from the German Aerospace Center (DLR).

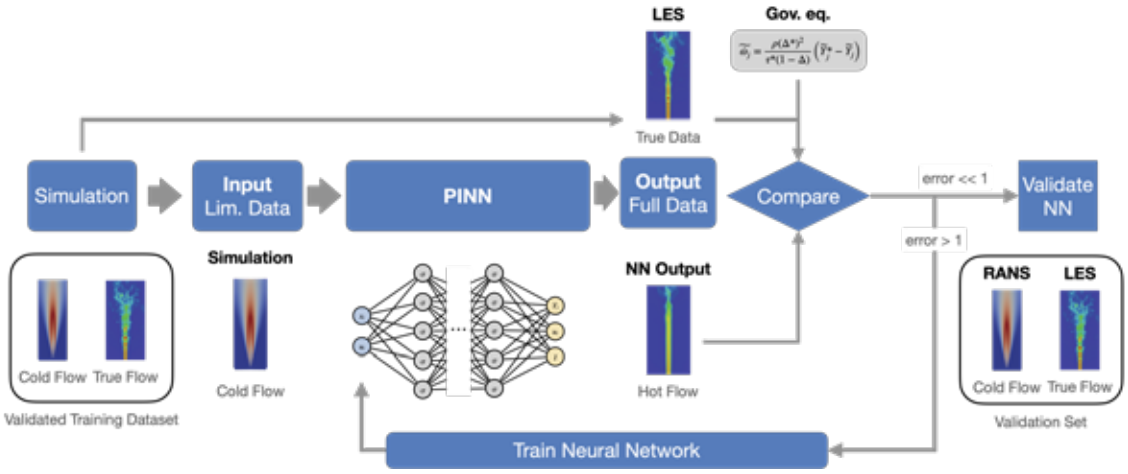

Fig. 1. Illustration of the research concept.

The study case of this research is an $H_2/CH_4/N_2$ Jet Diffusion Flame (= DLR Jet Flame)[5, 6]. The fuel consists of 33.2% H_2, 22,1% CH_4, and 44,7% N_2, and it is supplied from a tube having an internal diameter of 8 mm velocity of 42 m/s. Around the fuel inlet, the co-flow air is supplied from a nozzle having an internal diameter of 140 mm and velocity of 0.3 m/s.

The numerical simulation is conducted using the open-source software OpenFOAM[7], with the reactingFoam solver. The numerical setup is based on the previous paper by Mitani et al. [8]. For this study, a cylindrical computational domain has been used. The non-dimensionalized sizes based on the fuel tube diameter are 17.5D in the radial direction and 62.5D in the axial direction. This has been divided into 75 cells in a radial direction, 60 cells in a circumferential direction, and 500 cells (Fig. 2).

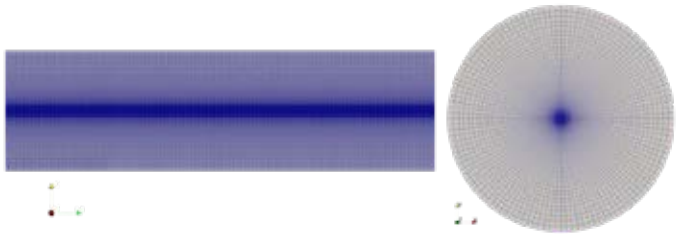

Fig. 2: Computational domain: side view (left) and top view (right)

The boundary condition is set according to Mitani et al. [8]. The fuel inlet velocity profile is according to the 1/7-th law of the turbulent pipe flow.

$$V_{axial} = V_{\max}\left(1 - \frac{r}{1.01R}\right),$$

with $V_{max} = 49\ [m/s]$.

The co-flow air is assumed to have a uniform velocity of 0.3 m/s. The domain is under atmospheric pressure, whereby the inlet has a zero gradient pressure condition. The surrounding hull of the domain is considered as free-boundary, to prevent unwanted pressure vibration. For the turbulent and combustion turbulent modelings, the Smagorinsky and eddy dissipation models have been adopted.

After obtaining the result of the simulations, the training of the artificial neural network is conducted. The cold flow field is fed into the neural network, and by comparing it with the true combustion field and the governing equation, the parameter of the network is adjusted. Once the error of the output has reached the tolerance value, the network is validated by new data that differs from the training data set.

RESULTS

As the preliminary results of the study, an LES for non-reacting flow has been conducted, continued with the reacting flow. Fig. 3 shows the instantaneous velocity and the pressure field obtained in this study. In general, the fuel is distributed well starting from from the fuel nozzle to the outlet, and has an intereaction with the air which is fed from

its surrounding. The pressure across the combustion chamber is also distributed uniformly. These preliminary results (non-reacting simulations) are very important for further simulation and data training.

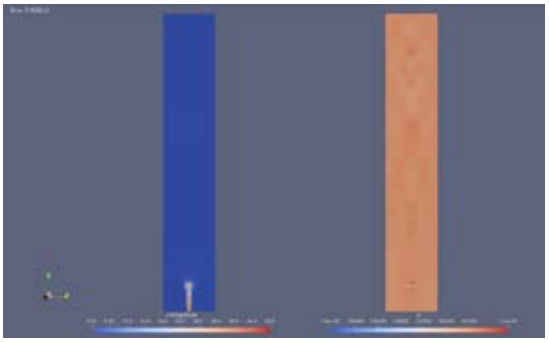

Figure 3: Preliminary result of the velocity (left) and pressure (right) field of the non-reacting flow.

CONCLUSIONS AND FUTURE OUTLOOK

This research aims to shorten the development process of the hydrogen combustion chamber. The number of optimization iterations can be decreased by emulating the combustion field by inputting a cold flow field. The emulation is performed by a neural network; hence, the result can be obtained in a very fast manner and significantly cost-effective. Nevertheless, a beforehand training of a neural network is necessary, but considering the universal applicability, the merit like the development process enhancement exceeds the cost. Besides the development process, it is also expected to function as a digital twin. By changing the input for the neural network to real-time data instead of simulation data, an actual combustion field can be emulated. This can be used for monitoring or failure prediction in the after-market.

ACKNOWLEDGEMENT

This research was conducted using the FUJITSU Supercomputer PRIMEHPC FX1000 and FUJITSU Server PRIMERGY GX2570 (Wisteria/BDEC-01) in the Information Technology Center, The University of Tokyo.

ABSTRACT

In this study, the novel PEMFC-assisted ground source heat pump system (PAGSHPs) was investigated by transient simulation. The mathematical model was developed and simulated in TRNSYS software. The annual performance and ground temperature degradation during the 5 years were analyzed by the simulation results. The heating and cooling COP were evaluated as the annual performance of PAGSHPs. The performance of GSHPs was compared with that of PAGSHPs. As a result, the average heating COP of PAGSHPs was enhanced by 26.5% compared to the conventional system. However, the average cooling COP of PAGSHPs was degraded by 7.65% owing to high ground rise.

Keywords: Proton exchange membrane fuel cell, Ground source heat pump, Waste heat recovery.

INTRODUCTION

Ground source heat pump system (GSHPs) is an efficient system that can efficiently supply heating and cooling energy [1,2]. Since the fluctuation of underground temperature is more stable than the outdoor temperature, GSHPs can achieve higher heating and cooling coefficient of performance (COP) than conventional heat pumps. However, in a heating dominant region, there is a critical issue that the underground temperature decreases when the GSHPs are used for a long time [3].

In order to mitigate this issue, solar-assisted ground source heat pump systems (SAGSHPs) have been studied for decades [4]. SAHGSHPs are the combined system of GSHPs and solar collectors [5]. By utilizing high-temperature solar energy, they can mitigate the long-term ground temperature degradation issue and enhance the COP [6]. However, SAGSHPs require a large space to install solar collectors and complex control logic to use solar energy with severe temperature fluctuations [7]. These shortcomings have become a major hindrance to the use of SAGSHPs.

Further efficient way to resolve this issue is the integration of proton exchange membrane fuel cells (PEMFC) and GSHPs. PEMFC waste heat can be used as an auxiliary heat source for GSHPs. Therefore, the underground temperature degradation could be relieved by the integration of these two systems.

In this study, the novel PEMFC assisted ground source heat pump system (PAGSHPs) was proposed and analyzed. To analyze the operating characteristics and performance of PAGSHPs, transient simulation during the 5 years was performed through the mathematical model. Mathematical modeling was developed in TRNSYS software. The simulation was performed under the meteorological conditions of Sam Cheok, the heating dominant region in Korea. As a result, both heating and cooling COP, and the underground temperature degradation over 5 years were analyzed and compared with GSHPs through the simulation results.

SYSTEM DESCRIPTION

Fig. 1 shows the Schematic diagram of PAGSHPs. The system can be divided into a power line and a thermal line. The power line consists of PEMFC, DC/AC inverter (DAI), and energy storage system (ESS). DC power produced by PEMFC is stored in ESS through DC/AC Inverter or converted into AC and used for RES. The thermal line consists of PEMFC, heat exchanger-1 (HEX-1), heat exchanger-2 (HEX-2), ground heat exchanger (GHEX), heat pump (HP), and heat storage tank (HST). The waste heat recovered from the PEMFC can be stored directly in the ST or exchanged with an ethylene-glycol water mixture (EGW) from the underground heat exchanger through HEX-1. EGW, which has undergone heat exchange with deionized water (DIW), is used as a heat source for heating in a heat pump or is injected into GHEX to prevent a decrease in underground temperature.

PEMFC waste heat is used in various ways to increase energy efficiency. In summer, the heat pump supplies cooling energy, so when a hot water supply energy load is required, the PEMFC waste heat directly supplies heat to the HST through the HEX-2. On the other hand, when there is no hot water energy load, the HEX-1 reduces the temperature of the dielectric water returning to the PEMFC and stores heat in the ground simultaneously. In winter, another operating

strategy is available in addition to the above two methods. When the heat pump is heating, the COP of the heat pump can be enhanced by increasing the temperature of the heat source through HEX-1. Through the above operation method, it is available to enhance the overall energy efficiency of the system and decrease the coolant of the PEMFC simultaneously.

RESULTS AND DISCUSSION

Fig. 2 (a) shows the change in the geologic temperature of GSHPs and PAGSHPs over 5 years. For both GSHPs and PAGSHPs, the underground temperature decreased over the years. For GSHPs, the average underground temperature decreased by about 2.36°C for 5 years. On the other hand, for PAGSHPs, the underground temperature decreased by

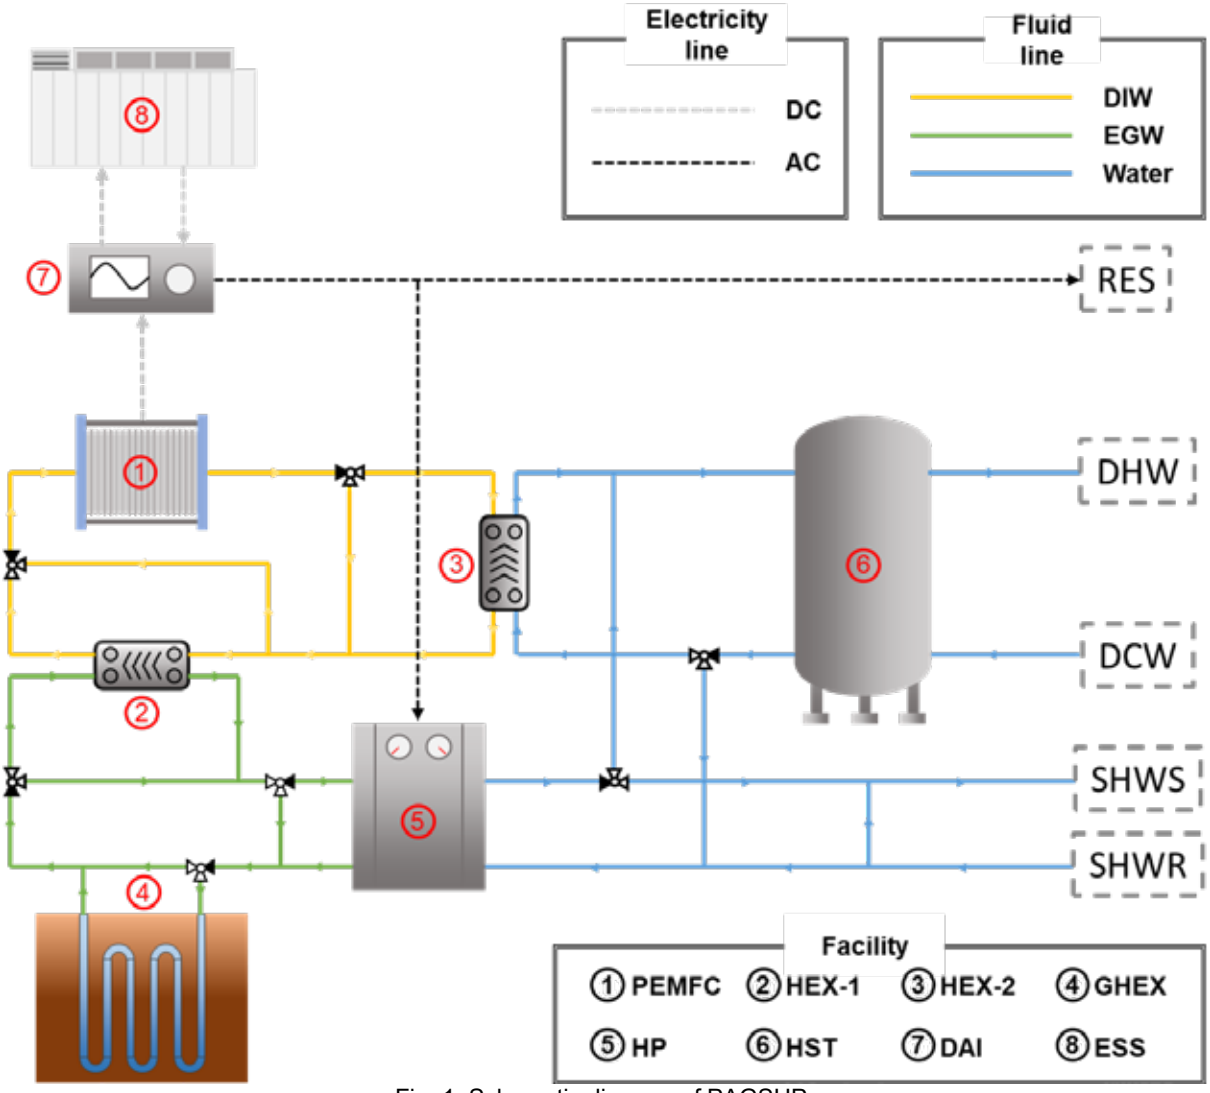

Fig. 1. Schematic diagram of PAGSHPs

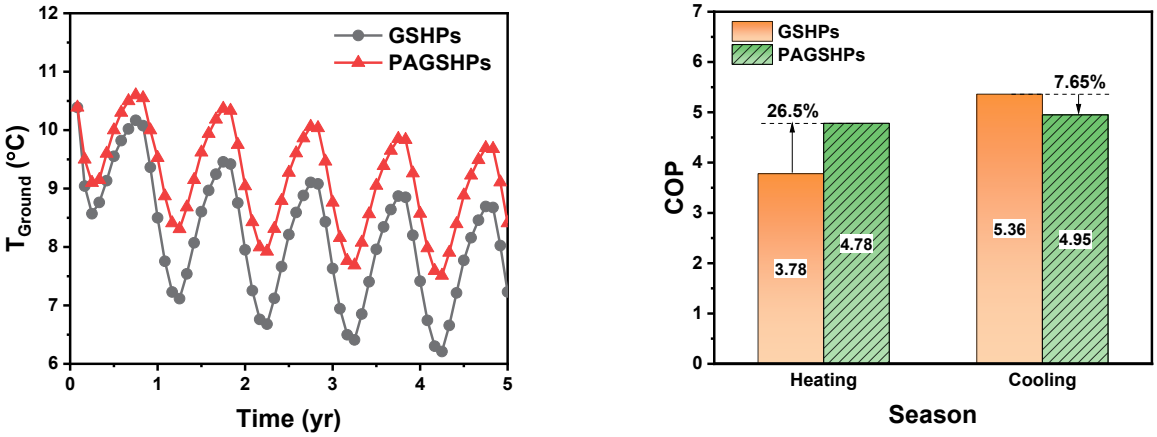

Fig. 2. (a) Variation of the average ground temperature and (b) average heating and cooling COP

1.59 for 5 years. Therefore, PAGSHPs could mitigate the ground temperature decrease by about 32.7% compared to GSHPs.

Fig. 2 (b) shows the average heating and cooling COP of GSHPs and PAGSHPs over 5 years. PAGSHPs had a heating COP of 4.78, which was improved by about 26.5% compared to GSHPs. This indicates that the temperature increase of the heat source of the heat pump was very effective by recovering the fuel cell waste heat. However, in the case of Cooling COP, it was 4.95, which decreased by about 7.65% compared to GSHPs. This is because the underground temperature of PAGSHPs was higher than that of GSHPs, so the heat source temperature increased.

CONCLUSIONS

In this study, the performance of PAGSHPs was analyzed by transient simulation. By the simulation results, the variation of average ground temperature was investigated during the 5 years. The heating and cooling COP was evaluated as the final performance. As a result, the average ground temperature degradation was relieved by 32.7% compared to GSHPs. Furthermore, the Heating COP was enhanced by 26.5%. However, the cooling COP was slightly decreased by 7.65% owing to the higher ground temperature.

In conclusion, the heating COP degradation issue by the ground temperature decrease of GSPHs could be supplemented by the integration of PEMFC. Thus, PAGSHPs could be considered as another attractive option for prospective renewable energy systems. However, the cooling temperature degradation issue has remained as future work.

IMPROVED REACTOR DESIGN FOR A METAL HYDRIDE REFRIGERATION SYSTEM IN HYDROGEN POWERTRAINS

[1] Alexander Wimmer, [1] Steffen Feierfeil, [1*] Inga Bürger, [1] Marc Linder
[1]German Aerospace Center (DLR), Department of Engineering Thermodynamics, Pfaffenwaldring 38-40, Stuttgart, Germany

*Corresponding author e-mail: inga.buerger@dlr.de

ABSTRACT

By means of metal hydrides the so far unused potential energy of compressed hydrogen in a hydrogen powertrain can be utilised for air condition of the cabin. The main problem in the latest development is the low power to mass ratio of the reactor component. That is why in this work a new reactor design is proposed, which shows mayor improvements in the key factors for high power to mass ration. Special focus is set on the outer heat transfer to a heat transfer fluid. By numerical simulation optimal design and operations points could be identified for the new reactor design.

Keywords: Metal hydrides, Unused energy, Refrigeration, Power to mass ratio

INTRODUCTION

To bring renewable energy in to the transport sector, hydrogen powered power trains are a promising technology especially for heavy duty vehicles with high range requirements. State of the art on-board storage is realised with high pressure tanks. For the compression work roughly 15% of the energy content is needed [1] and during unloading not recovered in any way. This so far unused potential energy from the compressed gas can be utilised by means of a reversible gas-solid reaction of hydrogen with metal hydrides. The exothermic and endothermic reaction can be used to generate refrigeration power for instance for the cabins air conditioning. A functional demonstration of this machine in an application relevant configuration is published in [2]. However, to reach the requirements of a mobile system in the automotive environment a significant higher power output with a lower system weight has to be realised. The focus on this work is to design a reactor which can achieve a higher thermal power density.

WORKING PRINCIPLE OF THE METAL HYDRIDE REFRIGERATION SYSTEM

Two reactors are arranged in the hydrogen flow path between a high-pressure tank and a hydrogen consumer (fuel cell or internal combustion engine). They are operating in anticyclic mode: One reactor exothermically absorbs hydrogen on medium pressure level releasing heat to the ambient. The second reactor endothermically desorbs hydrogen at low pressure level producing cold. After the specific hydrogen capacity of the metal hydride in the reactors is reached, the first reactor switches from absorption to desorption and the second from desorption to absorption. In this way a quasi-continuous hydrogen flow from a medium to a low pressure side is realised where heat is pumped quasi-continuously from a cold temperature level to the ambient level. A more detailed system description can be found in [2].

NEW REACTOR CONCEPT

The overall requirements for the new reactor concept are specified as modular scalable, manufacturable through conventional processing (suitable for mass production) and easy adjustable in the main dimension to allow future improvements. Due to the systems alternating working principle, in each half cycle a part of the reaction heat is used to heat or cool down the respective reactor to the temperature level, where the heat or cold should be generated. Consequently, this part of the reaction heat does not contribute to the refrigeration or heating output off the system and therefore is denoted as internal temperature switching loss. From this intrinsic behaviour of a metal hydride refrigeration system, one can deduce a key requirement for its reactor component: The heat capacity of the empty reactor structure should be as low as possible. An indicator to evaluate a specific reactor design can be defined as the ratio of the heat capacity from all reactor parts to the heat capacity of the metal hydride (MH) material inside.

$$k_c = \frac{\sum_i C_i}{C_{MH}} \quad (1)$$

With the below described metal hydride pellets and a thin walled double tube geometry the achieved ratio k_c is 4.9.

A second key requirement is a good heat transport behaviour. Most reactor configurations are limited in their thermal power, due to bad heat transport properties. This means the intrinsic reaction kinetics could reach higher rates and consequently higher thermal power, but the high occurring temperature difference causes the material to reach reaction its equilibrium temperature very fast and as a consequence the reaction stops early.

In order to reach a high inner heat conductivity, the metal hydride is not used as loose powder, which exhibits values of around 1 W/mK [3], but compacted in a graphite matrix [4]. In this work the fabricated ring pellets showed a radial heat conductivity of 30 W/mK. With an outer diameter of 26 mm and an inner diameter of 20 mm the ring thickness corresponds to a maximum heat transfer distance of only 3 mm, confer with fig. 1. The pelletized metal hydride powder has the additional advantage that it can be easily handled and filled into the reactor during the assembly process.

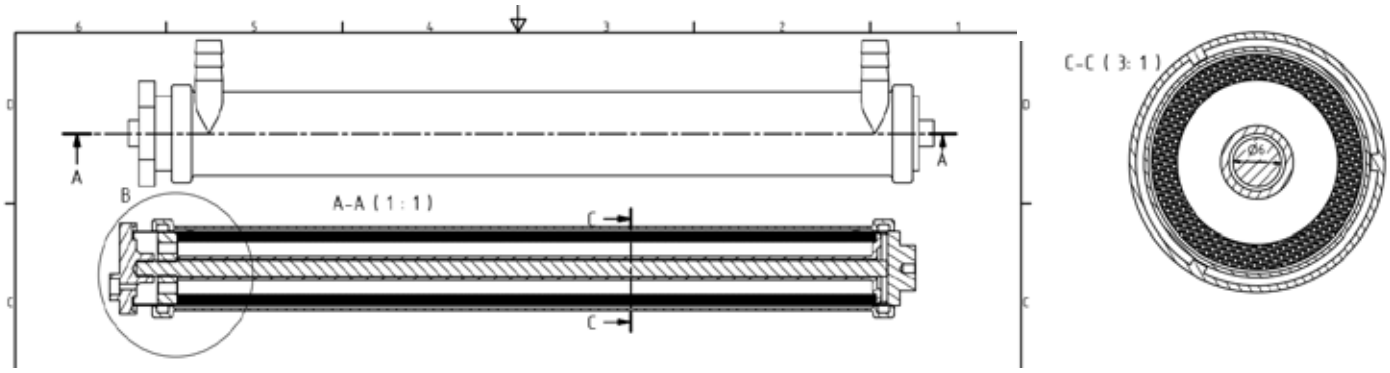

Fig. 1: Technical drawing reactor design

On the outer surface of the reactor, the heat is transferred to a heat transfer fluid (HTF), which flows in an annular gap. This channel should have a small height for two reasons. Firstly, a smaller channel height reduces the fluid volume and therefore the heat capacity of the reactor's fluid part leading to a lower value of k_c, according to eq. (1). Secondly a lower channel height, which is two times the hydraulic diameter d_h, increases the heat transfer coefficient h according to the definition of the Nusselt number. The heat transfer coefficient can be calculated by appropriate correlations [5]. For example, for a gap height of 0.5 mm and a fluid rate of 1 L/min the heat transfer coefficient is 2000 W/(m^2K). To sum up, the new reactor has a low value of k_c and good heat transport properties when compared to similar studies in the literature [2]. Thus, an improved thermal power density especially at higher temperature differences between hot and cold side is expected. When considering the pressure drop in the fluid gap, the question for the optimal gap height and flow rate occurs. Therefore, a simulation model in combination with an evaluation method is applied and descripted in the following section.

SIMULATION MODEL

The reactor is described as 2-dimensional rotary symmetric domain discretized with the finite element method for a time-resolved simulation. For the reaction behaviour of the metal hydride detailed information on kinetics and pressure-temperature-concentration properties of a real measured material are implemented. The outer heat transfer to the HTF is implemented with a local heat transfer coefficient [6] and a one-dimensional differential equation in flow direction instead of a discretized flow simulation in the gap. A more detailed description and its successful validation is published in [7]. The initial conditions are the absorbed metal hydride at equilibrium conditions of 30 °C and 35 bar representing the condition at finished absorption. As boundary conditions the HTF inlet temperature is set to a constant value of 20 °C, and the constant outlet hydrogen mass flow to 75 standard liter per minute. Considering the parasitic loss of electricity needed for the fluid pump, an evaluation parameter is defined. In this the resulting mean thermal power is reduced by a fictive thermal power that a state-of-the-art refrigeration machine could generate with the respective electrical power at a usual Coefficient of Performance (COP):

$$\dot{Q}_{eff} = \bar{\dot{Q}} - COP\ P_{Pump} \quad (3)$$

RESULTS AND DISCUSSION

Figure 1 shows the effective thermal power normalized to one kilogram of MH material over the gap's hydraulic diameter. It can be seen that for each flow rate there is an optimal gap height for which the effective thermal power reaches its maximum. This is due to the two opposing trends: If d_h decreases, on the one hand the heat transfer coefficient is higher and hence the thermal power increases. On the other hand, the smaller channel induces a higher pressure loss, increasing the negative right hand term in eq. (3). On the opposite, if d_h increases, the pressure loss decreases, but also the heat transfer coefficient and thus the thermal power is reduced.

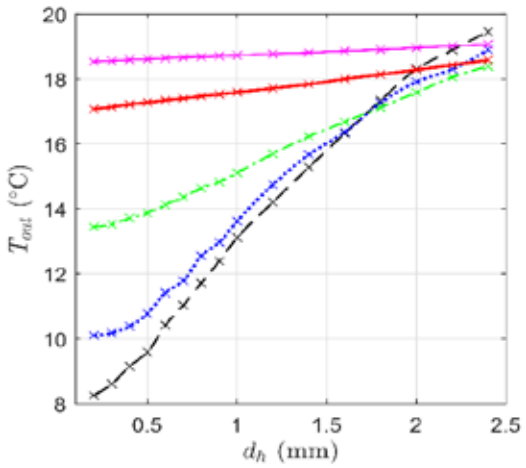

Fig. 2. eff. therm. Power for diff. hydraulic diameters and flow rates

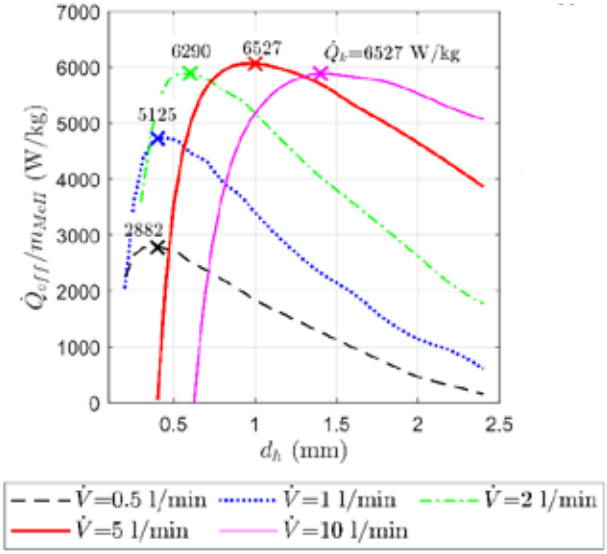

Fig. 3. Mean outlet temperature for diff. hydraulic diameters and flow rates

Moreover, it can be seen, that higher flow rates result in higher eff. thermal power. This is obvious as higher flow rates enhance the heat transfer coefficient. But a second reason is due to the fact, that higher flow rates lead to less fluid cooling, seen by the higher outlet temperatures for higher flow rates in fig. 3. A higher HTF temperature implies a higher temperature difference between the HTF and the equilibrium temperature, which in turn induces a higher reaction rate according to the kinetic equation [7]. Right hand side of the optimum the eff. thermal power decreases again at higher flow rates, caused by the dominating pressure loss. From fig. 3 it can be seen that for higher flow rates the cold is generated at higher outlet temperatures. From the two figures it also can be recognized: If the cold is required on lower temperature, lower thermal power is possible, which is physically feasible.

CONCLUSIONS

A new lightweight reactor design for the use of metal hydrides in a refrigeration machine is proposed. Based on a simple double tube configuration it enables easy filling, easy adjustment of the main dimensions and modular scaling. The important ratio of the reactors heat capacity (empty) to the metal hydrides heat capacity is 4.9 and 22% better than reported in the literature. Higher heat conductivity of the MH bed and higher heat transfer coefficient are reached through pressed MH-graphite pellets and a thin fluid channel. With the reduced value k_c and the enhanced heat transfer properties, the design improves both factors, which allow higher thermal power densities than demonstrated in other published works. For selecting an appropriate fluid channel height and fluid flow rate simulations based on a validated and published model where performed. Considering the pressure drop it could be shown that for every flow rate there exists one optimal channel thickness. The maximal thermal power density of the given reactor depends on the temperature level, where the cold is generated.

ABSTRACT

Currently, in the Tennessee project realized by the Polish energy group Tauron Polska Energia, work on the construction of an installation that integrates MCFC modules with SOE modules is nearing completion. The installation is to enable highly effective production of the CO_2/H_2 mixture based on the process of high-temperature electrolysis and process of CO2 separation carried out in MCFC modules from flue gases generated in the coal-fired unit. The article summarizes the results of analytical work and describes the first experiments on the first trial runs of the installation.

INTRODUCTION

In Poland, as in many European countries, many activities have been initiated in recent years to contribute to the development of the hydrogen economy. Objectives in this respect were set out in the "Polish Hydrogen Strategy until 2030 with an outlook until 2040" [1] adopted in 2021. Although the country is the third largest producer of hydrogen in the European Union (production amounts to over 1 Mt of hydrogen per year), there is a need to organize green hydrogen production systems, and in the transition period, also to implement technologies for its economic use, as well as conversion to energy carriers that can now be transported, stored and used safely and efficiently. One such product of the chemical synthesis of hydrogen is synthetic natural gas (SNG). Large chemical and petrochemical companies as well as energy groups are involved in these activities. Among them is the Tauron Polska Energia Group - the second largest producer of electricity in Poland. Tauron Polska Energia also conducts activities aimed at launching the first systems representing the CCUS technology [2,3]. These two directions of technological development identified in Poland significantly correspond to the urgent need to decarbonize the economy, which is at the forefront of world economies most heavily dependent on coal (nearly 70% of electricity is produced from this fuel). One of the activities in both technological areas is the initiation and launch of the Tennessee project by the Tauron Group, which involves the demonstration of the technology of producing a CO_2/H_2 gas mixture that is compatible with the needs of the generation of synthetic natural gas, which is, according to the assumptions, to be carried out in reactors enabling the Sabatier reaction. The Sabatier reaction is a simple reaction of hydrogen with carbon dioxide taking place at moderate temperatures and pressures in the presence of metallic catalysts, leading to formation of methane and water.

Hydrogen and carbon dioxide necessary for the Sabatier reaction are obtained most often in separate processes, but nowadays, due to the ecological nature, it is most often proposed to use the popular low-temperature PEM or alkaline electrolyzers to generate hydrogen. In turn, for the obtaining of carbon dioxide, separation processes from flue gases or process gases are proposed. The separation process itself can be carried out with the use of adsorption, absorption, membrane separation or cryogenic processes. Both the production of hydrogen, which is not in free form on Earth, and the extraction of carbon dioxide from gas mixtures, regardless of the methods used, are related to the need to use electricity and/or thermal energy for this purpose. For this reason, the production of synthetic natural gas is associated with the need to incur high operating costs. In addition, technologies enabling the separation of carbon dioxide, based, for example, on the methods of chemical absorption, physical adsorption, or oxygen combustion, are intended for large-scale applications, which excludes their implementation in small distributed systems. The technology that is being prepared to be demonstrated as part of the Tennessee project will allow for the reduction of energy demand and is intended for applications with a wide range of capacity.

PILOT-SCALE SOE-MCFC HYBRID SYSTEM

The diagram of the installation built in the Tennessee project is shown in Fig. 1. MCFC modules, along with SOE modules, are the basic elements of an integrated system, which is to demonstrate how to improve the process of storing energy in chemical form through the production of synthetic natural gas (SNG). MCFCs proved their usefulness in capturing carbon dioxide from coal power plant flue gases without energy penalty for host power plant, and even they generate additional power. This feature is very welcome in power-to-gas systems, where hydrogen needs to be mixed with carbon dioxide. Anode outlet gases contain a mixture of carbon dioxide (captured from flue gases) and hydrogen (depleted fuel) what meets the inlet requirements of the Sabatier reactor for methane synthesis [4]. In pilot installation the hydrogen will be generated within two modules of SOE. The reference technology for the technology being the subject of the project, which is also a reference for estimating the effects of the improvement, is the power-to-SNG technology demonstrated by Tauron, also at the Łaziska Power Plant, in which the production of gases required for the Sabatier process, i.e., hydrogen and dioxide carbon, takes place due to the operation of the alkaline electrolyzer and the installation using chemical absorption.

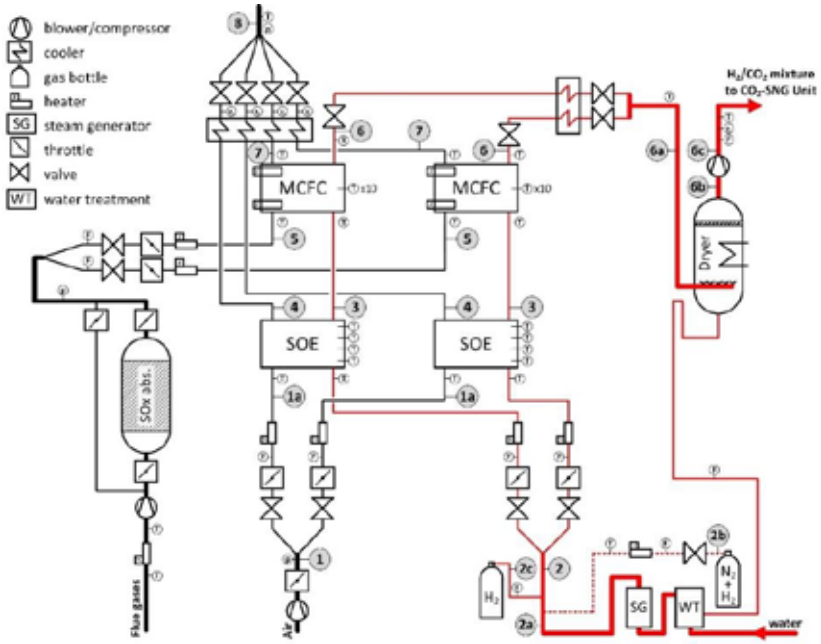

Fig. 1. Diagram of pilot-scale SOE-MCFC hybrid system

The power to gas system can be improved by the following three key novelties which will be introduced in the existing power–to–gas installation:

- Using Solid Oxide Electrolysis for generating hydrogen
- Using Molten Carbonate Fuel Cells for capturing carbon dioxide from coal fired boiler flue gas
- The electric and thermal integration of MCFC with SOE for thermal and power support of electrolysis by fuel cells

It is possible to integrate both MCFC and SOE for thermal management, to produce hydrogen and carbon dioxide at adequate temperature level for the methanation process (200–400 °C). The heating by using the electric heaters will be avoided, what increases effectiveness of the installation. Additional value—MCFC can be combined with SOE by Direct Current to support electrolysis.

RESULTS

The development of the concept of a prototype installation, for which the diagram is shown in Fig. 1, was accompanied by analytical works, aimed mainly at determining the structure of the system, which would enable the conduct of widely profiled research works. A very important issue was the design the measuring equipment of the installation that will allow to determine the performance characteristics of individual components under various load conditions, including the identification of their degradation. For a specific structure, on the basis of simulation analyzes, the parameters of factors at characteristic points of the installation were selected. The results of these analyzes, which are presented in Table 1, became the basis for the development of the detailed design of the installation.

Table 1. Parameters in characteristic points of installation

No.	Composition, %							Temperature, °C	Pressure, mbar	Mass flow, kg/h	Specific heat, kJ/kgK
	N_2	O_2	H_2	H_2O	CO	CO_2	CH_4				
1	79.0	21.0	-	-	-	-	-	20	1030	18.25	1.01
1a	79.0	21.0	-	-	-	-	-	687	1020	9.13	1.13
2	-	-	5.0	95.0	-	-	-	570	1020	6.66	2.26
2a				100.0				150	2000	6.63	2.07
2b	95.0	-	5.0	-	-	-	-	20	1500	11.27	1.09
2c	-	-	100.0	-	-	-	-	20	1500	0.04	14.24
3	-	-	81.0	19.0	-	-	-	710	1020	0.98	6.20
4	63.0	37.0	-	-	-	-	-	704	1020	11.48	1.13
5	66.5	7.5	-	12.5	-	13.5	-	380	1020	17.70	1.17
6	-	-	43.1	39.8	5.5	11.0	0.6	646	1020	3.34	2.54
6a	-	-	43.1	39.8	5.5	11.0	0.6	200	1010	6.68	2.31
6b	-	-	70.2	2.0	9.0	17.9	0.9	20	1000	3.63	2.49
6c	-	-	70.2	2.0	9.0	17.9	0.9	90	14000	3.63	2.61
7	73.7	5.0	-	13.8	-	7.5	-	646	1010	15.34	1.25
8	69.3	18.3	-	8.0	-	4.4	0	60	1000	53.64	1.07

By applying the proposed novelties, a several goals will be reached. First of all, power necessary to hydrogen generation will be decreased by ca. 25%. This makes the system more competitive to the other technologies for energy storage and makes the substitute of natural gas cheaper. Based on the experimental investigations, the achievable CO_2 separation rate was determined at above 90% by adjusting the cathode inlet flow. In this way, potentially consumption of heat from host coal fired power plant for CO_2 capture will be eliminated. Thus, there will be no energy penalty for the host power plant what makes the power plant efficiency and power at the desired level. Thirdly, the whole installation will be more simple, compact, and modular—thus any scale–up procedure can be done without any technological difficulties.

CONCLUSIONS

The conducted analytical works indicate the possibility of obtaining satisfactory technical effectiveness indicators for the installation, and thus a potential reduction of costs ultimately incurred to produce SNG. The analytically identified effects of the integration of SOE modules with MCFC modules will be confirmed only after the research campaign on the prototype installation is carried out. The work will be focused on the evaluation of the flexibility of changing the loads of individual components of the installation, the impact of changes in the composition of the flue gases fed to MCFC modules, and the impact of the electrical load on the respective modules. Ultimately, as part of the project, guidelines for scaling the technology for industrial requirements will be developed. Preparatory work for the formation of fuel cell stacks is currently underway at the Tennessee Project. Corrections are also being made at the installation for the identified leaks within the SOE modules. The commissioning of the installation, which will start the research phase, is scheduled for the first half of 2022.

ABSTRACT

Due to zero greenhouse gas emissions, hydrogen fuel production from methane cracking is a cleaner pathway than steam methane reforming. Co-produced carbon black is valuable and can be used in other industries. Using solar energy for the high-temperature requirement can further improve the sustainability of the process. This paper evaluates an integrated solar methane cracking where its products are utilized in fuel cells to generate electricity. The CO_2 produced in the system is co-electrolyzed with water to produce syngas which is further converted to methanol. The process is simulated in Aspen Plus®, and its energy and exergy efficiencies are evaluated by conducting a detailed thermodynamic analysis. The proposed system has an energy and exergy efficiency of 37.4% and 31.2%, respectively

Keywords: Methane cracking, Turquoise hydrogen, Solid oxide electrolyzer, Synthetic fuel, Methanol

INTRODUCTION

Hydrogen fuel is a clean energy carrier that can meet the decarbonization targets of increasing energy demand. However, alternative processes need to be considered that lower the environmental impact during its production [1]. Industrially, hydrogen is produced via steam methane reforming (SMR). The hydrogen produced using SMR is termed 'gray hydrogen' because it has high CO_2 emissions. When carbon capture and storage (CCS) are added to the process, the hydrogen derived is termed as 'blue hydrogen'. A cleaner pathway is methane cracking at high temperatures termed 'turquoise hydrogen' where carbon black is formed as a by-product that can be useful in several industries [2]. Solar energy can reach the required high temperatures making it a cleaner process utilizing renewable energy [3].

Integrated systems increase efficiencies, minimize losses and reduce costs [4]. Both products from methane cracking can generate electricity in fuel cells. Moreover, the produced hydrogen needs to be converted to a suitable energy form to make it more easily transportable. With these in mind, an integrated system shown in Fig. 1 is proposed for cleaner utilization of methane resources with carbon management and the production of clean energy carriers.

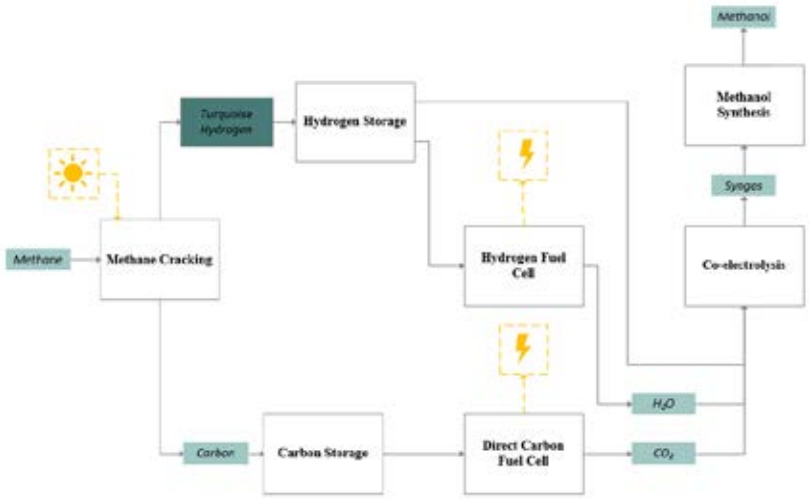

Fig. 1. Block flow diagram of the process

SYSTEM DESCRIPTION

The system consists of a solar methane cracking subsystem (SMC) that decomposes methane into turquoise hydrogen and carbon in the presence of concentrated solar energy, as shown in Fig. 1. The hydrogen produced is stored and used in a proton exchange fuel cell (PEMFC) to generate electricity. The carbon is also used in a direct carbon fuel cell (DCFC) to generate electricity with an exhaust stream consisting of pure CO_2. The CO_2 that is produced then undergoes co-electrolysis with water to produce syngas in a solid oxide electrolyzer (SOEC) using electricity generated using solar PV. Syngas can be used to produce a variety of other chemicals. This system converts syngas to methanol (MEOH), a suitable liquid hydrogen carrier.

THERMODYNAMIC ANALYSIS

A detailed thermodynamic analysis was conducted for the proposed integrated system. Aspen plus® was used to simulate the process and obtain the thermodynamic properties of the state points of the process. The developed model is shown in Fig. 2. The fuel cells are simulated using a Gibbs reactor and separator as the electrodes. Similarly, the co-electrolyzer is modelled using three reactors in series based on the model reported in [5].

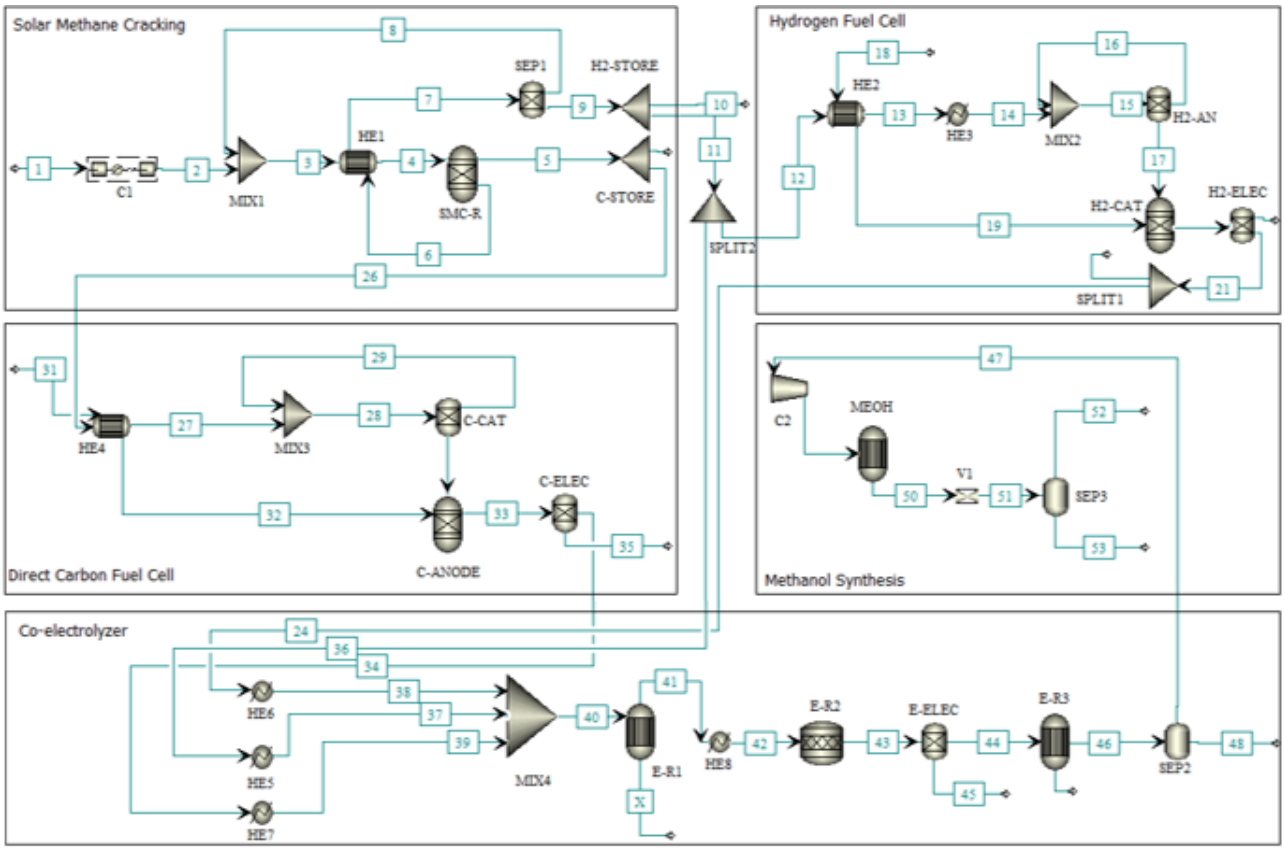

Fig. 2. Aspen flowsheet of the entire processes

Mass, energy, entropy, and exergy balances were carried out over each unit of the system. The entropy generation and exergy destruction rates of the components were found. In addition, the energy and exergy efficiencies of the overall system and the subsystem were calculated. The general balance equations are as follows:

$$\sum_{in} \dot{m}_\iota = \sum_{out} \dot{m}_\iota \quad (1)$$

$$\dot{Q}_{in} + \dot{W}_{in} + \sum_{in} \dot{m}_\iota h_i = \dot{Q}_{out} + \dot{W}_{out} + \sum_{out} \dot{m}_\iota h_i \quad (2)$$

$$\frac{\dot{Q}_{in}}{T_s} + \dot{S}_{gen} + \sum_{in} \dot{m}_\iota s_i = \frac{\dot{Q}_{out}}{T_s} + \sum_{out} \dot{m}_\iota s_i \quad (3)$$

$$\dot{E}x_{Q_{in}} + \dot{E}x_{W_{in}} + \sum_{in} \dot{m}_\iota ex_i = \dot{E}x_{Q_{out}} + \dot{E}x_{W_{out}} + \sum_{out} \dot{m}_\iota ex_i + \dot{E}x_D \quad (4)$$

RESULTS AND DISCUSSION

The thermodynamic properties were obtained for each stream from Aspen Plus, and the balances were performed. The efficiencies were calculated, and the results are displayed in Fig. 3. The process utilizes a 0.5 kg/s feed of pure

methane, cracked in a Gibbs reactor block operating at 1200℃ and 10 bar giving a methane conversion rate of 95%. 5.3 MW of solar thermal power is required with an efficiency of 75% to crack the methane feed.

Due to the intermittency of solar energy, the produced hydrogen and carbon produced during the day are stored. 5.4 tonne/day of H_2 and 16.1 tonne/day of carbon are produced that are used in fuel cells to generate an overall 7.71 MW of electricity. Co-electrolysis of CO_2/H_2O in the SOEC is performed using electricity generated in a solar PV system with an efficiency of 20%.

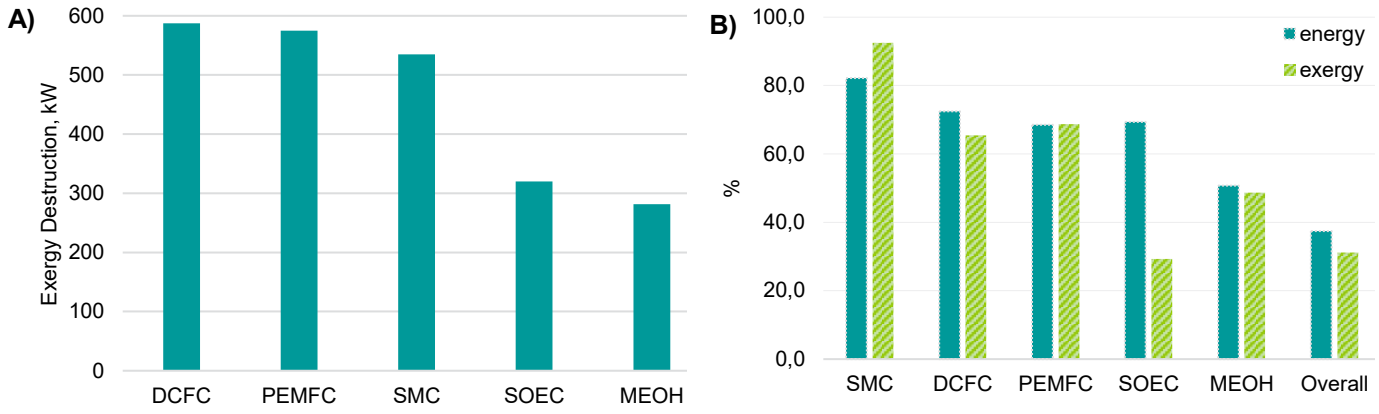

Fig. 3. A. Exergy destruction rates of the subsystems B. Energy and Exergy Efficiencies of the systems

Fig. 3A shows the exergy destruction rates from the different subsystems; it can be noted that the highest exergy destruction occurs in the direct carbon fuel cell followed by the hydrogen fuel cell. Fig. 3B shows obtained efficiencies. The overall system has an energy and exergy efficiency of 37.4% and 31.2%, respectively.

CONCLUSIONS

This study outlines the thermodynamic analysis of a methane cracking system for clean hydrogen production. The products are utilized in fuel cells to generate electricity. The CO_2 exhaust from the DCFC is pure and can be further co-electrolysed with water to efficiently produce syngas and then converted to methanol. The proposed system was modelled on Aspen plus to obtain the thermodynamic properties of the streams. Balances were carried out over each component to identify the losses within the system. The solar methane cracking subsystem has energy and exergy efficiency of 82.2% and 92.5%, respectively. It was found that the overall system produces electricity and methanol with an energy and exergy efficiency of 37.4% and 31.2%, respectively.

ABSTRACT

Light olefins are considered the backbone of chemical industry, and a broad variety of derivatives, used in our daily lives, are produced from these building blocks. Notably, it is estimated that the $C_{2-4}^{=}$ demand will face an annual growth of 3.5% by 2030, as a combined result of global population growth and rising living standards. The current leading technology for light olefins production is the steam cracking of natural gas and/or crude oil fractions but this process is linked with a high carbon footprint. Concerns associated with the depletion of fossil fuels and the threat of global warming have recently initiated efforts to explore alternative pathways and feedstocks to produce light olefins through CO_X hydrogenation by employing either excess RES-powered electrolytic hydrogen combined with captured CO_2 industrial emissions or syngas mixtures generated through biomass gasification or biofuels reforming. Therefore, the present work aims to examine the thermodynamic aspects of the CO_X hydrogenation to light olefins at a range of temperatures and pressures of industrial practice by feeding several carbon-neutral CO_X-H_2 mixtures. For this end, the Aspen Plus software and the Gibbs free energy minimization method have been compiled in a series of simulation scenarios.

Keywords: Thermodynamic analysis, CO_X hydrogenation, Light olefins production, Industrial CO_2 capture, Bio-syngas

INTRODUCTION

Light olefins, $C_{2-4}^{=}$, are the top chemicals in terms of global production rates with an annual ethylene and propylene capacity of ca. 150 million tons [1], and are deemed as the key building blocks for a range of products, such as plastics, gels, fibers, pharmaceuticals, cosmetics, etc. Olefins are industrially produced by the steam cracking of naphtha or the thermal ethane cracking, both highly energy intensive processes that charge each ton of olefin with 0.75 up to 11.5 tons of CO_2 emissions, depending on the employed production route, raw materials and energy sources (usually 2 – 5 $tnCO_2/tnC_{2-4}^{=}$ for oil and natural gas) [2]. EU Green Deal recognizes the necessity to detach chemical industries from fossil carbon towards the transition to complete decarbonisation at 2050. Recently, new approaches to generate light olefins by neutral carbon sources and renewables have been proposed including among others the employment of syngas by biofuels reforming and biomass gasification, as well as, the hydrogenation of industrially captured CO_2 emissions by renewable electrolytic hydrogen.

CO_2 to $C_{2-4}^{=}$ olefins is a catalysis benchmark and includes a complicated reaction system due to i) the multiple reaction pathways of CO_2 hydrogenation to various products (CO, CH_4, light olefins, higher hydrocarbons, methanol, etc.) and ii) its sensitivity to operational conditions (e.g., temperature, pressure, $H_2/CO_2/CO$ feed ratio, presence of other substances) and catalyst properties (e.g., active phases, dispersion, acidity-basicity). The challenges of this process highlight the importance of obtaining a thorough understanding of the reaction's thermodynamics prior to catalytic studies. To the best of the authors knowledge, there are only a few relevant works in literature thermodynamically exploring the effect of operational temperature, pressure and feed composition on conversion, selectivity and light olefins/paraffins product distribution [3], [4].

In the present study, an extensive thermodynamic analysis of industrially relevant CO_X hydrogenation reaction systems to light olefins is conducted, using the Aspen Plus software and the Gibbs free energy minimization method. More specifically, carbon-free and renewable H_2/CO_X upstream industrial feed mixtures were considered and the performance in terms of conversion, selectivity and yields to light olefins was explored over a wide range of operational parameters (i.e., temperature, pressure, H_2/CO_X reactants ratio). Moreover, the methodology took into consideration the presence of other chemical substances (CH_4, H_2O) existing in practical feedstock mixtures.

METHODOLOGY

For the current thermodynamic analysis, the ASPEN Plus software was used to calculate the equilibrium compositions, utilizing the Gibbs reactor (R_{Gibbs}). The non-ideal behavior in Gibbs energy values was introduced by the Soave-Redlich-Kwong thermodynamic package in order to calculate the substantial properties per component and per reaction mixture. Ethylene, propylene, butylene, hydrogen and carbon dioxide were considered as the only products of the aforementioned reaction system. It is highlighted that paraffins were excluded from the study since the aim was to identify the pathway towards olefins (in other words, paraffin production is thermodynamically favoured and masks the production of olefins through a tailor-made catalytic system). The equations that define the conversion of CO_2, the selectivity and yields of light olefins (C_nH_m) are presented as follows:

$$X_{CO_2}(\%) = \frac{\mathrm{CO_{2\ inlet}} - \mathrm{CO_{2\ outlet}}}{\mathrm{CO_{2\ inlet}}} \times 100 \quad (1)$$

$$S_{C_nH_m}(\%) = \frac{nC_n\mathrm{H_{m\ outlet}}}{\sum_1^n nC_n\mathrm{H_{m\ outlet}}} \times 100 \quad (2)$$

$$Y_{C_nH_m}(\%) = \frac{X_{CO_2} \times S_{C_nH_m}}{100} \quad (3)$$

RESULTS AND DISCUSSION

For the thermodynamic calculations a reacting mixture consisting of captured CO_2 and electrolytic hydrogen by excess RES power is initially considered. Figure 1 depicts the effect of operational temperature on the CO_2 conversion and light olefins selectivity at various pressures ranging from 10 to 30 bar and for a stoichiometric H_2/CO_2 = 3. The increase of the temperature leads to lower CO_2 conversions for all employed pressures, as expected due to the exothermic nature of the investigated reactions. Butylene is the main olefin product at low temperatures following a decreasing trend with temperature. On the other hand, ethylene starts to formulate at ca. 300 °C and increases with temperature and appears to be the prevailing olefin at higher temperatures. The corresponding selectivity profile for propylene follows a volcano behavior showing a maximum at approximately 500 °C. In general, higher pressures favour butylene selectivity, whereas ethylene/propylene selectivities decrease with pressure.

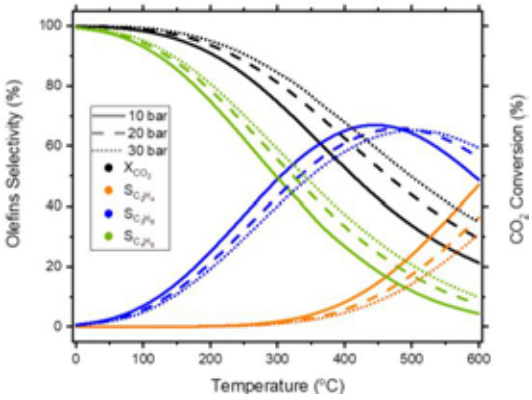

Figure 1: Effect of temperature on $C_{2\text{-}4}^{=}$ selectivity and conversion at 10, 20 and 30 bar for a stoichiometric H_2:CO_2 feed

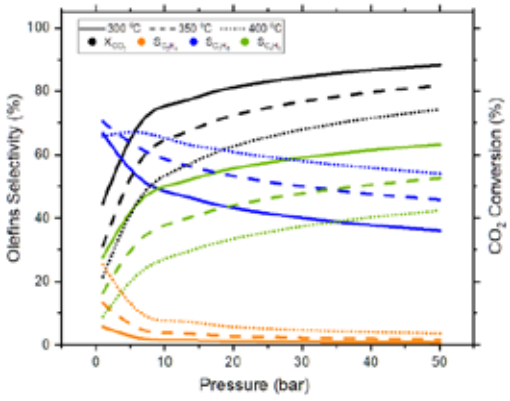

Figure 2: Effect of pressure on $C_{2\text{-}4}^{=}$ selectivity and conversion at 300, 350 and 400 °C for a stoichiometric H_2:CO_2 feed

As a volume-reducing reaction system, the conversion of CO_2 is expected to increase with pressure according to the Le Chatelier's principle. This is confirmed in Figure 2, which presents the effect of pressure (1 – 50 bar) at three different temperatures (300, 350 and 400 °C) and at stoichiometric feed ratio H_2/CO_2 = 3. The selectivities for ethylene and propylene decrease with pressure, whereas butylene exhibits an increasing trend with the operating pressure being the main product for pressures higher than 10 bar and T= 300 °C. At 400 °C, propylene exhibits the highest selectivity in the whole pressure range. At 350 °C, propylene's selectivity is higher than butylene's for pressures up to 30 bar, while above 30 bar an inverse behavior is observed. Figure 3 shows the effect of H_2:CO_2 molar feed composition from sub- to over-stoichiometric ratios (1 – 9) at three different temperatures (300, 350 and 400°C) and for the pressures of 20 and 30 bar. It is clearly observed that the CO_2 conversion linearly increases with the feed ratio increase, while the corresponding effect on olefins selectivity is essentially negligible. Finally, in the case of upstream derived syngas mixtures from biomass gasification or biofuel reforming containing CO_2, CO, H_2, CH_4 and H_2O, the results revealed that CO_2-rich syngas mixtures favor the selectivities of ethylene and propylene, while the corresponding values for butylene are suppressed.

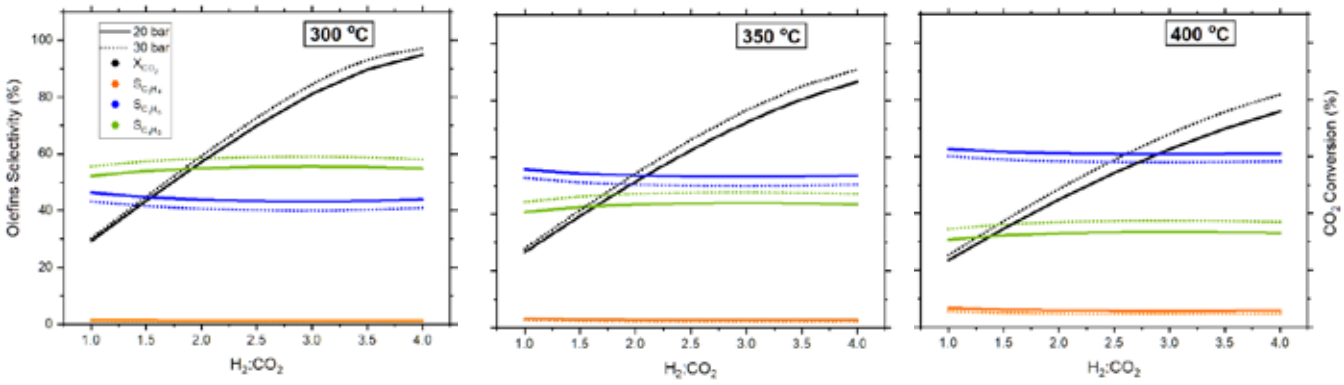

Figure 3: Effect of H_2:CO_2 feed molar ratio on $C_{2-4}^{=}$ selectivity and CO_2 conversion at 300, 400 and 500 °C and for 20 and 30 bar pressures

CONCLUSIONS

A detailed thermodynamic analysis of CO_X hydrogenation to light olefins was conducted and the effect of the operation temperature, pressure and feed composition on the conversion and selectivity to light olefins was thoroughly investigated. As an exothermic and mol-reducing reaction, the conversion is favored at low temperatures and high pressures, while the increase in H_2 feed concentration shift the reaction equilibrium to the right. In the case of syngas mixtures derived by upstream biomass gasification or biofuel reforming processes with high CO_2 contents, the selectivities to ethylene and propylene are enhanced at the expense of butylene formation.

ABSTRACT

The adverse impact of fossil fuels' on the environment and the increasing concerns regarding climate change, have intensified research efforts towards the exploitation of renewable energy sources (RES). Biomass can be utilized as a CO_2-neutral fuel in several energy conversion technologies. For instance, biomass gasification converts solids to syngas, which can be directly used as a fuel or as a valuable building-block toward synthetic liquid fuels and/or chemicals. The scope of the present study is the simulation of a combined process that exploits olive kernel (OK, 833 kg/day) for the production of electrical power and bio-oil. The integrated process includes: a) the slow pyrolysis of the olive kernel at 500 ^oC to solids (biochar, 252 kg/hr), liquids (336 kg/hr) and non-condensable gases (245 kg/hr), b) the autothermal gasification of biochar to syngas (1126 kg/hr) and c) the direct utilization of syngas in a solid oxide fuel cell (SOFC), for the cogeneration of electrical (1.35 MW_{el}) and thermal (1.1 MW_{th}) power. The combined process approaches a 50 % electrical efficiency, upon the raw biomass lower heating value (LHV). The integrated process was simulated using Aspen Plus® software and based on the experimental results of a previous study.

Keywords: Olive kernel, Pyrolysis, Gasification, SOFC, Co-generation of electricity and io-oil

INTRODUCTION

In 2019, the European Commission announced the European Green Deal to direct the EU economy on a pathway towards climate neutrality by 2050 [1]. The increase of renewables share in gross energy consumption and the adoption of the circular economy principles through innovative and efficient processes constitute crucial actions for this direction. Biomass is a cheap and widely available renewable form of energy. Agricultural and industrial activities are the main sources of residual biomass that could be used as renewable feedstock, thus enhancing local economies and minimizing problems of waste handling. Greece has a biomass potential of 3.5-5 Mtoe, with agro-industrial residues constituting 70% of the available capacity. Specifically, olive kernel and olive prunings account for almost 20% of the exploitable potential of agricultural residues, in Greece. In specific, Greece represents the third largest olive oil industry worldwide with an annual capacity of approximately 400,000 tons of olive kernel waste [2]. Despite the positive impacts of bioenergy on the way to combat climate change, biomass has lower energy density compared to fossil fuels and high logistic costs comprising harvesting and collection, storage, pretreatment and transportation. The biomass combustion route, in typical steam turbines, obtains a net efficiency of ca. 30% of biomass low heating value (LHV) [3]. The present work aims on increasing the energy efficiency through the thermochemical conversion of residual biomass to electricity and high added-value energy products (bio-oil). Considering the system as a combination of three technologies (Pyrolysis-Gasification-SOFC), a technical assessment is conducted and simulated using Aspen Plus® software and the experimental results from our previous study [4].

SYSTEM DESCRIPTION AND ASSUMPTIONS

The proposed system, based on the biomass pyrolysis reactor, the gasifier and the SOFC sub-systems, is demonstrated in Fig. 1. The biomass feedstock is olive kernel (OK) with physicochemical characteristics as presented in our previous work [4]. The OK feedstock enters the pyrolysis reactor (RYield) at ambient conditions (e.g. 20 ^oC / 1 bar) through a solid conveyor belt. For this study, the throughput of biomass was set at 20 tn/d (or 833 kg/h) and the endothermic pyrolysis takes place at 500 ^oC. Two streams exit the pyrolysis reactor: a) a solid phase stream rich in carbon (biochar) that enters the gasification reactor (RGibbs, 800 ^oC) and b) a gaseous stream that refers to a mixture of non-condensable gases and tar-oil. The gaseous stream is flash-cooled at 45 ^oC in heat exchanger 1 (HX1) in order to separate the constant gases (H_2, CO, CO_2, CH_4) from the tar-oil. The bio-oil is separated from the aqueous phase of the tar-oil and is a readily marketable-product of low oxygen content. The aqueous phase of the tar-oil is sent to the gasifier, whereas the pyrolysis gases are mixed with the syngas from the gasifier. The latter is then cleaned (in a cyclone) in order to remove the ash content and the syngas stream is preheated at 800 ^oC (HX2) prior entering the Solid Oxide Fuel Cell's (SOFC) anode.

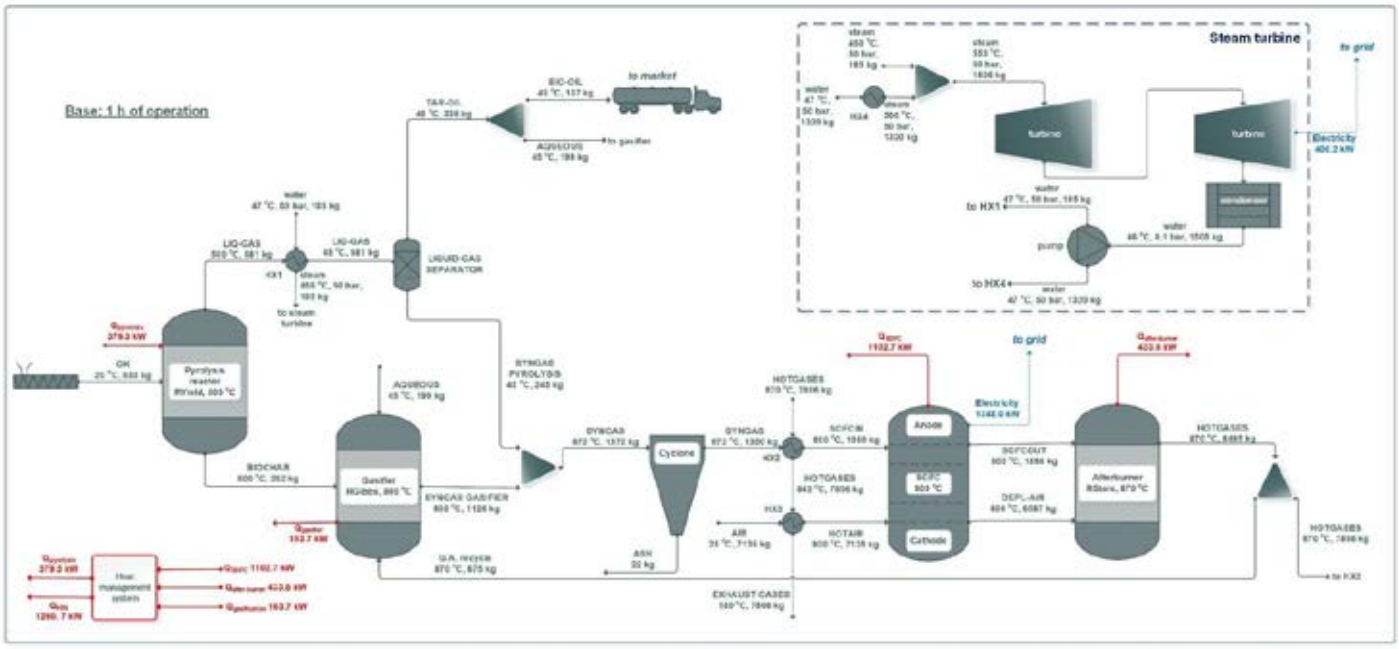

Fig.1 Process flow diagram of the olive kernel-to-power/bio-oil configuration.

In the SOFC, a combined heat and electrical energy production takes place and the anode/cathode effluents are sent to a series-connected burner (RStoic, 870 °C). The hot effluent gases from the burner split and an 8 % fraction is recycled back to the gasifier as the gasification agent. Finally, The residual heat of the SOFC and the after-burner is directed to a Rankine cycle for additional power generation.

RESULTS AND DISCUSSION

Regarding the mass balances of the integrated process, Table 1 summarizes the main input and output streams of the three sub-processes.

Table 1. Stream flowrates (kg/hr) and temperatures

	OK	pyrolysis gas	bio-oil	tar-oil aqueous	biochar	syngas	$anode_{in}$	gasification agent	exhaust gases

Total	**833**	**245**	**137**	**199**	**252**	**1126**	**1350**	**675**	**7806**

The simulation of the olive kernel slow pyrolysis was based upon our previous work [4], regarding the elemental composition of pristine olive kernel and of the produced biochar, as well as the yields towards solid, liquid and gaseous products. For these yields and elemental compositions, a typical gaseous products' composition was assumed, in agreement to slow pyrolysis literature [5], allowing the calculation of the elemental composition of the liquid products, by the elemental mass balances. The elemental composition of the aqueous and bio-oil phases were calculated assuming that a) the 40 wt. % of liquids corresponds to the organic phase (bio-oil) and the 60 wt. % to the aqueous phase and b) the 90 wt. % of the liquids' elemental carbon content, the 55 wt. % of hydrogen and the 40 wt. % of oxygen end up to the d.a.f. bio-oil phase (5 wt. % moisture), in agreement to slow pyrolysis literature [6,7]. The pyrolysis heat requirements were calculated at 1.83 MJ/kg of d.a.f OK biomass, which corresponds to the 9.8 % of its HHV_{daf} (18.80 MJ/kg), which is in accordance to literature [8]. Concerning the solid stream of pyrolysis (biochar, 252 kg/hr), it is driven to a fixed-bed gasifier (RGibbs) where the total char gasification takes place at 800 °C and

atmospheric pressure. The gasification-syngas was then mixed with the syngas derived from pyrolysis, and the total syngas is driven to the anode of the solid oxide fuel cell (SOFC) for the co-generation of electricity (1.35 MW_{el}) and heat (1.1 MW_{th}). The air inlet to the SOFC's cathode was adjusted so that the oxygen utilization factor to be 0.8, according to the literature [9]. Depleted air, as well as the non-utilized fuel from the SOFC, were sent to the afterburner, the exhaust-gases of which (N_2, O_2, H_2O, CO_2) were split and partially recycled as gasification agent. The exhaust-gases recycle percentage (8 %) was selected in order to almost sustain the autothermal operation of the gasifier at complete bio-char gasification.

Regarding the heat management of the integrated process, the heat generated at the SOFC and the after-burner (1.55 MW_{th}), was found adequate to cover the pyrolysis endothermic operation and the preheating of both air and cleaned syngas at the SOFC's inlets. The residual heat of the SOFC and the after-burner (after the coverage of internal heat requirements) generates high-pressure steam (1505 kg/h, 50 bar, 553 ^oC), for the steam turbines to produce additional electricity (0.40 MW_{el}). The total electrical power produced equals to 1.75 MW_{el}, corresponding to an efficiency of 49 %, with respect to the lower calorific value of the raw olive kernel.

CONCLUSIONS

The overall simulation showed that, despite the valorization of the 16.4 % of biomass feed as bio-oil, the remaining 83.6 % generates 1.75 MW_{el}, compared to the 1.07 MW_{el} of the total biomass feed, in a potential biomass combustion and steam turbine process. Thus, the integrated biomass pyrolysis/gasification/SOFC process can contribute to the economic sustainability of either the bioelectricity generation in SOFCs (by the cogeneration of high added-value bio-oil) or the bio-oil production (by the highly efficient co-generation of electricity). The economic assessment of the integrated process is currently under progress.

ABSTRACT

An overview of HySA Systems activities related to the development, demonstration and implementation of hydrogen fuel cell vehicles and their refuelling infrastructure is presented. The activities are focused on the integration, prototyping and validation of niche vehicles, including forklifts and scooters, as well as their hydrogen refuelling infrastructure.

Keywords: Hydrogen South Africa, Niche vehicles, Refuelling infrastructure, System integration, Testing and validation

INTRODUCTION

A long-term (15-year) Hydrogen and Fuel Cell (HFC) Technologies Research, Development, and Innovation Strategy "Hydrogen South Africa" (HySA) was officially launched in September 2008 by the Department of Science and Technology (DST; Department of Science and Innovation / DSI since 2019). HySA Systems, a Systems Integration and Technology Validation Centre of Competence, was established in 2007 at the South African Institute for Advanced Materials Chemistry (SAIAMC) at the University of the Western Cape (UWC). The main objective of HySA Systems is to perform system integration and validation of HFC technologies, including hydrogen fuel cell vehicles (HFCVs) [1,2].

Hydrogen mobility and related refuelling infrastructure is a significant component in further implementation of HFC technologies in South Africa according to the Hydrogen Society Roadmap (HSRM) approved by the Cabinet on September 14, 2021 [3] and prepared on the basis of contribution of the DSI, in collaboration with the South African governmental institutions (SANEDI) and business (Anglo American, Bambili Energy, Engie) [4]. The HFCV-related activities are focused on the heavy-duty vehicles (buses, trucks, trains), as well as some operational niche vehicles for underground mining and materials handling.

This presentation overviews HySA Systems activities related to the development, demonstration and implementation of HFC niche vehicles and their refuelling infrastructure.

INTEGRATION OF NICHE VEHICLES AT HYSA SYSTEMS

The R&D on the integration of HFCVs at HySA Systems is focused on some niche vehicles including light vehicles (golf cart, bi- and tricycles, scooters), as well as forklifts. Common features of the integration solutions on the basis of commercial electric vehicles include:

(a) Hybrid "battery + fuel cell" powertrain where the battery is used for the start-up and compensating peak loads, and the fuel cell provides the electric power during the main driving cycle. The use of range extender configuration along with careful balancing of the battery capacity and the fuel cell power allows to minimise consumption of hydrogen fuel and to maintain the optimal state of the charge of the battery [5].
(b) Use of metal hydrides for the compact on-board hydrogen storage which requires lower H_2 refuelling pressures and, in turn, allows to use less complicated and expensive and more safe and reliable refuelling infrastructure as compared to conventional H_2 refuelling stations with dispensing pressures of 350 and 700 bar.

Table 1 presents list of the related prototypes developed by HySA Systems during the period 2010–2019. Some recent examples are shown in Fig.1. As mentioned above, due to low-pressure on-board H_2 storage in MH, refuelling of HySA Systems HFCVs takes place at the lower dispensing pressures, below 150 bar for the forklifts and below 40 bar for the cartridge-type hydrogen storage canisters for the light vehicles. It allowed us to develop simple, inexpensive and reliable hydrogen refuelling stations (## 7, 10 in Table 1; Fig. 2).

Table 1. Summary of HFCV prototypes and their refuelling facilities developed by HySA Systems

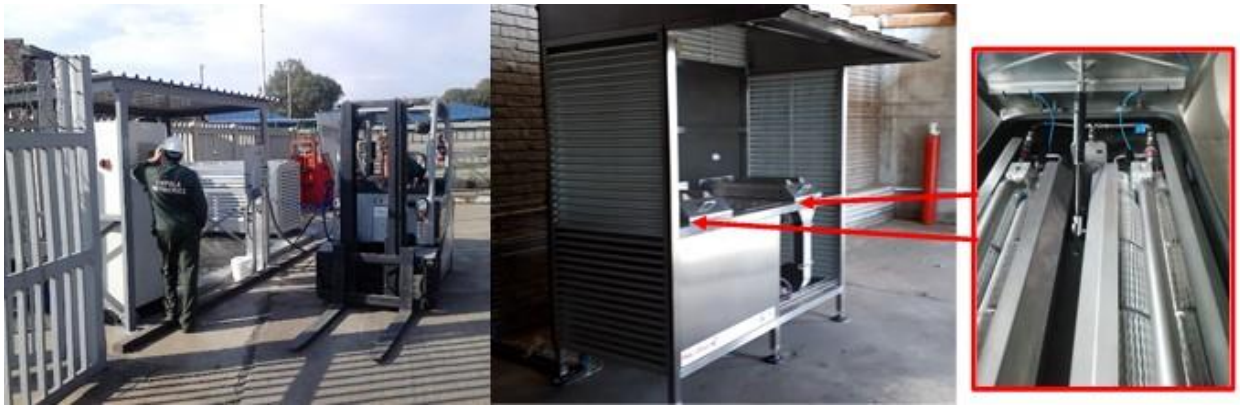

Fig. 2. HySA Systems hydrogen refuelling stations for FC forklift (left) and MH cartridges for FC scooters (right).

For the refuelling which requires hydrogen compression, HySA Systems solutions use thermally driven hydrogen compression utilising MH. Realisation of this approach is particularly beneficial for the industrial customers who possesses necessary services, first of all, low-pressure hydrogen and waste heat (low-grade steam) in their infrastructure. Along with MH compressors for low-pressure refuelling stations (150 bar; see Fig. 2(left)), HySA

Systems presently develops MH technology for high-pressure (up to 1000 bar) H_2 compression to be further used in conventional hydrogen refuelling stations with dispensing pressures of 350 and 700 bar [11].

CONCLUSIONS

HySA Systems activities in hydrogen and fuel cell technologies for mobile applications are focused on the integration, prototyping and validation of niche vehicles, including forklifts and scooters, as well as their hydrogen refuelling infrastructure. The integration is carried out on the basis of commercial electric vehicles by introducing hybrid power train where fuel cell plays a role of the range extender. Another feature of the developed prototypes is in the use of metal hydride on-board hydrogen storage which provides compactness, safety, as well as less stringent requirements for the refuelling infrastructure due to the lower refuelling pressure.

ACKNOWLEDGEMENT

The work described was carried out at HySA Systems and funded by the Department of Science and Innovation of South Africa, as well as by South African business partners including Impala Platinum Ltd. and South African Post Office. The international collaboration activities started in 2018 and related to the development of fuel cell forklifts and their refuelling infrastructure utilising metal hydrides were supported by the EU Horizon 2020 Program; Grant Agreement 778307 – HYDRIDE4MOBILITY – H2020-MSCA-RISE-2017.

MODELING AND DESIGN OPTIMIZATION OF CARBON-FREE HYBRID ENERGY SYSTEMS WITH THERMAL AND HYDROGEN STORAGE

[1]Jacob Bryan, [1] Aiden Meek, [1] Seth Dana, [1] Md Sajedul Islam Sakir, [1*] Hailei Wang
[1]Utah State University, Mechanical and Aerospace Engineering, 4130 Old Main Hill, Logan, UT, USA

ABSTRACT

The study is focused on replacing all coal and natural gas electricity generation in the state of Texas with solar, wind, and nuclear power. As an integral part of the designed hybrid energy system, both thermal and hydrogen storages are used to minimize overproduction and allow for load following. The Dymola system model uses wind speed and solar irradiation data for 2020 to meet the real load data for Texas in 2020. An optimization algorithm is developed to find an optimum design point, aiming to minimize the system's levelized cost of electricity (LCOE) while meeting the demand at all times of the year. The optimized LCOE of the system was $73.04/MWh, which results from 61 Natrium nuclear power plants, 5317 3.2-MW wind turbines, and 307.9 km2 of solar panels. Most of the demand is met by nuclear power with the rest being a near even split between wind and solar. While this optimized LCOE is greater than the current LCOE, it provides carbon-free electricity for the entire state of Texas. Although the stored hydrogen in salt caverns contributed only to a small portion of the total electricity production, it provides a large amount of green hydrogen to future clean energy markets.

Keywords: Hydrogen, Hybrid energy system, Nuclear, LCOE, Dymola/Modelica

INTRODUCTION

Continuing to rely on fossil fuels for our energy needs results in further carbon emissions and increased CO2 levels in the atmosphere. Society faces the problem of reducing fossil fuel consumption, while maintaining the power generation required to maintain our way of life. Texas has installed significant numbers of wind turbines to help reduce its dependence on fossil fuels. However, Texas still has a significant dependence on fossil fuels that needs to be reduced. The goal of this study is to determine an economically optimized hybrid energy system (HES) that can provide Texas' energy needs while eliminating the need for fossil energy. By increasing solar production, installing more wind turbines, building nuclear reactors, and incorporating energy storage, Texas could become carbon-free in its electricity production. The HES design would be capable of meeting Texas' energy demands while minimizing the cost of electricity in the new system. The HES would be built in, and provide power for, Texas (specifically for the ERCOT power company that provides electricity for nearly all of Texas). Solar would be installed in the west of Texas; additional wind production would likely be installed in the north of Texas. The nuclear reactors could be located anywhere in the state. Thermal energy storage, which allows nuclear reactors to follow load, would be installed on site next to the nuclear reactors. Additional energy storage, in the form of hydrogen, could be installed salt caverns in the north or east of Texas.

Texas is a state of both significant energy production, with abundant wind and solar natural resources, and energy consumption, consuming more energy than other state [1]. Despite these natural resources and having two large nuclear energy facilities, Texas still derives 63.7% of its energy from fossil fuel sources via a combination of coal and natural gas, as of 2020 [2]. With the goal to replace these coal and natural gas generation facilities with carbon-free alternatives – namely a combination of wind, solar, nuclear, and hydrogen fuel cells – the demand profile which the new HES must meet is determined by subtracting the energy generated from green energy sources from the total demand. This section will examine this demand profile and consider the wind and solar potential of the state through a look at the wind speed and solar irradiance at multiple locations in the state.

The demand profile which the HES is required to meet is equal to the total demand from the ERCOT data, minus the energy generated from existing carbon-free energy sources. The residual demand profile has several interesting characteristics. First, the demand increases significantly over the summer months, peaking in August. The demand is often 50-100% higher during the summer compared to the rest of the year. This seasonal variation poses a significant difficulty when trying to design a HES with a significant portion of nuclear power, as sizing the system to meet summer demand peaks will invariably result in significant energy overproduction during the winter, spring, and fall. Alternatively, extreme levels of seasonal energy storage may be required to meet the demand during summer if the HES is sized more appropriately (i.e. smaller) for the remainder of the year. The difference in demand profile during each season is further illustrated in Fig. 1, which shows

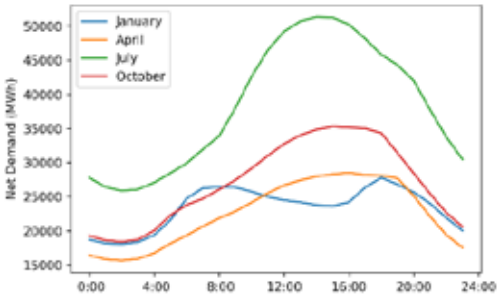

Figure 1: Average hourly demand profile for January, April, July, and October.

hourly average demand profiles for January, April, July, and October. Energy consumption in July is significantly higher than that in the other three months. Also, the January profile is bimodal with peaks around 7:00 am and 6:00 pm, while the other months are unimodal.

Wind speed and solar irradiance data were collected from NASA POWER, using the 50-m height (parameter "WS50M") for wind speed and all-sky surface shortwave downward irradiance (parameter "ALLSKY SFC SW DWN") for global horizontal irradiance (GHI) [3]. To make the data collected for wind speed and GHI less dependent on a specific location and more representative of a region, data from several locations were sampled from the regions of interest for each resource and averaged. The hourly averaged profiles for wind speed and GHI are shown in Fig. 2. As shown, wind speed at 50 meters has significant seasonal variation. First, wind speed tends to be higher at night than during the day. This is advantageous, as wind production will typically increase at night, when solar energy is no longer producing electricity. However, the average wind speed in the plot is lowest for July when demand is at its highest, potentially increasing the effective seasonal variation in demand that must be met by other resources.

Hydrogen, as a great energy carrier, have been drawn substantial interests in recent years to be produced using carbon-free energies such as nuclear. It is typically stored in artificial salt caverns. According to Ahluwalia, et al. [4], it holds up to 6000 metric tons of hydrogen with pressure between 50 and 150 bar. In this study, up to 20 artificial caverns is considered for hydrogen storage. Given Texas has large salt deposits in the north and the east of the state, these salt deposits could be used as geologic hydrogen storage. This is expected to be included in future works.

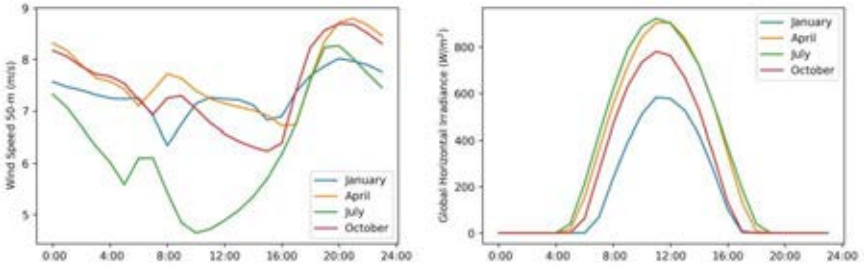

Figure 2: Hourly averaged wind and solar data for January, April, July, and October.

SYSTEM DESIGN, MODELING AND OPTIMIZATION

Given the significant wind and solar resources present in Texas, the proposed HES design includes both wind turbines and photovoltaic solar panels. However, these resources are intermittent and non-dispatchable; the HES uses nuclear power to complement these renewables. Specifically, the Natrium system developed by GE Hitachi Nuclear and TerraPower is used here due its ability to vary power output through its integrated molten salt thermal storage system. This thermal storage is useful short-term energy storage. Hydrogen storage is used for long-term storage. The proposed HES is modeled using Dymola, a software for modeling dynamic systems using the Modelica language. Models for each subsystem - Natrium, wind, photovoltaic solar, hydrogen storage, and hydrogen fuel cells - were developed and integrated in this software. This hybrid energy system (HES) is shown in Fig. 3.

The Natrium system operates a 840-MWt sodium fast reactor as its primary heat source. The reactor is cooled by molten nitrate salt, which is stored in a two-tank storage system. The molten salt can be drawn from the hot storage tank through a salt-steam heat exchanger to drive a steam cycle, outputting 345 MWe at steady state operation. The salt storage capacity allows to boost the power output to 500 MWe for up to 5.5 hours. The wind power production is based on the power curve for the GE 3.2 MW wind turbines, while the solar panels are modeled with 15% efficiency.

The high-temperature steam electrolyser (HTSE) is used to convert excess power to hydrogen with an efficiency of 0.83, which can be obtained by a Solid Oxide Electrolysis Cell (SOEC) [5]. When meeting peak energy demand, a Solid Oxide Fuel Cell (SOFC) with 60% efficiency is modeled to generate electricity. The power output of the fuel cell was capped at 35.5 GW with 2556 GWh of storage, which allows the storage to deliver electricity for 3 days at its full capacity. The excess hydrogen produced by the current optimal HES design needs to be sold for other markets in producing chemicals such as diesel, ammonia, and methanol. In the current model, green hydrogen is priced between $2.50-6.80/kg in calculating the system LCOE. Given the global hydrogen demand is 98.8 billion kg per year and a hydrogen market report predicts

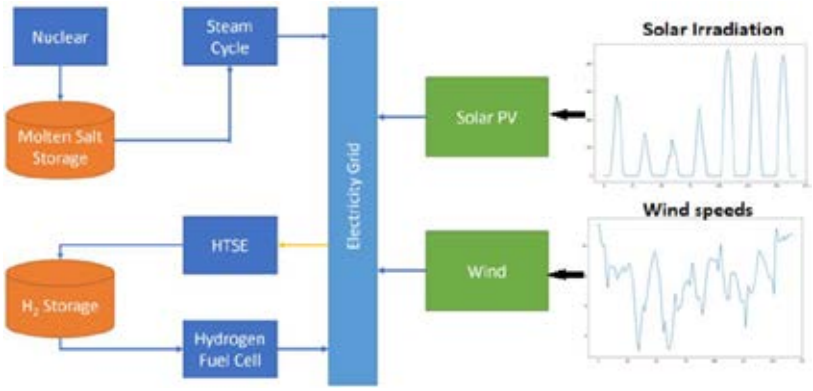

Figure 3: The schematic diagram of the HES design

the world demand for hydrogen to more than double in the next 10 years [6], the green hydrogen produced in the current HES could contribute significantly to those growing needs.

The optimal HES design is defined as the one which minimizes the LCOE of the system. To calculate this system-level LCOE, a weighted sum of the subsystem LCOEs is taken according to the amount of energy produced by each subsystem [4,5,7]. Then, the revenue from sold hydrogen is subtracted from the annual cost, and the difference is normalized by the total annual energy demand.

RESULTS AND DISCUSSION

The optimized HES consists of 61 Natrium reactors, 5317 3.2-MW wind turbines, and 307.9 km2 of solar panels. Given the significant amount of hydrogen being sold, the effective LCOE of the system is very sensitive to the hydrogen price. The estimated LCOE of the system is $73.04/MWh given the green hydrogen price being $6.80/kg. Figure 4 shows how the HES subsystems work together to meet the residual demand for summer 202 in a 10-day period. As shown, both wind and solar output are lower than demand. Besides the nuclear power is modulating significantly to try to match the peaks and valleys of the demand, the hydrogen storage and fuel cell systems are utilized heavily during these periods. Stored hydrogen is consumed at nights to mee the peak demand while during the day the excess energy is converted to hydrogen to replenish the hydrogen storage.

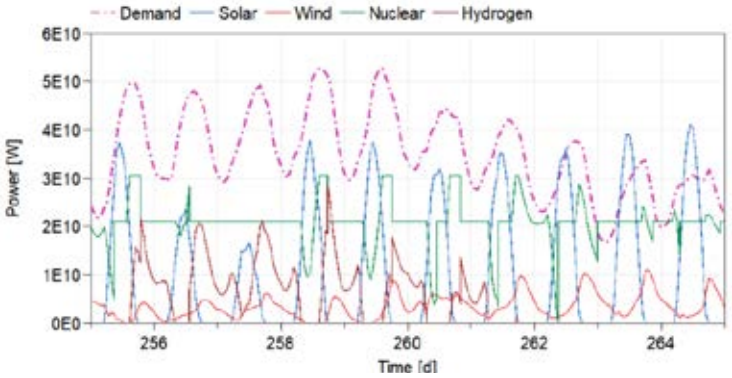

Figure 4: Simulation of 10-day operation of the HES (summer 2020)

CONCLUSIONS

The hybrid energy system presented in this report successfully meets the electricity demand in Texas without using fossil fuels by using a combination of wind, solar, nuclear, and hydrogen power, while also producing significant amounts of green hydrogen for growing industrial needs. However, it does not accomplish this goal particularly economically. The system has an overall LCOE of $73.04/MWh when adjusting the subsystem LCOEs for their respective capacity factors. Additionally, this study only considered the demand and weather data for one year. A more robust system design would need to account for the volatility more directly in wind speed, solar irradiance, temperature, demand, and the correlations between these variables. This could be accomplished by using synthetic time histories and a stochastic optimization to find robust designs with quantified uncertainty. Nevertheless, the proposed HES could be a design which can flexibly grow with the population and adapt to changes in demand with minimal modifications while avoiding carbon emissions.

OFFSHORE WIND ENERGY PROSPECTS FOR POWER-TO-DIRECT AIR CAPTURE AND POWER-TO-GAS

* *Muhammad Faisal Shehzad, Haris Ishaq, Curran Crawford*

ABSTRACT

Direct air capture of carbon dioxide (CO_2) is technically a feasible solution for reducing atmospheric CO_2 concentrations at scale, building on decades of global research. However, powering such systems even partially with CO_2-intensive fossil fuels results in more CO_2 emissions. This paper presents a novel energy management strategy (EMS) to further explore modular offshore wind energy off Canada's West Coast via power-to-direct air capture and power-to-gas systems. The system architecture includes a 15MW wind turbine paired with a hydrogen energy storage system, i.e. hydrogen production and storage, and direct air capture (DAC) units. Hydrogen production from wind generation is stored and used to deliver the thermal loads of the DAC system. In addition to meeting DAC thermal loads, any excess produced hydrogen is used to meet hydrogen demand for external consumers, such as hydrogen as a fuel for fuel cell vehicles. The effectiveness of the proposed EMS is shown through extensive simulations with different seasonal conditions.

Keywords: Offshore wind energy, Direct air capture, Hydrogen storage, Power-to-gas, Energy storage system

INTRODUCTION

It is now well recognized that climate scenarios for the Earth to stay within the limits set by the Paris Agreement [1] must include negative emission technologies (NETs) on a large scale. In the past, there has been concern that these technologies would be viewed as a replacement for actions to directly stop greenhouse gas emissions, but that view has changed. A recent report from the U.S. National Academy of Sciences [2] concluded that "NETs (removing CO_2 from the atmosphere and sequestering it) are best viewed as a component of the mitigation portfolio, rather than a way to decrease the atmospheric concentration of CO_2." Among all CO_2 capture strategies, it is understood that the net flow of CO_2 out of the atmosphere must be positive. However, powering CO_2 capture by fossil fuel, even fractionally, results in additional CO_2 emissions [3]. A potential replacement for powering a CO_2 capture system is to use CO_2-free power, such as wind or solar [4]. In this paper, conventional fossil energy is replaced by offshore-wind energy to power a system of CO_2 capture from air. The main entities of the scenario under investigation are offshore-wind energy, the electrolyzer (hydrogen production and storage), and DAC units.

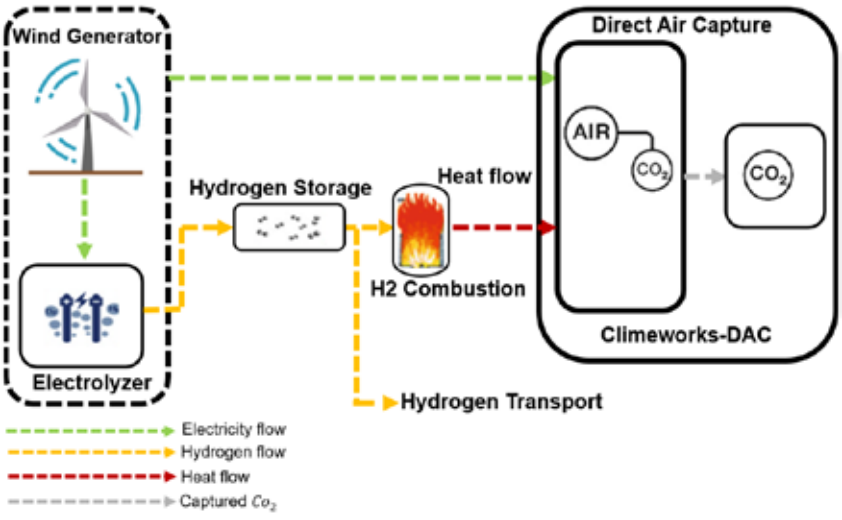

Fig. 1. The overall schematics of the proposed offshore wind-DAC system

In order to achieve the proposed research study goals, this paper presents a novel EMS as a carbon-free nearly zero emission-based solution. In particular, the EMS developed has to fulfill the following:

- to maximize the amount of CO_2 capture via DAC;
- to produce hydrogen for meeting DAC thermal loads (to avoid further CO_2 production in the process);

- to sell any excess of hydrogen produced (after meeting DAC thermal loads) to external consumers, such as hydrogen as a fuel for fuel cell vehicles.

DIRECT AIR CAPTURE SYSTEM MODEL

In order to efficiently utilize the logical dispatch behavior of the DAC units, the system is modeled employing a mixed logic dynamic framework. Two decision variables, namely, the DAC energy requirement (E), and its working state are determined at each time step interval. There is a linear relation between the energy required to operate the DAC and the total amount of CO_2 captured, as shown in Eq. 1. The energy requirement of the whole system for capturing 1kg of CO_2 per unit time is defined as μ, in kWh/kg [5].

$$E = \mu C_T \tag{1}$$

where C_T denotes the total amount of captured CO_2, and E represents both the electric ($P_{DAC}(k)$) and thermal energy requirements ($\dot{Q}_{DAC}(k)$) of the DAC system at each time interval.

HYDROGEN PRODUCTION SYSTEM MODEL

The dynamics of the stored hydrogen H at the next step $k+1$ depends on the level of hydrogen at each time step, on the hydrogen production/consumption efficiencies η and the power P of the electrolyzer. Therefore, we have:

$$H(k+1) = H(k) + \eta P_{elc}(k) T_s - H^{ext} - \sigma_c \dot{Q}_c(k) T_s \tag{2}$$

where T_s denotes the sampling period, H^{ext} is the hydrogen produced for external consumers, $\dot{Q}_c$ is the heat supply to the DAC from the H_2 combustor, σ_c is the heat conversion factor. Notice that, according to Eq. 3, the electrolyzer produces hydrogen whenever the input power is within the electrolyser's acceptable rates only.

POWER BALANCE CONSTRAINTS

The essence of the optimization model is to meet the electrical and thermal demands with renewable generation and hydrogen combustion. The following power balance equations must be satisfied at each time-step k:

$$P_{DAC}(k) \leq P_w(k) - P_{elc}(k) \tag{3}$$

$$\dot{Q}_{DAC}(k) \leq \dot{Q}_c(k) \tag{4}$$

NUMERICAL RESULTS

Parameters of the major components of the proposed modular power-to-DAC and power-to-gas system include a wind turbine with a rated output of 15 MW, and 28 units of CO_2 capture containers (126 kW of each unit and a total of 3.884 MW). These components could all fit on a single floating platform to form a modular, mass-produced architecture. The parameters of the major components are summarized below in Table 1.

Table 1. Parameters of the major components of the wind power-driven CO_2 capture system

Parameters	**CO_2 Capture system (Power-to-DAC)**	
	Adsorption	**Desorption**
Power requirements $E(k)$	44kW per DAC container	82kW per DAC container
$\mu(kWh/kg)$	0.98	1.82
Power consumption ratio	35%	65%
Total amount of the captured CO_2		
	Simulation Week Starting March 13	
C_T	292.34 t-CO_2/week	
Electrolyser (Power-to-gas)		
Efficiency $\eta = 0.23$kg/kW	$P_{elc}^{min} = 300kW$	$P_{elc}^{max} = 3000kW$

In this section, we validate via numerical simulations the proposed control strategy based on west coast Cascadia region wind profiles. In order to show the correct working and capabilities of the devices, week-long power production profiles are considered. As will be clear in what follows, the numerical results show that the proposed EMS is able to correctly satisfy both the electric and thermal demands of the DAC system. In particular, the thermal demands have been met via hydrogen combustion, and any excess of hydrogen is sold to the external consumers for meeting hydrogen as fuel demand for transportation purposes. Further, the system overall constraints are always respected.

The simulations have been conducted over a T=168h simulation horizon with $T_s = 1h$ sampling time. Fig 2(a) shows a typical week-long power production profiles, along with the DAC adsorption (Electric) and desorption (thermal) loads. The details of both the adsorption and desorption energy requirements are reported in Table 1.

It is worth noticing that the hydrogen production objectives in this study are two-fold: meting DAC thermal demand, and hydrogen as a fuel for meeting hydrogen vehicles' demand. Fig. 2(b) shows the excess hydrogen production and storage after meeting the thermal demands with the highest priority.

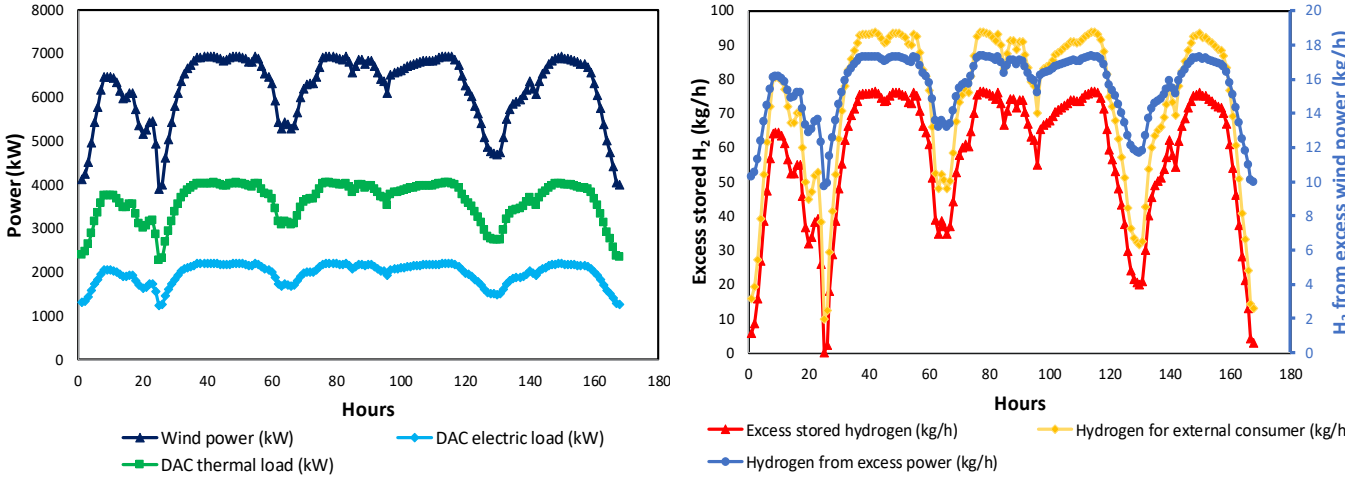

Fig. 2(a). Power production profiles, DAC adsorption and desorption loads (b) Excess hydrogen production and storage

CONCLUSIONS

In this paper, we proposed an EMS within the perspectives of offshore wind energy-driven power to DAC and power to gas. Offshore wind energy is employed with the highest priority to capture the maximum CO_2 by the DAC system. The hydrogen is produced and stored with the objectives of meeting DAC thermal demands (for the desorption phase of the DAC process) as well as hydrogen as a fuel for external consumers. Future works will investigate the proposed results in real-time to produce hydrogen for DAC process as well as for commercialization purposes according to the project goals and also the integration of battery storage system to capture CO_2 for shorter sub-hourly scale variations.

ABSTRACT

A novel renewable energy storage system based on reversible solid oxide fuel cell (SOFC) with integrated organic Rankine cycle (ORC), metal hydride hydrogen storage (MHHS) and absorption refrigeration cycle are proposed in the present study. The system utilizes the waste heat generated from the SOFC unit into the ORC evaporator to produce power using the turbine. After that, the rejected heat is being used for heating application and produces a cooling effect by implementing the single-effect absorption chiller. A part of high-quality exhaust heat from SOFC is transferred to the MHHS for the desorption process to facilitate the release of hydrogen. Exergy analysis of the trigeneration system and evaluation of the exergy destruction rates of system components is carried out. Furthermore, a detailed parametric study is conducted to study the influence of critical parameters such as current density, SOFC temperature and turbine inlet pressure on exergy efficiency and exergy destruction rates. It has been observed that the maximum value of trigeneration energetic efficiency of 74% is obtained at SOFC temperature of 800°C and current density of 0.8 A/cm². Moreover, maximum net electrical exergy efficiency is 67.39%, maximum heating exergy efficiency is 73.1%, maximum cooling exergy efficiency is 66.48%, and maximum ORC exergy efficiency obtained is 16.63%.

Keywords: Solid oxide fuel cell, Exergy analysis, Trigeneration, Organic Rankine cycle, Metal Hydride

INTRODUCTION

As fossil fuels are decreasing with time, efficient power systems are becoming an important subject. As a result, there is an increased focus on developing technologies that will provide better energy conversion efficiencies. SOFC is one such attractive technology that can be used to generate power. SOFC has a great advantage to working on multiple fuels as input such as hydrogen, biomass, hydrocarbons, etc. Also, reversible SOFC produces hydrogen by electrolysis and alternatively generating power output using hydrogen input while working in the fuel cell mode [1]. In addition, multiple concepts to use high-quality waste heat from SOFC have been proposed and investigated. Al-Sulaiman et al. has performed various studies on trigeneration system where they have investigated the biomass-based system and performed energy and exergy analysis [2]. One more study by Al-Sulaiman et al. explored the possibility of using solar energy to drive a trigeneration system [3,4]. Similar studies on SOFC driven trigeneration systems were proposed wherein the SOFC was driven by methane fuel, and the exhaust heat was utilised by ORC and single-effect absorption chiller [2, 5, 6].

The present study is focused on exergy analysis of the system novel energy storage system. The energy analysis of the proposed system is already performed in our previous study [7]. In order to utilize the waste heat from SOFC effectively, various heat recovery units are integrated with the system. The exergy destruction rates of various components of the system are also computed. A parametric study is also performed wherein the current density, SOFC temperature, and inlet turbine pressure are varied to observe the influence on the trigeneration system's exergy efficiency and exergy destruction rates.

System Description

The illustration of a conceptual renewable energy storage unit is shown in Fig. 1. The system comprises a SOFC, MHHS, ORC, heating process and absorption chiller. The operation takes place in two modes, i.e., SOFC and reversible SOFC or solid-oxide electrolyser cell (SOEC) modes. In the SOEC mode, hydrogen is produced by utilising renewable sources and is stored in the metal hydride tank. In the next phase, i.e., the SOFC mode, the stored hydrogen is fed to the SOFC, generating power and exhaust heat. This exhaust heat is further utilised to generate power and enhance the overall power output. The waste heat coming out from SOFC is provided to the H1 heat exchanger, where turbine power output is achieved. The exhaust heat from the turbine is thereafter used in heating applications using H_2 and to produce a cooling effect using the vapour absorption cycle.

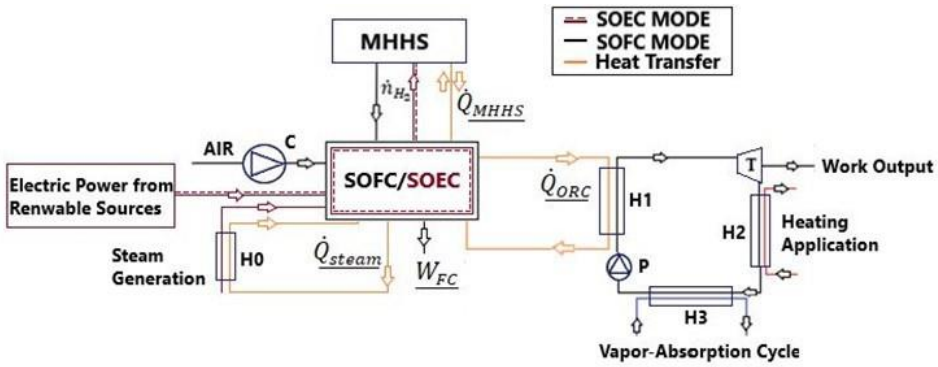

Fig. 1. Schematic representation of a Trigeneration plant with reversible SOFC, MHHS, ORC and vapour absorption cycle.

MODELLING AND ANALYSIS

The rate of exergy destroyed for each component considered in the system can be given by Eq. (1)

$$\dot{E}_{x_d=}\sum_j\left(1-\frac{T_0}{T_j}\right)\dot{Q}_j-\dot{W}_{cv}+\sum_i\dot{m}_i ex_i-\sum_e\dot{m}_e ex_e \tag{1}$$

where $\dot{E}_{x_d}$ and ex represents exergy destruction and exergy per flow rate. Exergy related with any stream can be defined as the sum of chemical and physical exergy per mass flow rate and can be given by Eq. (2).

$$ex_{total}=ex^{ph}+ex^{ch} \tag{2}$$

where ex^{ph} and ex^{ch} can be given by Eq. (3) and Eq. (4)

$$ex^{ph}=(h-h_0)-T_0(s-s_0)+\frac{V^2-{V_0}^2}{2}+g(z-z_0) \tag{3}$$

$$ex^{ch}=x_i ex_i^{ch,0}+RT_0x_i ln(x_i) \tag{4}$$

The SOFC exergy efficiency is given by Eq. (5)

$$\eta_{ex,SOFC}=\frac{W_{SOFC}}{Ex_{f,H_2}} \tag{5}$$

where Ex_{f,H_2} is the input exergy. The electrical exergy efficiency can be given by Eq. (6)

$$\eta_{ex,el}=\frac{W_{net}}{Ex_{f,H_2}} \tag{6}$$

The cooling exergy efficiency can be expressed using Eq. (7)

$$\eta_{ex,cog,c}=\frac{W_{net}+\left(1-\frac{T_0}{T_{evp}}\right)Q_{evp}}{Ex_{f,H_2}} \tag{7}$$

The heating cogeneration exergy efficiency is expressed as Eq. (8)

$$\eta_{ex,cog,\mathrm{h}}=\frac{W_{net}+\left(1-\frac{T_0}{T_{hp}}\right)Q_{hp}}{Ex_{f,H_2}} \tag{8}$$

The tri-generation exergy efficiency is given by Eq. (9)

$$\eta_{ex,\mathrm{tri}}=\frac{W_{net}+\left(1-\frac{T_0}{T_{hp}}\right)Q_h+\left(1-\frac{T_0}{T_{evp}}\right)Q_{evp}}{Ex_{f,H_2}} \tag{9}$$

RESULTS AND DISCUSSION

It is evident from Fig. 2 that the trigeneration exergy efficiency decreases as the SOFC current density increases. Also, the electrical exergy efficiency tends to reduce with increasing current density. As the current density rises, the voltage tends to decrease. As a result, less power is produced from the SOFC. The highest SOFC exergy efficiency value of 57.92% takes place at 0.6 A/cm² which drops down to 50.37% at 1 A/cm². As shown in Fig. 2, the cooling co-generation energetic efficiency is 1.5% more than the electrical exergy efficiency, which is attributed to the comparatively small amount of cooling effect being provided from the cooling cycle. On the contrary, the trigeneration exergy efficiency is also observed to be more than heating co-generation exergy efficiency by 1.5%. This is because of the small addition in the exergy efficiency due to cooling.

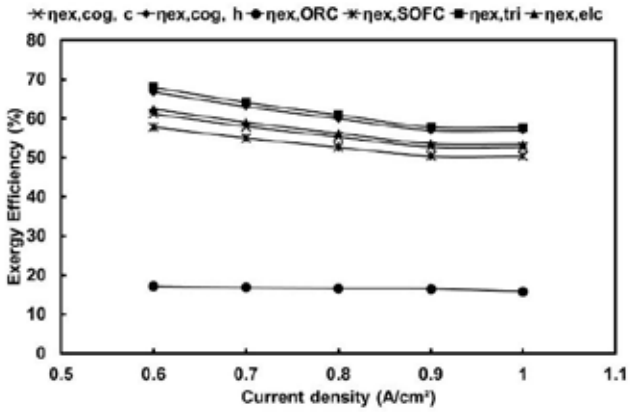

Fig. 2. Effect of current density on exergy efficiency at SOFC temperature=650°C, turbine inlet pressure=1600kPa.

CONCLUSIONS

The proposed study presents a novel design for renewable energy storage using reversible SOFC. Two modes, i.e., SOFC and SOEC, are described, and exergy analysis is performed. In SOFC mode, the maximum SOFC exergy efficiency of 57.92% is achieved at 0.6 A/cm². The electrical exergy efficiency is low at higher current density values. The ORC efficiency is found to decrease from 17.14% to 15.84% as the current density value changes from 0.6 to 1 A/cm². With SOFC temperature shift, the trigeneration exergy efficiency reaches its maximum value of 73.98%. However, the exergy efficiency of the system is observed to remain unaffected by the variation in the turbine inlet pressure.

SCIENTIFIC AND TECHNOLOGICAL SYNERGIES CONNECTING ELECTROLYSERS, FUEL CELLS AND ELECTROCHEMICAL COMPRESSORS FOR HYDROGEN USE

[1*] *Sonya Calnan,* [1,2] *Rutger Schlatmann*

ABSTRACT

Electrolysers, electrochemical compressors and fuels cells will be crucial to supporting the role of green hydrogen in the energy, transport and manufacturing sectors. In this contribution we discuss several scientific and technological synergies between these three types of electrochemical cells and their benefits towards fostering the wider deployment of these devices are outlined. The identified synergies can also be extended to the same type of electrochemical cells based on different dual use (energy and materials) chemicals for example ammonia.

Keywords: Hydrogen, Fuel cell, Electrolyser, Electrochemical compressor

INTRODUCTION

The green house emission targets set by the global community to mitigate the adverse effects of climate change require a massive reduction in the contribution of fossil-based fuels to the energy, transport and manufacturing sectors [1]. Thus, the contribution of renewable energy sources such as solar, wind, hydro- and geothermal energy is increasing to compensate the gradually reducing supply from fossil fuels. Despite the geographically wide dispersion of wind and solar energy resources, unlike hydro and geothermal sources, they are intermittent and thus need storage when electricity supply outstrips demand. Hydrogen (H_2) is the ideal chemical energy carrier because it can be produced and used with little or no green house gas emissions if electrochemical conversion processes are used.

Electrolysers (EC) use electrical energy to split water into oxygen and hydrogen, thus providing storage of excess electricity for later use. Electrochemical hydrogen compressors (EHC) operate by simultaneously compressing and purifying hydrogen supplied to the anode to a purer higher pressure H_2 stream at the cathode, thus increasing the volumetric energy density of stored hydrogen. Lastly, hydrogen fuel cells (FC) convert hydrogen into electricity and thus provide a route to recover stored energy from intermittent primary energy sources. All three devices use and/or produce only water, oxygen and hydrogen which are environmentally benign and sustainable. Thus, in a closed sustainable zero carbon hydrogen-energy cycle, the hydrogen would be generated by an electrolyser driven by either solar or wind energy, compressed using an electrochemical compressor driven by the same energy sources and then re-converted back to electricity in a hydrogen fuel cell. These technologies must be of low cost, operate efficiently and have a long service life to be established in the global energy system.

Since the underlying principal of operation of electrolysers, fuel cells and electrochemical compressors is similar, synergies between them can be leveraged to accelerate the transition to zero carbon or carbon neutral energy pathways. Although there is an implicit awarenes of these synergies in the interested community, e.g. in unitary reversible fuel cells [2] and for fuel cells and EHCs, the development of each of the technologies is largely mutually exclusive. Moreover in recent years, the attention to and advances in fuel cells have exceeded those for electrolysers with EHCs lagging far behind. This unbalanced interest and rate of development of the technologies may lead to missed opportunities of knowledge transfer accross the technologies and unnecessary re-inventions since relevant new insights may be overlooked. This contribution serves to identify and create an overview, that is till now missing in the contemporary publications, of aspects of these devices in which useful scientific and technological synergies may exist. A comprehensive catalogue of such synergies would accelerate the elimination of the barriers that hinder the widespread adoption and deployment of hydrogen based electrochemical devices in the global energy system.

POSSIBLE SYNERGIES AND THEIR BENEFITS

Identification of synergies

The layout and relevant half-reactions, assuming a proton exchange membrane (PEM) electrolyte, of a fuel cell, an electrochemical compressor and an electrolyser, indicating the essential components are shown in Fig 1. The architecture of electrochemical cells such as fuel cells, electrolysers and electrochemical compressors is similar in

that a membrane (which may also act as a solidstate ionic electrolyte) is sandwiched between a pair of oppositely charged electrodes. Electrochemical half reactions that take place at the interface of the electrolyte and each of the electrodes affect the conversion of energy to a chemical and vice-versa. Also, the backbone hardware of all the devices is essentially the same although slight modifications. particularly of the flow field geometry and microporosity of the catalyst interfaces may be required, to enhance functionality that is distinctive to the specific device reactions. The similarity of the fundamental electrochemical principles and device architecture also provides a platform enabling the use of similar numerical models for accelerated optimisation. These devices use similar auxillary hardware for the management of the flows of reactants, products and cooling water, control and safety monitoring, as well as for temperature management. Thus, there would be clear synergies in the development of component manufacturing processes and plants, as well as in the circular economy and recycling of these systems.

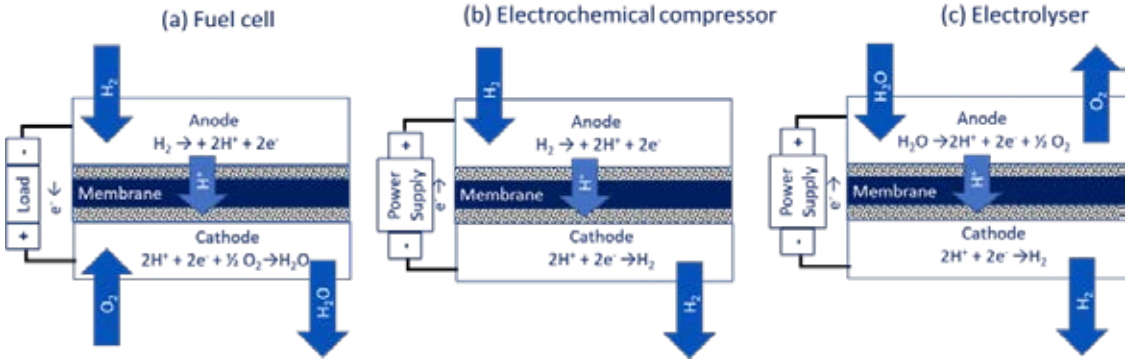

Fig. 1. Schematics of proton exchange membrane (PEM) electrolyte based hydrogen electrochemical cells (a) fuel cell, (b) electrochemical compressor (EHC) and (c) electrolyser. Notice that the anode and cathode, of the EHC, are exactly the same as those of the fuel cell and the electrolyser, respectively. For anion exchange membrane (AEM) based devices, the half reactions are slightly different but the overall reactions are the same.

An inspection of the cell schematics in Fig 1. reveals that the electrodes (electrocatalysts) may be interchanged between the devices. For instance, the EHC uses the hydrogen oxidation reaction (HOR) at the anode to split hydrogen molecules like the fuel cell and uses the hydrogen evolution reaction (HER) at the cathode to generate hydrogen as in the electrolyser. Additionally, the operation of unitary reversible fuel cells depends on availability of highly active, highly selective and stable bifunctional oxygen reduction/evolution reaction (OER/ORR) catalysts and bifunctional HER/HOR catalysts [3]. Indeed the synergies that enable unitary reversible fuel cells play a role in increasing the capacity factor of such devices and thus accelarating their amortisation thereby reducing the total cost of ownership when deployed for electrolysis driven by intermittent primary energy sources. EHCs also depend on the availability of bifunctional HER/HOR catalysts and platinum already shows significant activity in both acidic and alkaline conditions [4]. However, in view of the anticpated demand for platinum, the research community is actively searching for alternative bifunctional catalysts based on transition metals. This in turn drives the development of electrochemical cells employing anion exchange membrane AEM electrolytes, both for OER/ORR [5] and HER/HOR [6].

Additionally, the operational and performance behaviour of these electrochemical cells shows common patterns. For instance, increasing the operating temperature increases the performance but only to a certain extent, since high currents may lead to self-limitation caused by mass transport issues. Suboptimal removal of reaction products and/or delivery of reactants, under high current density, from the electrolyte-catalyst interface increases the internal resistance of the system thus reducing the power density with time. Increased operating pressure also increases membrane cross-over creating a safety risk for fuel cell and electrolysers and also increases back diffusion across the membrane in EHCs ultimately reducing the compression ratio.

For all device technologies, water management is becoming increasingly important because of the trend towards using PEM/AEM that are wetted using humidity supplied via one electrode. Thus, dehydration of the ionomer and membrane which reduces the membrane conductivity and thus the current density, must be avoided. Although electrolysers have previously been run with continuous loading, the majority are, in the future, likely to be operated using fluctuating renewable energy sources. Thus, insights from fuel cells, whose largest area of deployment will be in transportation characterised by high load variability, frequent starts and stops as well as steep ramps, will be useful to improve the durability of electrolysers and ultimately of EHCs in renewable energy cycles. For temperate climates, this also means that such devices may be required to work with „cold“ starts to save energy used to keep the device warm during idle times. Thus, learnings from the control regimes for operating one type of device, may

with some adjustments, be used to improve the operability of the others. All devices suffer from issues with durability mainly attributed to (electro)-chemically induced degradation namely, corrosion in oxidising conditions and embrittlement in hydrogen-rich conditions. For these, reliable analytical testing and stressing procedures are required to identify the causes and mechanisms of degradation which would be useful to prolong the economic service life.

Benefits of identified synergies

A comprehensive awareness of synergies may offer routes to innovative solutions to existing challenges (cost, performance and durability) in all devices. Researchers would then be able to select the priority research areas from which all the technologies may benefit. Research and discovery may benefit from combined efforts channelled to select the most promising material classes for catalysts and membranes, among others. All concerned parties would benefit from the development of test protocols and facilities hinging on common requirements for safety, plant control strategies and balance of plant. Electrochemical cell manufacturers would benefit from a quicker achievement of a critical mass, for economies of scale, to become an attractive market for raw materials supply. Synergies in device architecture and balance of plant may foster the development of common quality assurance practices, norms and standards for common components/subsystems. In turn, the end-users and operators of the electrochemical cells would benefit from reduced costs of ownership because of standardized common components/sub systems and a wider pool of maintenance and servicing providers. Research laboratories and electrochemical cell manufacturers may use synergies to widen their competences and product offerings, respectively. Lastly, collaboration between researchers and industry may be initiated, increasing knowledge transfer and spillover effects across applications.

CONCLUSIONS

Electrochemical cells namely, electrolysers, electrochemical compressors and fuel cells have the potential to contribute to the decarbonisation of the global energy supply by using hydrogen as a chemical energy vector. Commonalities in the device architecture, catalyst materials, electrolyte (and membranes), standards and balance of plant equipment may enable synergetic scientific and technological advancements in fuel cells, electrolysers and electrochemical hydrogen compressors. The benefits of these synergies would best be realised when the attention to, and pace of development of the three technologies is more equally balanced than at present where electrochemical compressors lag electrolysers which in turn lag behind fuel cells. These insights may also be relevant for the equivalent set of electrochemical cells based on other dual use (energy and material) chemicals such as ammonia.

ABSTRACT

Hydrogen has been considered a clean energy source, playing a crucial role in the energy transition. Due to its low-carbon intensity, green hydrogen appears to be an exciting solution to reduce greenhouse gas (GHG) emissions and increase secure energy supply. This study is the first attempt to evaluate the green production of hydrogen in Kazakhstan. At this stage, we have used the GIS tool to quantify solar, wind, and biomass resources in Kazakhstan. Most prospective areas for solar-based hydrogen include Jambyl, Kyzylorda, and Turkestan with hydrogen potential of 3800-4100 t/km^2/year, while Jambyl, Kyzylorda, and Central Kazakhstan regions favored the production of wind-based hydrogen with a hydrogen potential of 16 000-18 800 t/km^2/year. Southern Kazakhstan is also prospective for biomass-based hydrogen energy production (up to 47 t/km^2/year). Based on the hydrogen production estimated from the regions, Kazakhstan could be a supplier of new energy carriers globally, significantly contributing to future hydrogen energy system development.

Keywords: Renewable sources, Electrolysis, Gasification, Hydrogen energy systems

INTRODUCTION

Hydrogen as a part of future energy sources experiencing recognition from both industries and governments, with 39 countries recently announcing their hydrogen strategies [1]. There are multiple pathways to produce hydrogen, with principal production routes informally defined as gray, blue, and green, with the latter having the least carbon intensity. The future of hydrogen energy systems is closely linked with a rapid increase in green hydrogen production in the net-zero world, despite the currently prevailing role of gray hydrogen production (96% as of 2019) [2]. Kazakhstan can play a significant role in future hydrogen energy systems due to its considerable renewable resources and its will to expand renewable energy deployment in the future [3]. This study estimated the amount of potential green hydrogen production from Kazakhstan's wind, solar, and biomass resources using GIS tools.

METHODOLOGY

We consider three types of renewable resources for green hydrogen production: solar, wind, and biomass. We assume that electricity generated from solar and wind energy produces hydrogen from water splitting via electrolysis. Electrical potential obtained from sun and wind goes through AC output to convert it into DC voltage used in the electrolyzer within the AC/DC converter. The geographic distribution of electricity generated by wind turbines and solar panels was assessed using GIS-based average wind speed and global horizontal irradiation data respectively. PEM electrolyzers used electricity to generate hydrogen [4], which was modeled in our work. Wind turbine, solar panel, and electrolyzer parameters are shown in Table. For biomass hydrogen, our work modeled biomass feedstock as agricultural crop residues, which undergo a gasification process to produce hydrogen. Gasification of biomass has a Technology Readiness Level (TRL) value of > 7, which implies that the technology can be demonstrated in the operational environment [5]. Biomass feedstock and gasification parameters are shown in Table 1.

The data for wind and solar resources of Kazakhstan was obtained from the NREL database [6]. Agricultural crop production data for analysis was obtained from the Kazakhstan Agency of Statistics (KAS).

Table 1. Model assumptions for green hydrogen production

Hydrogen production methods	Operating strategy	
	Solar panel/wind turbine parameters [7]	***Electrolyzer parameters [4]***
Solar hydrogen	ElySun Monocristallin 250 Wc Solar Panel [7] PV module: mono-crystalline Efficiency of module conversion:15.28%	Electrolyzer type: PEM Hydrogen delivery pressure: 13.8 bar Power consumption (equivalent of 75% efficiency): 52.5 kWh/kg H_2
Wind hydrogen	Enercon E82 Wind Turbine [8] Hub Height: 82 m Rotor Diameter: 82 m Coefficient of performance of the wind turbine: 0.45	
	Biomass feedstock properties (KAS)	***Gasification parameters [9]***
Biomass hydrogen	Agricultural residues: grains, wheat, sugar beet, cotton, oil seeds and sunflower Moisture content: assumed to be 16% Crop residue to product ratios: specific for each crop type	Conversion rate of agricultural residues: 13.8 kg dry weight/kg H_2 Gasification pressure: 1.6 bar Gasification temperature: 870°C

RESULTS AND DISCUSSION

Estimated solar, wind, and biomass-based hydrogen production results are given in the unit of t/km^2/year, referred to as hydrogen production potential hereinafter.

The geographic analysis of solar electricity gave us the distribution of hydrogen potential across Kazakhstan: the lowest values were observed in the northern part of the country, whereas the highest ones were found in the southern Kazakhstan (Fig. 1). This pattern occurs due to higher horizontal solar irradiation in Shymkent, Turkestan, and Kyzylorda regions and is significantly lower in Petropavlovsk, Kostanay, and Aktobe. The former regions are located relatively closer to the equator, where the solar irradiation meets its peak. Thus, solar panels in South Kazakhstan can result in a hydrogen production potential of 3 800 to 4 100 t/km^2/year.

Overall hydrogen production potential from wind energy sources was similarly high across the country, ranging mainly from 10500 to 19000 t/km^2/year (Fig. 2). The tendency of average wind speed remaining at high levels comes from the continental climate in Kazakhstan and could be a promising energy source. However, the southern-eastern region is relatively lower at hydrogen production potential varying from 1900 to 6400 t/km^2/year. Such a difference occurs due to mountain landscapes that prevent the long flat ranges for developing high wind speed.

Fig. 3 depicts hydrogen production potential from gasification of residues of grain and legume, sugar beet, cotton, and oilseeds. High hydrogen production potential values up to 48 t/km^2/year resulted from cotton residues in South Kazakhstan. Oilseeds resulted in the hydrogen production potential of 11-19 t/km^2/year in numerous regions (Zhambyl, Northern Kazakhstan, Pavlodar, Almaty, Eastern Kazakhstan, Southern Kazakhstan). The hydrogen production potential of grain and legume and oilseed crop residues remains moderate (5-15 t/km^2/year) across the country.

Besides the growing interest in the deployment of renewable energy, hydrogen energy is also gaining momentum in Kazakhstan. Recently, German-Swiss company Svevind Energy GmbH announced the construction of a huge hydrogen production project in the Mangistau region that would launch in 2027-2031 [10]. Svevind Energy is willing to construct facilities that would benefit from wind and solar power stations for an estimated 30 GW capacity, which will produce 2 million tons of green hydrogen annually [10].

ABSTRACT

We present the analysis of the size and angle configuration of a solar photovoltaic (PV) plant connected to an alkaline electrolyzer without electrical storage nor support from the grid. Our approach is based on using the available energy in the most efficient way. To reach our objective, we allocated the available PV power to the stack and auxiliary components, then determined the produced hydrogen in one year. By defining 4 indicators, we determine that the PV plant should be oversized 1.6 times the rated power of the electrolysis stack. The orientation analysis of the PV modules shows that the optimal angles determined for maximum PV yield are not the same if other indicators are used and many of them are in conflict.

Keywords: Optimization, Energy efficiency, Green hydrogen

INTRODUCTION

Of all the production methods for hydrogen, water electrolysis is still a minority. In The Netherlands, water electrolysis contributed to only 1% of the produced hydrogen during 2021 [1]. If the country were to shift all of its production to electrolysis, a considerable amount of extra electricity is needed. To put things in context, the country needs 3.7 times more electricity than its goal for renewable energy set for 2030. For this reason, it is essential to ensure an energy efficient production of hydrogen. Previous studies have analyzed the optimization of PV-electrolysis systems targeting sizing of batteries, but ignoring the Balance-of-Plant[2]; optimizing grid connected systems [3], or optimizing the PV size for off-grid systems aiming at reducing the cost of hydrogen [4].

Our study contributes to the previous research by defining operation indices that describe the energy use of the electrolysis system. Our analysis leads to an optimization of the PV array. As we omit electric storage, the daytime available energy must be used as efficient as possible. We included the extra power needed to power the pumps, instrumentation and other equipment required to support the production of hydrogen. The PV array must meet the power demand of the electrolyzer and these additional components.

MODELLING METHODOLOGY

We modelled a PV-electrolyzer system to study the effect of plant size (in terms of nameplate power) and module angle configuration on the hydrogen production. We consider a fictitious horizontal PV plant located in Cabauw, The Netherlands. This system receives uniform irradiance and is connected to the electrolyzer by ideal power converters. Hence, we considered that the modules are always operating at maximum power point (MPP). All the generated power (P_{pv}) is consumed by the electrolyzer (P_{ele}) and Balance-of-Plant (P_{BoP}) (Eq. (1)). PV power that would violate the operating limits of the electrolyzer is curtailed.

$$P_{pv} = P_{ele} + P_{BoP} \quad (1)$$

The electrolyzer considered is a 100 kW, alkaline type and 186 cells (n_{cells}) in series. The stack voltage (V_{ele}) is modelled as a function of the applied current density (i) using Eq. (2) [5]. The operating limits lie within 20% of nominal current and 100% of nominal power. We assumed a constant operating temperature of 60 °C, considering that the power needed to keep this condition is absorbed by the Balance-of-Plant.

$$V_{ele} = n_{cells}(1.29 + 4.0468 \cdot i + 0.1803\, log(2.2709 \cdot i + 1)) \quad (2)$$

To support the operation of the electrolyzer, auxiliary components (pumps, power electronics) are included as Balance-of-Plant. These components consume power that is a percentage of the power demanded by the stack as in Eq. (3) [6].

$$P_{BoP} = 0.19276 \cdot P_{ele}^{0.249} \quad (3)$$

The performance of the system is measured using 4 indicators: (i) total produced hydrogen (kgH_2), (ii) system energy usage per kilogram hydrogen produced (kWh/kgH_2), (iii) wasted energy (kWh) and (iv) the utilization factor, defined as a ratio of the monthly energy used by the stack to the energy used if it was operated at nominal power during the same period.
The irradiance data was obtained from the Royal Meteorological Institute of the Netherlands (KNMI) and corresponds to the measurements of 2013 with a resolution of one minute.

RESULTS AND DISCUSSION

We first analyzed the oversizing of the PV-electrolyzer system. We kept the electrolyzer nominal power fixed while changing the PV nameplate capacity (kW) as a fraction of the electrolyzer's power. As seen in Figure 1, downsizing the electrolyzer (i.e., increasing the PV plant peak power) results in an improvement of all indices. The hydrogen production (Figure 1 (a)) benefits the most from an increased PV plant, in part due to a higher utilization of the electrolyzer (Figure 1 (d)). However, there is a limit in the PV plant size at which the energy is best utilized. This limit corresponds to a PV plant rated power that exceeds by 1.6 times the nominal power of the electrolyzer (Figure 1 (b)). The minimum wasted energy is achieved with a PV size that is 1.2 times larger in power than the electrolyzer (Figure 1 (c)).

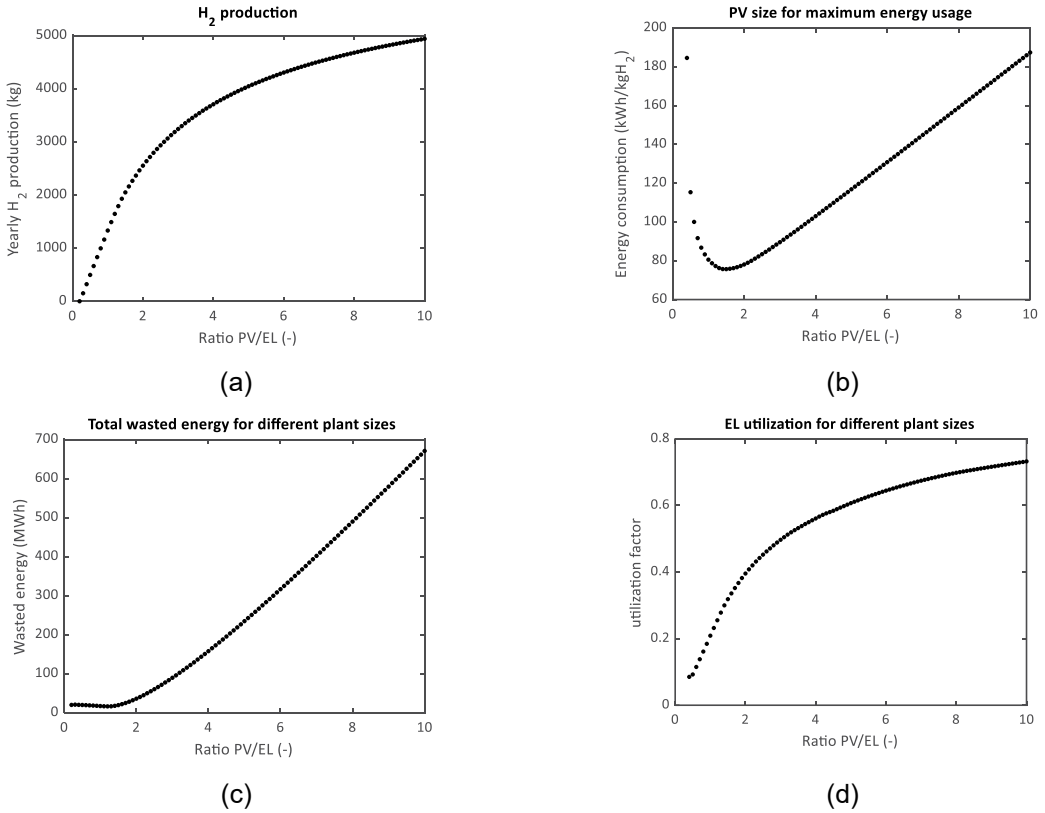

Figure 1. Analysis of PV rated power with respect to the electrolyzer nominal power. The horizontal axis shows a ratio of the two powers. Different indicators are analyzed. (a) hydrogen production, (b) the system efficiency expressed as a measure of the energy needed to produce 1 kg of hydrogen; (c) the energy that cannot be used for exceeding or not being enough to power up the process and (d) the amount of time the electrolyzer operates at nominal power .

We chose the ratio PV/electrolyzer that minimizes the utilization of energy (Figure 1 (b)) and studied the effect of different module orientations (azimuth and tilt) on the 4 indicators. Figure 2 shows the optimal module angles for each indicator. From the figure, it becomes clear that the indicators compete. In particular, setting the array at an optimal angle for minimizing the energy use can potentially reduce the produced hydrogen, but results also in lower wasted energy.

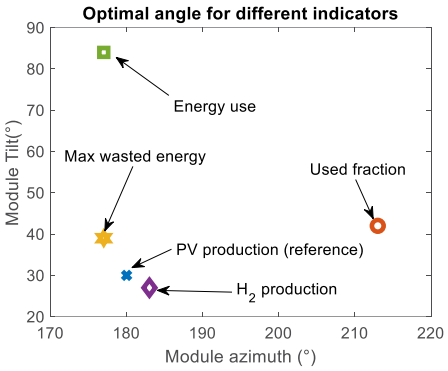

Figure 2. Optimal angles of the different indicators. The 'x' is the optimal angle for maximum PV production at the site and is included as a reference. Note that none of the indicators coincides with this configuration.

Even when increasing the PV size leads to an improved hydrogen production, the analysis of wasted energy imposes a limit on the oversize of the system. Note that this indicator never drops to zero even for very small PV systems as low power levels are not enough to start the electrolyzer, which remains off and hence curtailment is unavoidable. At an oversize ratio (PV power/electrolyzer rated power) of 1.2 the wasted energy is minimized. Interestingly, this is not the point for highest efficiency (oversize ratio of 1.6). At low power, the auxiliary components demand more energy, making the process more inefficient. The most efficient point occurs then when the correctly allocated to produce hydrogen, instead of supporting the Balance-of-Plant, at a cost of more energy spilled.

CONCLUSIONS

We presented an analysis and method for sizing a PV system connected to an alkaline electrolyzer and its auxiliary components. Our approach gives priority to a best utilization of the available energy from the Sun, trying to reduce the amount of unused energy. We found that spilling is unavoidable without storage. Further, minimizing the wasted energy can be detrimental for a high-efficiency process mainly due to the Balance of Plant. We found an optimal ratio of PV peak power to rated power of electrolyzer equal to 1.6.
We concluded a module orientation analysis concluding that the PV system should not be oriented aiming at maximum PV production but to a specific target. The selection of this target needs to be selected carefully as the module orientations are different for each one.

ABSTRACT

The article presents the results of a study of the effect of the addition of hydrogen-containing gas on the indicator and effective indicators of a gasoline engine. Experimental and numerical analysis studies of the combustion process in a gasoline engine when operating without additives and with the addition of different quantities of hydrogen-containing gas have been carried out. As a result, it was found that the addition of a hydrogen-containing gas leads to a reduction in the duration of the combustion process and an improvement in engine performance. The addition of hydrogen-containing gas leads to an increase in the indicated efficiency of the engine, the heat utilization factor and an increase in the indicated power. As a result of bench tests, an increase in the effective power and a decrease in the brake specific fuel consumption of the engine were found.

Keywords: hydrogen, hydrogen-containing gas, H_2/O_2, combustion process, indicated parameters, gasoline engine.

INTRODUCTION

Decreasing global oil reserves and pollution of the environment with exhaust gases from vehicle engines are prompting scientists around the world to look for ways to reduce the consumption of petroleum-based fuels and reduce the negative impact on the environment [1]. One of the promising areas is the use of additives obtained from renewable sources to improve the combustion of traditional fuels. The most promising additive is hydrogen, which is the most abundant substance in the universe [2]. In addition, the combustion of hydrogen produces water that does not have a negative impact on the environment.

It was found that with the addition of H_2/O_2 to a gasoline engine, which operates with an excess air coefficient λ = 0.92 - 0.94, the thermal efficiency of the engine increases by 1.2 - 5.6%. CO_2 and HC emissions are reduced by 30 and 40%, respectively. CO and NOx emissions are practically unchanged. When the engine is operating with an excess air ratio λ = 1.18 - 1.2, the thermal efficiency of the engine increases by 3 - 17%. HC, CO and CO_2 emissions are reduced by 67, 54 and 18%, respectively. In addition, the scientific novelty is the method of calculating the indicated parameters of the engine, taking into account the addition of hydrogen-containing gas.

RESEARCH METHOLOGY

Experimental studies were carried out in the engine testing laboratory of the Department of Engines and Heat Engineering of the National Transport University (Kyiv, Ukraine.). The object of research is Opel C30 NE engine with a working volume of 3.0 liters, with a gasoline injection system, on which a system for adding hydrogen-containing gas H2/O2 to the intake manifold is installed. To substantiate the improvement of fuel efficiency and environmental performance of a gasoline engine when using a hydrogen-containing gas as an additive, an indexing of the working process was carried out at various values of H_2/O_2 additives. A measuring device was developed to record gas pressure in the cylinder. The main element of the device is a high-temperature strain gauge pressure transducer 6 MIDA-DI-12P-081. Hydrogen-containing gas was obtained using an ATW-1000 electrolysis unit, which operates from an external current source with a voltage of 220 V. The amount of hydrogen-containing gas added to the air charge was varied in the range from 0 to 7.88% of the mass fuel consumption (the H_2/O_2 flow rate was varied from 0 to 9.5 l/min). To confirm the reliability of the obtained characteristics, the characteristic of fuel burnup was calculated according to the expression of Vibe [3]:

$$x = 1 - e^{-6.908 \cdot \left(\frac{\varphi - \varphi_{s.c.}}{\Delta \varphi_c} \right)^{m+1}} \quad (1)$$

where φ – angle corresponding to the moment of ignition crank angle, deg.;
$\varphi_{s.c.}$ – start of combustion, deg;
φ_z $\varphi_{c.d.}$ – combustion duration, deg;

m – an indicator of the nature of combustion, is determined by enumerating numerical values in order to obtain a theoretical characteristic of heat release as close as possible to the experimental curve of the characteristic of fuel burnup.

RESULTS AND THEIR ANALYSIS

In fig. 1 shows indicated parameters diagrams when the Opel C30NE engine is running on gasoline and when the engine is running with the addition of 7.88% hydrogen gas based on the mass fuel consumption. Also, the dependences of changes in pressure, temperature, characteristics of heat release and heat utilization on the angle of rotation of the crankshaft are shown. As can be seen from Fig. 2, when the engine switches to a power supply with the addition of a hydrogen-containing gas, the total duration of the combustion process is reduced from 73.35 deg to 69.4 deg. In this case, the main phase (phase II) has the main effect on the duration of the combustion process, which decreases by 3.36 deg. The initial combustion phase (phase I) and the later burning phase on the expansion line (phase III) decrease relatively insignificantly: by 0.085 and 0.026 deg., respectively.

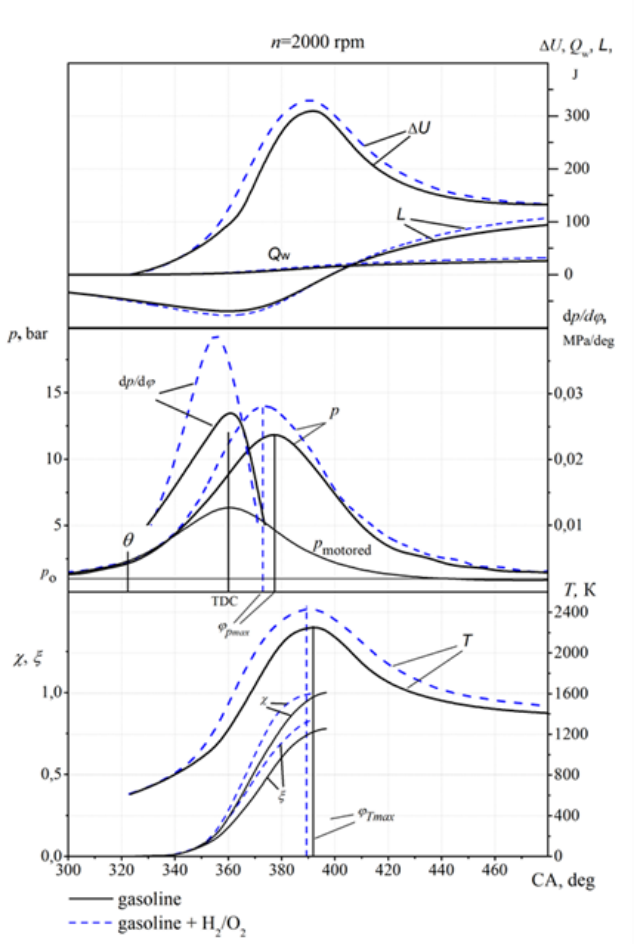

Fig. 1 Indicated parameters of the engine Opel C30NE when the engine is running only on gasoline and on gasoline with the addition of hydrogen-containing gas

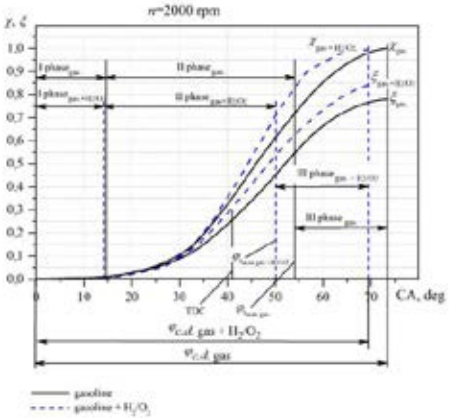

Fig. 2 Characteristics of heat release and heat use of the engine Opel C30NE when the engine is running on gasoline and with the addition of hydrogen-containing gas H_2/O_2

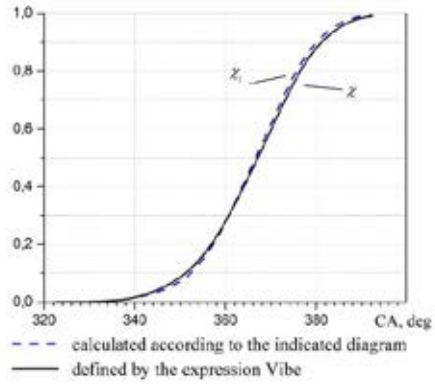

Fig. 3 Characteristics of heat release of the engine Opel C30 NE with the addition of hydrogen-containing gas; χi – calculated according to the indicated diagram, χ – defined by the expression Vibe

An example of the calculated characteristics of fuel burnup according to the expression Vibe when the engine is running with the addition of a hydrogen-containing gas, it is shown in Fig. 3. As can be seen, the curves of heat release characteristics obtained by different methods differ insignificantly, which indicates the reliability of the results of calculation studies.

The results of processing the indicated parameters diagrams of the working process of the Opel C30 NE engine when the engine is running on gasoline and with the addition of hydrogen-containing gas are given in Table 1.

Table 1. The results of processing the indicated parameters diagrams of the working process of the engine Opel C30 NE when running on gasoline and with the addition of hydrogen-containing gas

Workflow parameters	**Gasoline**	**Gasoline+ H_2/O_2**
Vacuum in the intake manifold Δp_m, kPa	59	59
Ignition advancing angle θ, deg. before TDC	41	41
The maximum pressure p_{max}, bar	11.82	13.98
The maximum temperature T_{max} , K	2260.3	2456.5
Duration of the initial phase of combustion φ_I, deg.	14.7	14.1
Duration of the second (main) combustion phase φ_{II}, deg.	39.4	36.0
Coefficient of active heat release in TDC, χ_0	0.24	0.26
Active heat release coefficient at p_{max}, χ_{pmax}	0.72	0.715
Active heat dissipation coefficient at T_{max}, χ_{Tmax}	0.97	0.99
Heat utilization coefficient in TDC, ξ_0	0.175	0.215
Heat utilization coefficient at p_{max}, ξ_{pmax}	0.55	0.55
Heat utilization coefficient at T_{max}, ξ_{Tmax}	0.755	0.82
The angle of rotation of the crankshaft from TDC to p_{max}, deg.	17.37	13.0
The angle of rotation of the crankshaft from TDC to T_{max}, deg.	31.85	29.4
The duration of the combustion process $\varphi_{c.d}$, deg.	73.35	69.4
Maximum rate of pressure rise $dp/d\varphi$, MPa / deg	0.0272	0.04

CONCLUSIONS

It was found that the addition of hydrogen-containing gas H_2/O_2 has a positive effect on the indicated parameters of a gasoline engine. When the engine is running with 7.88% hydrogen-containing gas added to the fuel mass flow rate, the maximum cycle pressure increases from 11.82 bar to 13.98 bar (~15%). This was due to the higher rate of hydrogen combustion and the more complete oxidation process of the fuel.

The duration of the combustion process is reduced from 73.35 degrees to 69.4 degrees. In this case, the second (main) phase has the largest influence on the duration of the combustion process, which decreases by 3.36 deg. The first (initial) and third (later) combustion phases are reduced comparatively slightly. At the moment of maximum pressure, there is an increase in the heat utilization coefficient at the end of the third combustion phase from 0.78 to 0.84 due to the optimization of the combustion process.

ABSTRACT

As ecological requirements getting stricter and the new manners of decreasing emissions of pollutants are being researched. One of them is to focus the usage none or small count of carbon fuels as a fuel for internal combustion engine. Therefore, usage perspective of bioethanol with HHO gas as an additive fuel to petrol lean mixtures, is presented in this research. Ecological (CO, CO_2, HC, NO_x) and energetic (M_B, B_f, BTE) parameters were measured when using petrol ant bioethanol mixtures (E10 and E70) enriched with HHO gas. Experimentation was done by using spark ignition engine changing the ignition timing from 16° to 42° BTDC and changing stoichiometric mixture (λ = 1.0) to a lean (λ = 1.1; 1.2; 1.3; 1.4). Hydrogen and oxygen gases are produced using mobile electrolysis unit – HHO gas generator. It was concluded that for all air / fuel ratios tested the maximum torque was reached with 70% bioethanol additive to petrol, HHO gas has positive effect when mixtures are lean. The NO_X emission has increased, however CO, CH and CO_2 were lower when HHO was supplied.

Keywords: petrol, bioethanol, HHO, hydrogen, combustion.

INTRODUCTION

Modern development trends in motoring are focused on the greening of vehicles - the promotion of less polluting vehicles, but also the substitutability of vehicles and the economic aspect of their use. These issues call for alternatives to be sought in transforming the current fleet of vehicles from fossil fuels to alternatives that generate less CO_2. Various new generation fuels, such as Hythane (a mixture of hydrogen and natural gas) and biomethane, serve this purpose (“Biomethane CNG hybrid,” 2011). Thus, there remains a need to use more affordable alternative fuels such as methane (Biomethane) (Abdul Rahman and Ramesh, 2017), hydrogen (can be used pure or in the form of HHO)
Another product used in spark ignition engines is bioethanol. Its use is currently widespread and is regulated as a mandatory additive to petrol (up to 10%) throughout the European Union (AEE., 2019). As a fuel, bioethanol in a spark ignition engine increases combustion efficiency, cylinder pressure, cylinder temperature and flame rate. It also reduces combustion time, combustion rate, combustion temperature and maximum heat release rate (HRR)(Thangavelu et al., 2016).

In summary, the additional supply of HHO gas without the need for additional modifications to the engine systems is very promising in trying to address some aspects of engine performance when it comes to the use of bioethanol and gasoline blends. These would be ecological aspects like reducing the emissions of PN cells. On the other hand, a decrease in the burning rate with lean bioethanol and gasoline blends has been found in the literature, and low levels of HHO should address this issue. An analysis of the literature shows that the use of such fuel blends (bioethanol and gasoline blends and in addition to HHO gas) is still poorly researched, but the topic is very promising.

RESEARCH METHOLOGY

The experiment investigates the effect of hydrogen and oxygen (HHO) gas on the energy and environmental performance of a spark ignition (SI) engine, when conventional fuels E10 (90% petrol / 10% ethanol by volume) is replaced by E70 (30% petrol / 70% ethanol by volume). The test was performed using a Nissan Qashqai SI engine HR 16DE.
Engine is controlled by MoTeC M800 programmable electronic control unit (ECU), the engine load is created using AMX 200/100 load stand.

Fuel mixtures E10, E70 are prepared by mixing pure petrol (produced at the ORLEN Lithuania refinery) and bioethanol (produced at the JSC Kurana bioethanol plant).
A constant flow of (3.8 l / min) HHO gas is additionally supplied to the engine trough the intake manifold. HHO gas is produced using an electrolysis unit that uses an external energy source. The electrolyte consists of 4% KOH alkali and distilled water mixture. The unit uses 700 W of power, this power is evaluated to determine the brake thermal

efficiency of the engine. Specific electrical power for HHO gas production 184 W / (l / min). HHO gas consists of a stoichiometric mixture of H_2 and O_2 gases, which the volume of hydrogen occupies 2/3 and oxygen 1/3 of the total volume in the mixture (https://doi.org/10.1016/j.energy.2018.03.087). An anti-backfire device was installed in the gas supply system to protect the HHO unit from the reverse flame from the intake manifold. The low density of hydrogen (ρ_{H2} = 0.09 kg / m^3) compared to oxygen (ρ_{O2} = 1.43 kg / m^3) results in a mass fraction of H_2 and O_2 in the HHO gas mixture of 0.111 and 0.889, respectively. With HHO gas flow of 3.8 l / min, H_2 and O_2 gas are supplied at ~ 0.0137 kg / h and 0.1087 kg / h, respectively. After estimating the H2 flow and the LHV, the additional energy supplied to the engine is 1,642 MJ / h, which corresponds to a power of 456 W. This means that the efficiency of the HHO generator used is ~ 0.65.

RESULTS AND THEIR ANALYSIS

Engine power indicators

Break thermal efficiency (*BTE*) was highest running E10 when λ = 1.1 (1.9% more compared to E10 when λ = 1.0) (Fig.1). Using E10 when λ = 1.0–1.2 the HHO gas did not have a major impact on BTE, when λ = 1.3–1.4 a positive effect of HHO gas is observed, but the BTE remains lower compared to E10 when λ = 1.1. We only see a better result when using lean high ethanol mixture E70 with HHO gas. Oxygen in ethanol and hydrogen and oxygen in HHO gas increased the burning rate of the lean mixture. The maximum positive effect of HHO is when E70 + HHO and λ = 1.4. In this case, the BTE increases by ~ 2% compared to E70 when λ = 1.0, and increases by ~ 3.1% compared to E10 when λ = 1.0.

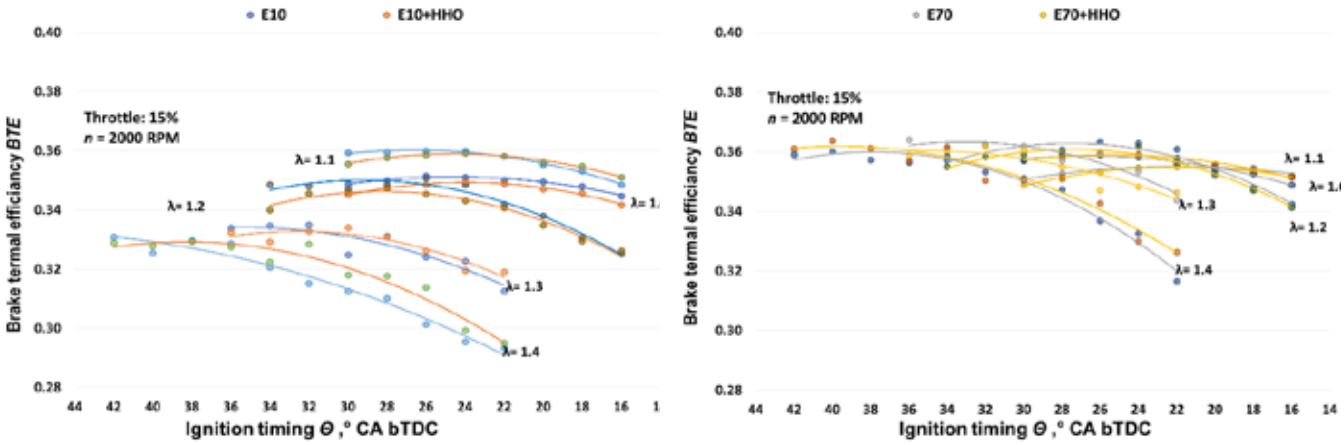

Fig. 1 Brake thermal efficiency running on different fuel blends, changing spark timing

Engines ecological indicators

The ecological performance of the engine is calculated by looking at the specific emissions (g / kWh), changing the fuel and excess air ratio changes the engine power.

Changing E10 fuel to E70 and changing the air excess ratio from 1.0 to 1.4 reduces CO_2 emissions by 1–3% (Fig. 2). This is due to the lower C / H ratio and higher BTE of the E70 fuel. The additional use of carbon-free HHO reduces CO_2 emissions by 0.3-1.5% and is close to the share of hydrogen energy in fuels.

Lowest CO_2 emissions are achieved with the engine running E70 + HHO at λ = 1.4, as these fuels have the lowest C / H ratio and the highest BTE (Fig. 1), but the brake torque achieved by the engine is reduced. The next best option is to use E70 + HHO when λ = 1.0. In this case, CO_2 emissions are up to 2.7% lower compared to E10, optimal ignition timing is similar to E10, and brake torque increases by 2.2%.

CONCLUSIONS

Experimental tests on SI engines running on petrol-bioethanol mixtures of E10 and E70 were performed at 2000 rpm with the throttle open at 15%, changing the ignition timing and the air excess ratio (λ = 1.0, 1.1; 1.2; 1.3; 1.4). Adding an additional 3.8 l / min HHO gas to the intake manifold. The share of hydrogen energy in the fuel during leaning of the mixture varies from ~ 1.2% to ~ 1.8%.

Increasing bioethanol concentration in the fuel mixture from 10% to 70% decreases the C / H ratio by 22%, increases the oxygen concentration by 6.7 times, increases the stoichiometric air to fuel ratio by 24.5%, decreases the lower heating value by 24.0% (mass) and 20.7% (volume) the octane number of the fuel increases, and the evaporation of

bioethanol cools the intake fuel mixture better. Hydrogen in HHO gas reduces the C / H ratio, increases lower heating value and burns.

With the engine running at the set air excess ratio, the E70 injects 18 to 20% more fuel than the E10. Depending on the operating conditions, the torque was 2… 10% higher using E70. For E10 fuel, the maximum thermal efficiency is reached when λ = 1.1 and leaning the mixture efficiency decreases. The BTE of E70 does not decrease even in the case of very lean mixtures (λ = 1.3; 1.4). In the case of E70 + HHO (λ = 1.4), HHO gas accelerates combustion and BTE increases by ~ 2% compared to E70 when λ = 1.0, and by ~ 3.1% compared to E10 when λ = 1.0.

E70 fuel CO_2 emissions are 1–3% lower compared to E10, and the addition of HHO additive lowers it by 0.3–1.5%. In regard to CO_2 emissions it is more rational to use E70 with HHO, when λ = 1.0, since without changing ignition timing CO_2 emissions are reduced by 2.7% and brake torque is increased by 2.2%, while comparing with E10.

ABSTRACT

Hydrogen-assisted diesel injection is suitable for low-power and high-power-to-weight ratio in-cylinder piston direct injection engines. The jet characteristics of hydrogen-assisted diesel direct injection have an important effect on engine performance. The effects of fuel injection duration and mixture duration, hydrogen pressure and fuel/hydrogen premix time on spray penetration distance and diffusion area were qualitatively analyzed by high-speed photography on a constant volume chamber test bench. The results show that increasing the fuel injection duration increases the penetration distance and decreases the spray projection area. Increasing hydrogen pressure will increase both penetration distance and spray projection area. Increasing the duration of air injection will increase the penetration distance and decrease the spray area. The spray area increases with the increase of fuel/hydrogen premixing time, and tends to be stable when the premixing time is 3ms, which has no effect on the spray penetration distance.

Keywords: Piston engine, Hydrogen-assisted injection system, Direct injection, Diesel, Spray characteristics

INTRODUCTION

The development of high-altitude small aircraft has received unprecedented attention worldwide due to the demand of future information warfare[1]. Gas-assisted fuel injection is suitable for high-altitude small aircraft [2]. Hydrogen is considered as the most ideal clean energy because of its high calorific value per unit mass, fast combustion rate and no pollution to the environment[3,4]. Hydrogen-assisted fuel injection can help improve fuel atomization effect and combustion performance, improve engine performance and reduce exhaust emissions.The experimental research by Wu et al.[5] showed that the air-assisted spray tends to produce smaller droplet size and more uniform distribution. Bai et al.[6] studied the influence of injection duration on spray characteristics and pointed out that increasing air injection volume could improve fuel atomization effect and significantly reduce the sauter mean diameter (SMD) of spray.

In this paper, hydrogen/fuel internal mixture injector is designed, and experimental research is carried out under different control parameters. Diesel spray penetration distance and spray projection area are used for quantitative analysis, which provides a certain theoretical basis for the application and parameter matching of hydrogen-assisted injection in practical engines.

EXPERIMENTAL SETUP AND METHODOLOGY

As shown in Fig. 1, the experimental apparatus for hydrogen-assisted fuel spray characteristics mainly include visual constant volume chamber system, hydrogen-assisted fuel injection system, intake and exhaust system, schlieren imaging system, high-speed camera and image acquisition system.

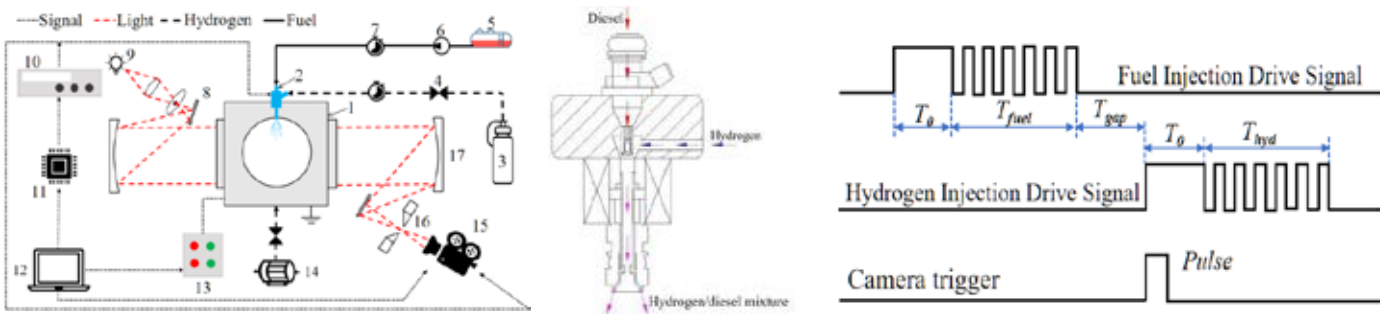

Fig. 1. Schematic diagram of test bench, fuel and air assisted signal control timing. (1) constant volume chamber, (2) gas-assisted nozzle, (3) hydrogen container, (4) relief valve, (5) fuel tank, (6) fuel pump, (7) pressure gage, (8) minor reflector, (9) light source, (10) synchronizing signal generator, (11) ECU, (12) computer, (13) temperature controller, (14) exhaust system, (15) high-speed camera, (16) knife edge, (17)main reflector.

Fig. 1 illustrates the timing phase diagram of the nozzle of the hydrogen-assisted fuel injection system and the driving signal of the high-speed camera. Nozzle signal T_{fuel} is the fuel injection duration, T_{gap} is the fuel/hydrogen premix time, and mixture nozzle opening signal T_{hyd} is the mixture injection duration.

In order to quantitatively analyze the spray morphology of hydrogen assisted injection, the parameters of spray penetration distance and spray diffusion area were introduced. Spray penetration distance refers to the distance from the nozzle to the furthest end of spray, and spray diffusion area refers to the total distribution area of spray in space (longitudinal section), as shown in Fig. 2. The test was repeated 5 times for each test condition and the average was used to determine the penetration distance and diffusion area. Through MATLAB programming software, the spray images are binarized. Diesel was used as fuel in this study, and the test conditions are shown in Table 1.

Table 1. Experiment conditions

Parameter (unit)	Value
Ambient pressure (MPa)	0.1
Fuel injection pressure (MPa)	1
Fuel injection duration (ms)	2/3/4/5
Hydrogen injection pressure (MPa)	0.6/0.7/0.8/0.9
Hydrogen injection duration (ms)	2.5/3.5/4.5/5.5
Interval of fuel and hydrogen (ms)	1/2/3/4

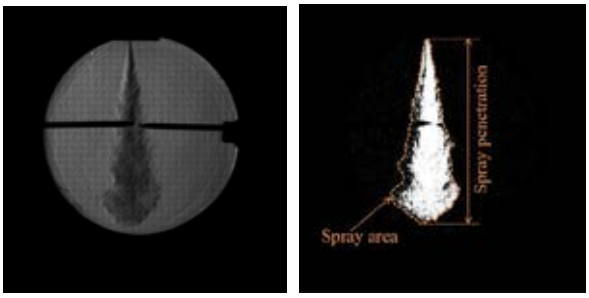

Fig. 2. Spray picture, spray characteristic definition.

RESULTS AND DISCUSSION

Fig. 3 shows that the increase of fuel injection duration will lead to the decrease of spray penetration distance and the increase of spray area. Because a large amount of gas kinetic energy is converted into fuel droplet kinetic energy and surface energy in the premixed chamber, the first atomized fuel is accelerated in this process. The increase of single injection amount leads to the increase of hydrogen fuel ratio in the premixed chamber, and the increase of fuel content in the mixture reduces the motion capacity of compressed hydrogen, which reduces the jet kinetic energy of the mixture to a certain extent. Increasing the fuel injection duration weakens the atomization effect of compressed hydrogen on fuel in the premix chamber, and the spray particle size will increase. The edge of the fuel vapor spray field that is not easy to be vaporized and gasified will be easier to identify, and the spray area will also increase.

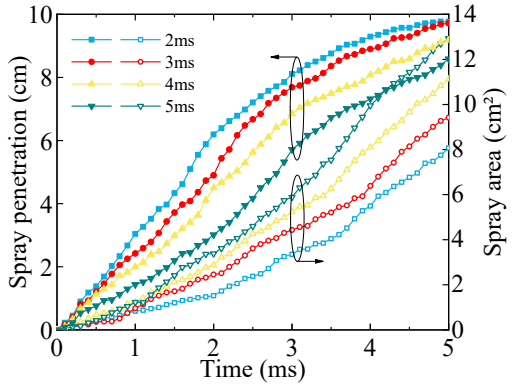

Fig. 3. Different duration of fuel injection.

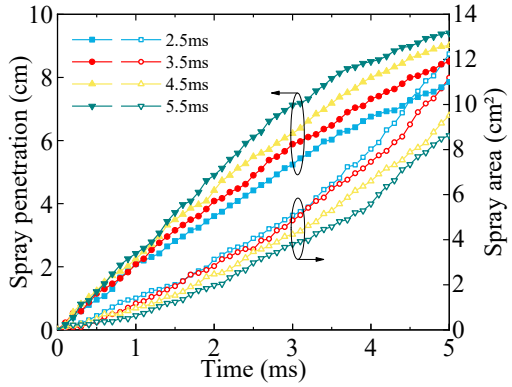

Fig. 4. Different fuel/hydrogen mixture injection duration.

As shown in Fig. 4, the spray penetration distance increases with the increase of injection mixture duration, while the spray area is on the contrary. This is because the mixture duration increases, the amount of high-pressure hydrogen injected into the cylinder increases, and the interaction time between droplet and compressed hydrogen increases, which accelerates the droplet movement and increases the penetration distance. At the same time, the time for hydrogen to flow through the nozzle is prolonged, which increases the capacity of spray expansion and breakage and reduces the spray particle size, which is conducive to the rapid evaporation of fuel. After the evaporation and vaporization of fuel, the spray width will be reduced, which leads to a smaller spray area.

Fig. 5 shows that under different hydrogen pressures, spraying is divided into two different stages: in the first stage, the spraying speed is large and the spray penetration distance increases rapidly; In the second stage, the spray speed decreases obviously and the spray development becomes slow. The higher the hydrogen pressure is, the greater the initial kinetic energy will be when entering the constant volume indoor spray. In the case of the same environmental pressure, the resistance will be the same and the through-distance will be larger. The projection area of spray increases linearly with time under different air injection pressures. The spray projection area is mainly affected by two factors: the axial distance (that is, the through-distance) along the spray and the radial development distance. As the air injection pressure increases, the axial distance increases, and the radial development generally shows an increasing trend, so the spray projection area also increases.

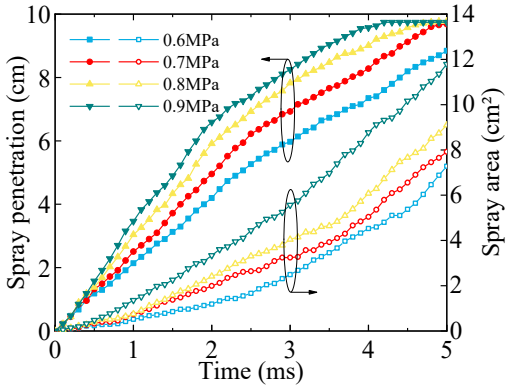

Fig. 5. Different hydrogen injection pressures.

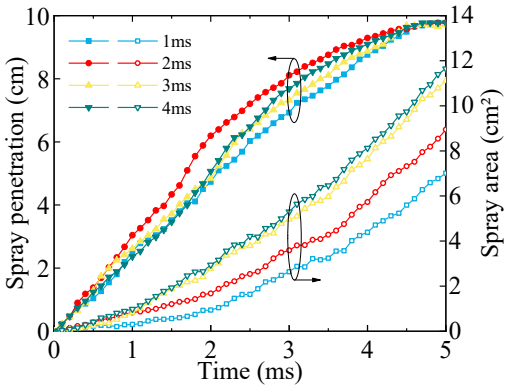

Fig. 6. Different fuel/hydrogen mixing times.

According to the comparison in Fig. 6, the mixing time of fuel/hydrogen hardly affects the spray penetration distance, because the pressure difference at both ends of the mixture nozzle is not changed, and the initial spray velocity does not change, and the penetration distance does not change significantly under the same environmental back pressure. If the mixture nozzle is opened immediately after fuel injection, the atomization effect of spray is relatively poor. With the increase of mixing time, the spray area increases, but when the interval time is more than 3ms, the change of spray area slows down. In other words, the spray area increases and tends to be stable with the increase of mixing time.

CONCLUSIONS

In this paper, the spray characteristics of hydrogen-assisted fuel were experimentally studied, including the effects of fuel injection duration, mixture injection duration, hydrogen pressure and fuel/hydrogen premix time on spray characteristics. From the results, it can be concluded that:

- When the fuel/hydrogen premix time is 3ms, the liquid fuel and compressed hydrogen can be fully mixed and the atomization effect is the best.
- The hydrogen assisted injection penetration distance is similar to the traditional single fuel injection. The spray penetration distance presents a two-stage development trend, and the spray projection area mainly presents a linear growth trend. Increasing hydrogen pressure and mixture injection duration can improve spray penetration and fuel atomization.
- Reducing the injection pulse width or increasing the injection pulse width can promote the ability of the oil beam to run through the direction of the injection hole. At the same injection time, the spray penetration distance tends to increase, which helps the mixture of liquid fuel and compressed hydrogen to be completely ejected by the mixture ejector.

ABSTRACT

Greenhouse gas emissions have led to the imminent global warming crisis, which has motivated scientists and engineers to search for creative solutions for this problem. Rail transportation is known to emit greenhouse gases because of its reliance on fossil fuels. This paper investigates an integrated design of a locomotive engine to replace the traditional internal combustion engines. The integrated system consists of a gas turbine with double compressors and double turbines, two fuel cells, and an energy recovery system including two thermoelectrical generators and an absorption refrigeration system. The proposed engine is analyzed thermodynamically to examine its performance using methane and hydrogen fuel blends. It was found that the integrated engine can generate 9 MW of total power, which is threefold of the traditional locomotive engines with 70.6% of thermal efficiency and 42% of exergetic efficiency.

Keywords: Locomotive engine, Fuel cells, Energy recovery system, Thermodynamic analysis.

INTRODUCTION

The COVID-19 pandemic alerted the world to the severe impact of global warming, and a major contributor to this impact is the transportation sector due to its dependency on fossil fuels [1]. Tremendous efforts are made to develop and redesign transportation engines in different sectors in order to reduce carbon emissions and improve engine performance. Hybridization and new design engines are introduced to rail transportation, including fuel cells, batteries, new efficient engines instead of internal combustion engines (ICE), and alternative fuels. For example, Akhoundzadeh et al. [2] studied a hybridized train operated by lithium-ion battery and proton exchange membrane fuel cell (PEMFC). They utilized a blend of diesel and hydrogen fuels at various ratios for diesel multiple unit (DMU) rail commuters. Seyam et al. [3] proposed a hybridized locomotive engine, which involves ICE, gas turbine, and molten carbonate fuel cell with clean fuels such as hydrogen and hydrocarbons. The overall engine power is increased by 25%, with 43% and 55% of energetic and exergetic efficiencies, respectively. Moreover, Locomotive engines release massive heat as heat loss, which reduces the overall thermal efficiency. A convenient approach is to apply an energy recovery system by converting thermal energy into electrical energy using thermoelectric generators (TEG). For instance, Ma et al. [4] constructed a platform of 32 TEG units around an exhaust pipe of a truck. The inlet mass flow rate varied from 12 to 24 kg/h, and inlet temperature changed from 100 ℃ to 300℃. The units can produce 0.66 to 3.17 W of electricity with an efficiency of 0.67%. The main objective of the current paper is to propose a new powering system for locomotives consisting of a gas turbine with two compressors and three turbines, fuel cells such as high-temperature proton exchange membrane fuel cell (PEMFC) and solid oxide fuel cell (SOFC), an energy recovery system including two thermoelectric generator (TEG) and an absorption cooling system (ARS). The proposed new engine design uses a methane and hydrogen blend and is investigated thermodynamically to examine its performance and compare it with the EMD 16-710G3 of 3355 kW traditionally used for Canadian rail transportation.

SYSTEM DESCRIPTION AND ANALYSIS

The proposed locomotive engine design is presented in **Error! Reference source not found.**. This design consists of an intercooled gas turbine system, an energy recovery system, and a fuel cell system. The gas turbine comprises two compressors (C1 and C2), two turbines (T1 and T2), an intercooler (IC), a combustion chamber (CC), and an afterburner (BR). The fuel cell system involves a high-temperature proton exchange membrane (PEMFC) and solid oxide fuel cell (SOFC). The energy recovery system contains two thermoelectric generators (TEG1 and TEG2) and an absorption refrigeration system (ARS). The ARS consists of a generator (AGN), condenser (ACN), evaporator (AEV), absorber (ABS), and heat exchanger (AHX).

The intake air passes through the first compressor C1, which is pressurized in the intermediate compressor. Then the air is cooled by IC and split into two parts; the main part is passed through the second compressor to be pressurized to a high pressure, the secondary part passes through the high-temperature PEMFC. Then the fuel blend is burnt with compressed air in the CC to reach its high temperature producing exhaust gases. These gases are expanded by the high-pressure turbine (T2) to generate electricity. After that, some of the exhaust gases is utilized in the SOFC to produce electricity, while the remaining is recombusted in the afterburner (BR) with the exhaust of SOFC to ensure the

complete combustion of the fuel blends before expanding in the low-pressure turbine (T1) to be released to the atmosphere. The exhaust gases leave the engine at high temperature with large thermal waste energy, which can be recovered by the energy recovery system (ERS) by transferring thermal energy into electric power using TEG1 and TEG2 and into a cooling load for air conditioning the trains by the ARS, which is operated using an ammonia-water refrigerant.

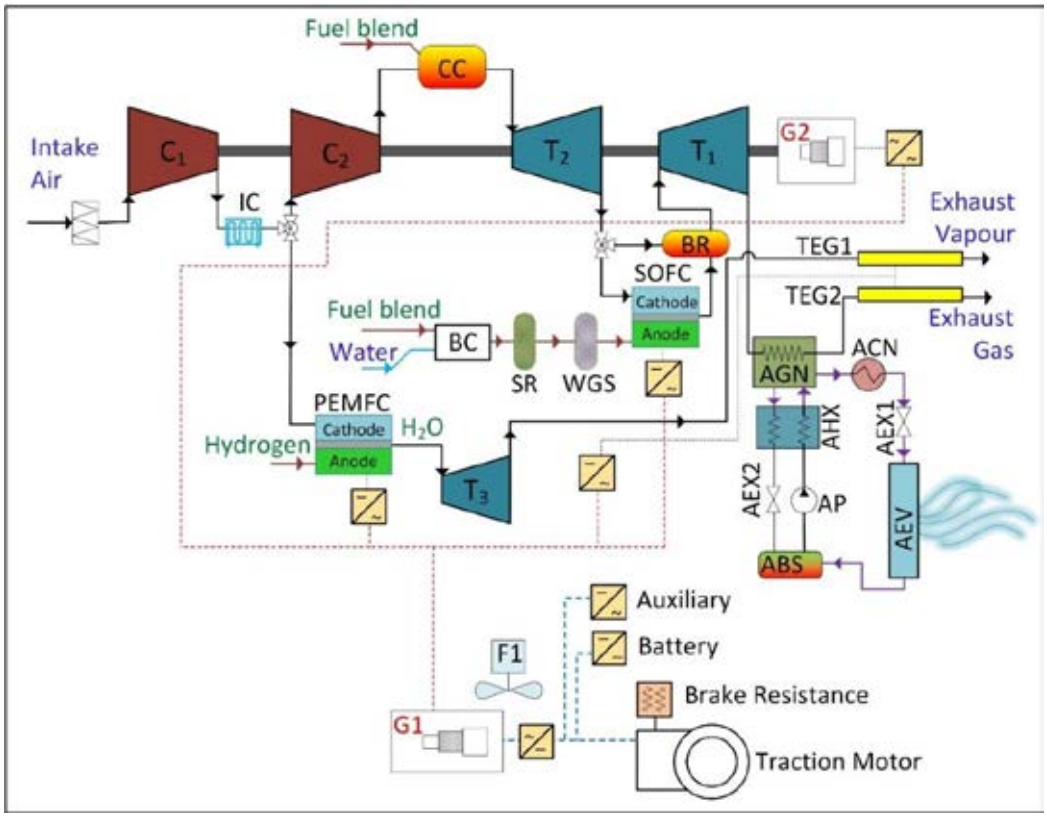

Fig. 1. Schematic layout of the hybridized gas turbine based locomotive engine

The engine power ($\dot{W}_{eng}$) and heat required ($\dot{Q}_{eng}$) are given as follows:

$$\dot{W}_{eng} = \dot{W}_{GT} + \dot{W}_{TEG1} + \dot{W}_{TEG2} + \dot{W}_{SOFC} + \dot{W}_{PEMFC} \quad (1)$$

$$\dot{Q}_{eng} = \dot{Q}_{CC} + \dot{Q}_{BR} \quad (2)$$

The overall performance of the hybrid locomotive engine can be measured using thermal efficiency (η_{eng}) and exergetic efficiency (ψ_{eng}) of the engine, which are written below:

$$\eta_{eng} = \frac{\dot{E}_{out,eng}}{\dot{E}_{in,eng}} = \frac{\dot{W}_{eng} + \dot{Q}_{AEV}}{\dot{Q}_{eng}} \quad (3)$$

$$\psi_{eng} = \frac{\dot{E}x_{out,eng}}{\dot{E}x_{in,eng}} = \frac{\dot{W}_{eng} + \dot{E}x^{Q}_{AEV}}{\dot{E}x^{Q}_{CC} + \dot{E}x^{Q}_{BR}} \quad (4)$$

RESULTS AND DISCUSSION

The newly designed engine is modelled and analyzed thermodynamically to present the energetic efficiency and exergetic efficiency using the Aspen Plus software package. The equation of state is selected to be the Peng-Robinson. The highest power is gained by the high-pressure turbine (T2) (8978 kW). The total generated power of the turbines is 13978.1 kW, and the total required power of the compressors is 10320.8 kW. The heat from the combustion chamber (CC) and afterburner (BR) is 5759.3 kW and 7632.7 kW, respectively. The exergy destruction rate reaches its high value for the BR then CC because of the extreme temperature differences and chemical reactions of the substances. The fuel cells of PEMFC and SOFC release heat losses of about 9 MW and produce a total power of 6 MW. The released heat rates from the SR and WGS are 414 kW and 29 kW, respectively. The intercooler (IC) releases heat from the air after pressurization by C1 by 880 kW to drop 50℃. The waste heat from the engine after the turbine T1 is 3638 kW, and that of after T3 is 184 kW. This waste energy has been transferred to two useful forms of energy: electric power by using TEG1 (9 kW) and TEG2 (16 kW), and cooling load by the AEV (615 kW) by the ARS. Therefore, the total useful energy is 623 kW (excluding the pump power), which increases the efficiency by 16.3%. The integrated engine has an overall thermal efficiency of 70.6% and an exergetic efficiency of 42%. The gas turbine only engine can produce a power of 3181 kW, while the integrated one can produce 9166 kW, which is about threefold the traditional engine. In addition, the engine can produce 1.09 kg/s of CO_2, meaning an 80% drop in carbon emissions compared to any fossil fuel-operated engines [5]. Also, the performance of traditional gas turbine engines using methane and hydrogen blend is 25.4% and 31.6% energetic and exergetic efficiency, respectively.

CONCLUSIONS

The proposed integrated locomotive engine consists of a gas turbine, two fuel cells, and an energy recovery system. This engine is investigated thermodynamically using the Aspen Plus simulation to address its performance. The integrated engine is operated using 75% methane and 25% hydrogen blend as a replacement for fossil fuels. The proposed engine can produce a total power of 9 MW, which is threefold the value of traditional locomotive engines with 70.6% of thermal efficiency and 42% of exergetic efficiency. The proposed engine has a promising potential as the future of locomotive engines because of its great performance and environmentally benign fuels.

ABSTRACT

In this study, an integrated system is developed for environmentally benign and efficient combustion of natural gas in domestic applications. For this purpose, natural gas is blended with biogas and renewable hydrogen to combat fossil fuel usage and greenhouse gas emissions released to the environment. Different blending ratios are analyzed with Aspen Plus software and combustion emissions are investigated. While CO_2 emission and reactor heat rate are 6.48 kg/h and 27 kW when using only natural gas. These values decrease to 6.35 kg/h and 22 kW for 60%-40% natural gas-biogas blend and 5.06 kg/h and 18 kW for 40%-40%-20% natural gas-biogas-hydrogen blend, respectively. In the case of this triple blending, the natural gas consumption reduces from 2.46 kg/h to 0.98 kg/h.

Keywords: Hydrogen, Renewable energy, Biogas, Natural gas, Blend, Emissions, Performance assessment

INTRODUCTION

Although natural gas (NG) resources are still receiving high attention for use, high carbon dioxide emissions are unavoidable when burned. For this reason, researchers show great interest in studies on blending cleaner fuels such as renewable hydrogen and biogas into natural gas. Benaissa et al. [1] studied the combustion specifications of the biogas-hydrogen blend at several blending ratios for a non-premixed swirling flame in a combustor of the gas turbine, numerically. The hydrogen ratio was changed from 0% to 50% by volume. They revealed that CO_2 and CO emissions reduced with higher hydrogen addition. Ozturk and Dincer [2] proposed a geothermal based system for hydrogen and power production and blending hydrogen into natural gas for combustion applications. Hydrogen was blended into the natural gas network with blending ratios up to 20% by volume. The overall exergy and energy efficiencies of the investigated system were calculated as 77.9% and 46.8%, respectively. Gómez Montoya et al. [3] studied several strategies for spark-ignition engine performance. In their experimental study, biogas was blended with natural gas, hydrogen and propane to enhance combustion specifications. As a result, the power output and production efficiency were found out higher than the original operation of the diesel engine. Zhao et al. [4] investigated the effect of renewable gas ratio on the performance of operating for a residential room furnace. The results of their study showed that 15% hydrogen and 5% carbon dioxide by volume could be mixed with natural gas separately without substantial effects. The flashback and blow-off risks are the limiting factors for above these amounts. The main goal of this study is to propose a novel system for efficient and environmentally friendly combustion of natural gas with the help of blending biogas and renewable hydrogen in it. In this system, biogas is produced from biomass while hydrogen is produced from an alkaline electrolyzer fed by renewable sources of energy such as wind and solar. Several blending rates are utilized to analyze the effect of hydrogen and biogas amounts on combustion performance.

SYSTEM DESCRIPTION

The proposed system for the blending of biogas and hydrogen into natural gas is shown in Fig. 1. While biogas is generated from biomass in a biogas plant, hydrogen is produced by an alkaline electrolyzer. The required electricity for the electrolyzer unit is provided by renewable sources such as photovoltaic (PV) panels and wind turbines. Produced hydrogen and biogas are blended into natural gas in a blending unit at the same pressure of 4 bar. The generated blend has a volumetric flow rate of 3.5 Nm^3/h is fed to the household appliances.

METHODOLOGY

The proposed system is simulated with the Aspen Plus software [5]. The worksheet of the Aspen Plus simulation is shown in Fig. 2. Several blending rates are utilized for biogas and hydrogen as changed from 0% to 40 and 0% to 20%, respectively. For the analyses, natural gas and biogas content are taken as given in Table 1.

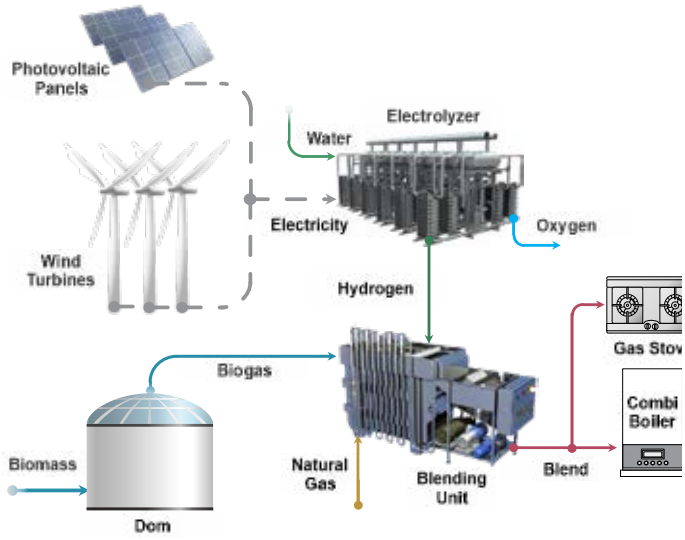

Fig. 1. The proposed system for blending of biogas and renewable hydrogen into natural gas

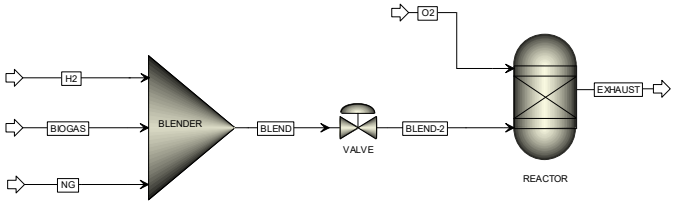

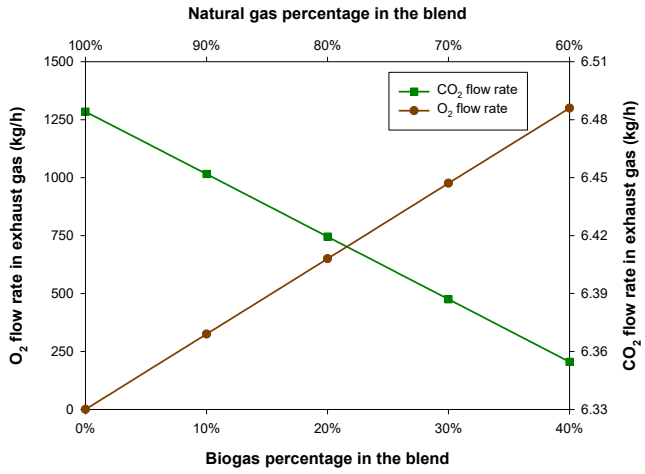

Fig. 2. The simulation flowsheet of the blending and combustion of the blend

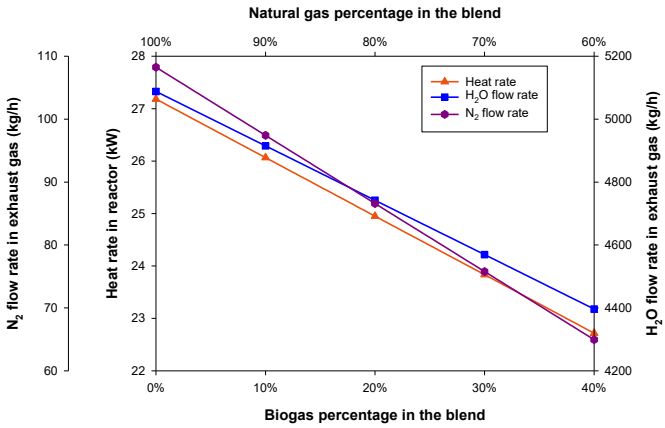
Table 1. Natural gas [6] and biogas [7] compositions



Gas	Composition	Fraction (%)
Natural gas	Carbon dioxide	0.38079
	Nitrogen	2.76014
	Hexane+	0.02362
	n-Pentane	0.05342
	i-Pentane	0.07035
	n-Butane	0.31704
	i-Butane	0.23230
	Propane	1.13812
	Ethane	3.48796
	Methane	91.5363
Biogas	CO_2 + CH_4	35 + 65

RESULTS AND DISCUSSION

The effect of biogas addition into the NG on combustion performance is shown in Figs. 3a and 3b. When biogas content in the NG changed from 0% to 40%, O_2 and CO_2 flow rates in the exhaust stream is changed from 0.19 kg/h to 1300 kg/h and from 6.48 kg/h to 6.35 kg/h, respectively. Moreover, the heat rate, N_2 and H_2O flow rates are decreased from 27 kW, 108 kg/h and 5088 kg/h to 22 kW, 64 kg/h and 4396 kg/h, respectively.

(a)

(b)

Fig. 3. The effect of biogas addition into the NG on a) O_2 and CO_2 flow rates b) N_2, H_2O flow rates and heat rate

The effect of both hydrogen and biogas blending into the NG on combustion performance is shown in Figs. 4a and 4b. When pure natural gas is employed for the combustion process, CO_2, O_2, N_2, H_2O flow rates and heat rate in the exhaust stream are 6.48 kg/h, 0.19 kg/h, 108 kg/h, 5088 kg/h and 27 kW, respectively. On the other hand, when 40%-40%-20% NG-biogas-hydrogen blend is available, these values are changed to 5.05 kg/h, 2700 kg/h, 43 kg/h, 3883 kg/h and 18 kW, respectively.

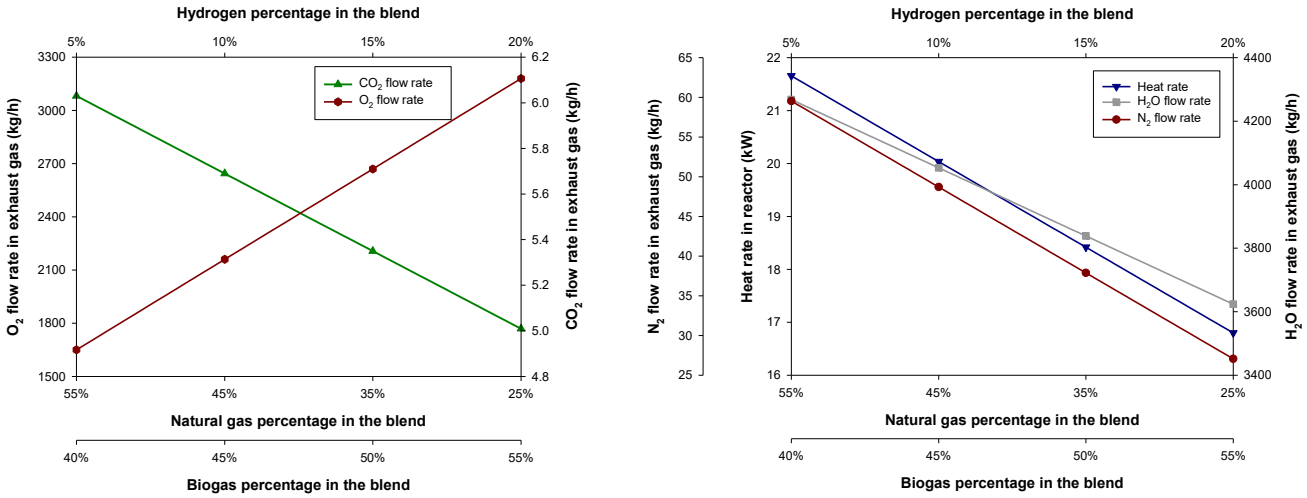


Fig. 4. The effect of biogas and H_2 addition into the NG on a) O_2 and CO_2 flow rates b) N_2, H_2O flow rates and heat rate

CONCLUSIONS

Some of the main conclusions are derived from this particular study as follows:

- With the triple blending, the natural gas consumption is decreased from 2.46 kg/h to 0.98 kg/h.
- When biogas addition rate into the NG varied from 0% to 40%, O_2 and CO_2 flow rates in the exhaust is changed from 0.19 kg/h to 1300 kg/h and from 6.48 kg/h to 6.35 kg/h, respectively. Also, the heat rate, N_2 and H_2O flow rates are reduced from 27 kW, 108 kg/h and 5088 kg/h to 22 kW, 64 kg/h and 4396 kg/h, respectively.
- When 40%-40%-20% NG-biogas-hydrogen blend is employed, CO_2, O_2, N_2, H_2O flow rates and heat rate in the exhaust stream are varied to 5.05 kg/h, 2700 kg/h, 43 kg/h, 3883 kg/h and 18 kW, respectively.

ABSTRACT

The aim of the research is to study a system that uses both non-renewable and renewable energy sources, fulfilling the energy requirements by using fossil fuels but also reducing the use of fossil fuels which are damaging the environment in hindsight by the introduction of a renewable energy system. The system provides a total of six different outputs, which are Electricity Generation, Desalination of Water, Heating of space, Cooling of space, Heating of Water and Waste Heat for Industrial Purposes. The performance of the system is studied through detailed energy and exergy analyses. Further the effects of variation in geothermal fluid's mass flow rate, pressure and quality on system outputs are evaluated. Additionally, multiple fuels including nano-based fuels with varying calorific values are evaluated and it is found that the fuels with highest calorific values provide the best possible system outputs.

Keywords: Nano fluids, Multigeneration, Exergy

INTRODUCTION

Energy crisis in the world is real and the difference between demand and supply is increasing day by day. The energy crisis is being dealt with using various non-renewable and renewable energy sources. These include fossil fuels, wind energy, solar energy, geothermal energy, biomass, etc. Among these, the most easily available ways to fulfill the power needs are fossil fuels in the form of Coal, Oil and Gas. Fossil fuels have been the major source of power generation for a long time as they have concentrated energy and the energy extraction methods are cheaper. According to Global Status Report 2018, about 77.9% of electricity is generated using fossil fuels [1].

However, the impact of fossil fuels on the environment cannot be ignored. Fossil fuels have been a big source of pollution in the environment and have contributed a lot towards Global Warming [2], a phenomenon of increasing average temperature of the planet due to the highly increased concentration of greenhouse gases in the atmosphere. These greenhouse gases chiefly consist of Carbon dioxide which is the prime product of combustion of fossil fuels. Greenhouse gases capture heat in the atmosphere and prevent it from escaping the Earth's grasp [3] which increase the overall heat content of the atmosphere and cause a heating effect more commonly known as Global Warming.

The only sensible way to counter the effects of fossil fuels on the environment is to introduce Renewable and Green energy sources. These sources can cater to two-thirds of global energy demands and can play a major role in the reduction of greenhouse gas emissions required to limit the global surface temperature increase to 2°C by the year 2050 [4]. As per research conducted on 38 countries with renewable energy consumption around the world, a positive impact was witnessed on the economic growth for about 58% of these countries from the year 1990 to 2018 [5]. Hence, it wouldn't be wrong to say that renewable energy is the way forward for a brighter and safer future.

The energy crisis in the world can effectively be dealt with by incorporating such systems in our everyday usage and expanding these to cater the needs of more and more people. The six outputs are all necessary for human life and are needed for a comfortable living anywhere. These could be achieved by using the conventional systems only that use fossil fuels as the prime source of energy. However, that would cause more damage to the environment and the atmosphere if fossil fuels and other conventional methods are solely used.

SYSTEM DESCRIPTION

The designed system consists of 2 Genset engines, which are a major source of electricity generation as shown in Fig. 1. The engines operate on natural gas and have a rated efficiency of 45.5%, resulting in power production of 3 MW.
In Genset engines, waste heat in the form of flue gases is produced as a by-product. Energy is recovered from these flue gases to be used mainly to operate Waste Heat Recovery Boiler and as a source of heat input to geothermal fluid, converting saturated vapor to superheated vapor before it enters the steam turbine. This reduces the fuel consumption cost.
Standard Gensets are available in market with fixed emission rates. The 1.5 MW Genset produces flue gases at a flow rate of 2.10 kg/s and releases energy of 650 kW. Since two Gensets are installed in the proposed system, flue gases from both the engines provide 1300 kW of energy.

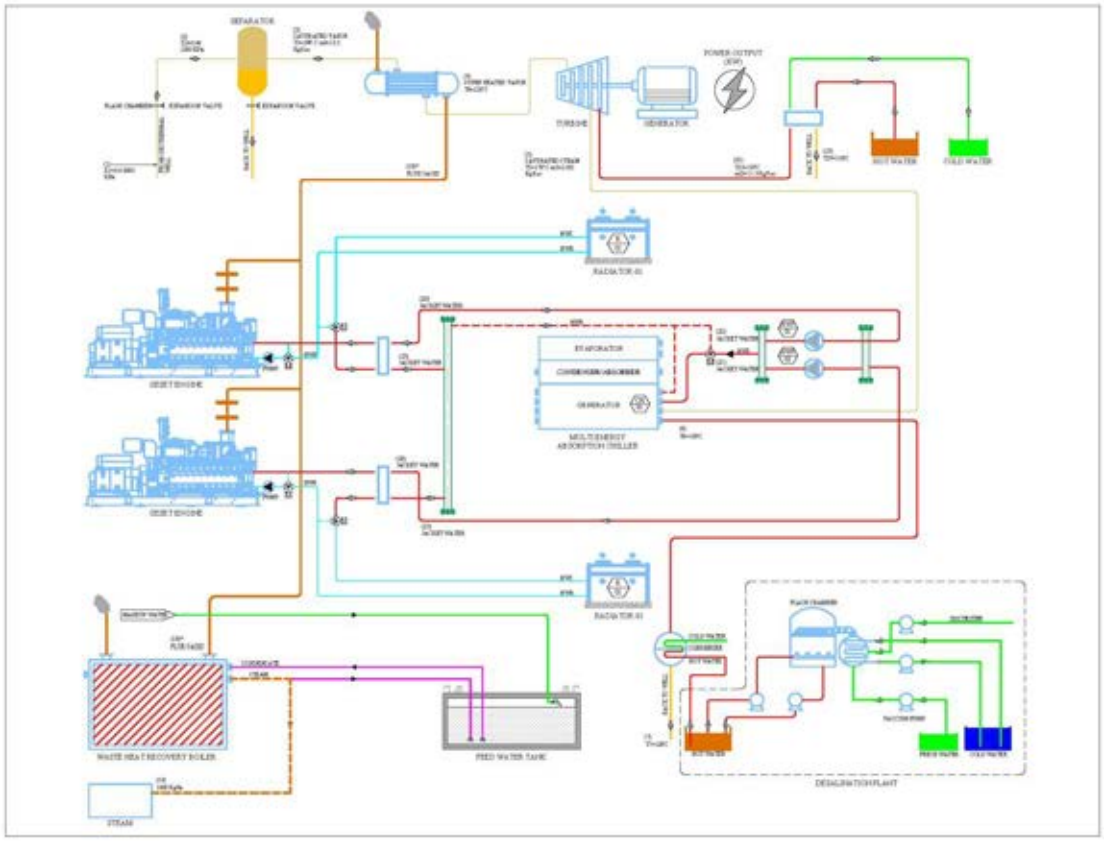

Fig. 1. Schematic of multigeneration system.

RESULTS AND DISCUSSION

The effect of fuel input was studied by performing calculations and plotting their results. Apart from the original fuel considered for the system, i.e., natural gas, twenty-one other fuels were considered including nano-based fuels. The variation in the system outputs due to change in the type of fuel was studied in detail. The overall effect of different fuels on system's energetic efficiency were also studied and as per the results shown in the Fig. 2, Boron with the highest calorific value provides the highest system efficiency of 40.79% and Ethanol with the lowest calorific value provides the lowest system efficiency of 40.42%. The variation in system efficiency, however, is not substantial as all the other system inputs are kept constant.

CONCLUSIONS

The multi-generation system proposed in this paper utilizes both renewable and non-renewable energy sources, keeping in mind the merits and demerits of both. This system is sufficient and capable enough to cater to the energy needs of an industry and the community within the premises of an industry. This industry is obviously located near a geothermal source which provides the geothermal fluid continuously to meet the requirements of the system. In addition, the industry location allows the supply of fuel required for Genset system.

Analyses of the multi-generation system working on Geothermal energy and Gensets has been done. Six outputs are generated which are Power Generation, Space Heating, Space Cooling, Heating of Water, Waste Heat Recovery, and Desalination of Water. The outputs of the system at general conditions are 6.7 MW of electricity, 650kW for Waste Heat Recovery Boiler, desalinated water at a rate of 10.54 kg/s, hot water at a rate of 41 kg/s, heated space at 30oC and 331.7 kW and cooled space at 5o C and 314.1kW.
Effects of variation in input conditions on the outputs and system efficiency have been studied. The plotted results show that an increase in geothermal water's quantity, quality, and pressure all result in an increase in system outputs. Similarly, an increase in the calorific value of fuel results in greater system outputs and efficiencies. This has been concluded after studying the impact of 21 different fuels on system outputs.
Hence, this system not only contributes to the renewable energy sector and greener earth narrative but also fulfills all the energy requirements. It does utilize fossil fuel which is contributing to global warming and has several other negative impacts on the environment but it derives the maximum possible energy out of the fuel by reusing or redirecting the

energy of flue gases and jacket water to either support the geothermal processes or to recover waste heat for other industrial purposes.

ABSTRACT

This paper discusses the use of Proton Exchange Membrane Fuel Cell (PEMFC) as the source of energy for installation in vehicles. The paper includes a Simulink model for a vehicle with a Thermo-Electric Generator (TEG), also showing the fuel cell and the method used for a stable energy output from it.

Considering the parameters for an automobile, especially weight and dimensional constraints, the paper is the study of waste heat recovery from a 50 to 70°C temperature difference produced by the fuel cell. The study has been done for a generalized scalable model of PEMFC, containing 20 cells per stack. The stacks are connected in parallel to keep the output voltage at a constant level. It was observed that under dynamic conditions an average of 10.85% power regeneration occurred. This regeneration percentage is directly proportional to the number of cells TEG modules used. Therefore, the study can be scaled to a variety of PEMFC models. However, increasing the number of cells does not affect the stack temperature significantly but provides a large area for heat transfer.

ABSTRACT

In this study, a performance assessment of a novel solar energy-based multigeneration system integrated with a thermochemical cycle is performed. A steam generator is also integrated to reach high temperatures which are required for the thermochemical cycle. While 550 °C is reached with solar tower, the temperature is increased to 750 °C, which is the maximum temperature of the cycle, with the steam generator. Hydrogen is produced by a calcium-iron bromide cycle and is blended with natural gas. The blend is supplied both to the boiler of the organic Rankine cycle and a community to utilize in combi boiler and gas cooker. The reverse osmosis and multi-effect distillation units are integrated to produce fresh water for the community which consists of one thousand houses. 9.3 MWh electricity is supplied by organic Rankine cycle with 41.27 million m^3 hydrogen and natural gas blend. Furthermore, a total of 7.2 million m^3 of the blend is utilized for household appliances including gas cookers and combi boilers.

Keywords: Efficiency, Hydrogen, Natural gas, Renewable energy, Solar tower

INTRODUCTION

Novel solutions and newly developed systems are required to provide technically, economically, environmentally sustainable energy. It is vital to overcome the increasing electricity, heat, and freshwater demand by supplying various fuels and integrating systems. Although fossil fuel-based systems are mainly used all over the world, environmental awareness is more significant than ever. CO, CO_2, SO_2, NOx emissions which are emitted due to fossil fuel usage are recognized as the primary environmental problems. Fossil fuel-based systems should be integrated with renewable energy-based systems and energy storage subsystems to utilize them wisely. Hydrogen is a promising solution to utilize natural gas resources effectively and to reduce emissions. This study presents energy, exergy, and environmental assessments on hydrogen injection into natural gas pipelines.

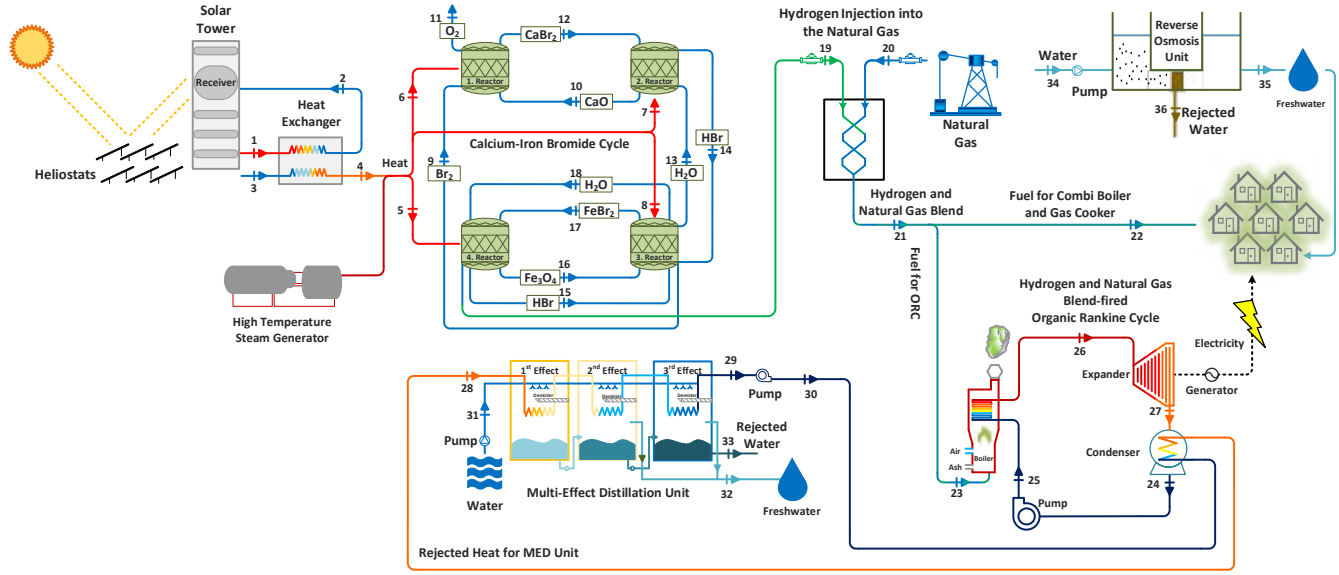

Fig. 1: Schematic illustration of the multigeneration system.

SYSTEM DESCRIPTION AND ASSESSMENT

A solar heliostat field, high-temperature steam generator, organic Rankine cycle (ORC), combi boilers, multi-effect distillation unit, and reverse osmosis units are utilized to produce electricity, heat, and freshwater. A schematic illustration of the multigeneration system is given in Fig. 1. Hexamethyldisiloxane (MM) is considered as the working fluid of the organic Rankine cycle [1]. The calcium-iron bromide cycle is considered to produce hydrogen. Hydrogen is injected into natural gas and utilized in the boiler of the ORC, gas cooker, and combi boilers. The average daily electricity consumption is considered as 8.38 MWh [2]. In addition to the electricity requirement for the community,

300 m³ freshwater is supplied by the reverse osmosis and multi-effect distillation subsystems. The requirements for electricity and freshwater for the community are given in Fig. 2. Mainly during sunny hours, hydrogen is produced by the thermochemical cycle. High temperatures, which are 600 °C for the first and fourth reaction and 750 °C for the second step of the cycle and high flow rates are required for the calcium-iron bromide cycle. Thermodynamic and environmental impact assessments of the integrated system are performed by utilizing the Engineering Equation Solver (EES) and Aspen Plus software.

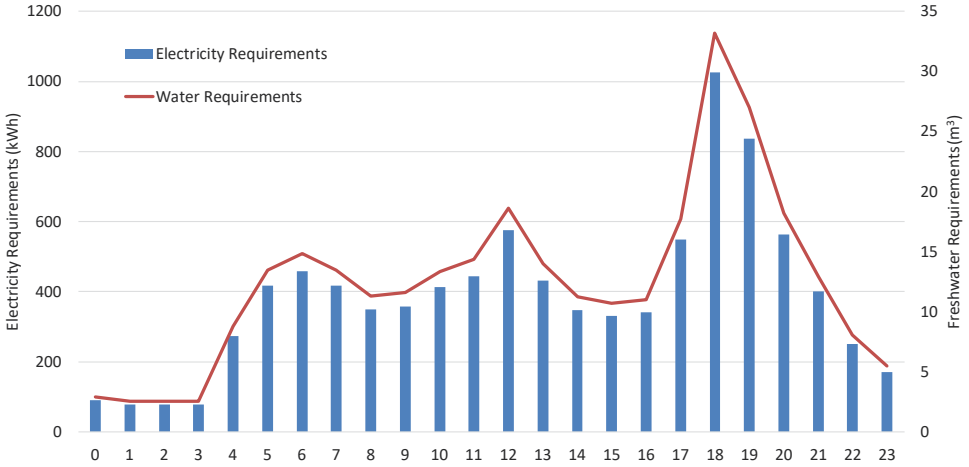

Fig. 2: Hourly electricity and freshwater amounts required for the selected community.

RESULTS AND DISCUSSION

In this study, solar tower, steam generator, organic Rankine cycle, thermochemical cycle, multi-effect distillation and reverse osmosis subsystems are considered for electricity, hydrogen, heat, and freshwater production. Here, hydrogen and natural gas blend is utilized as fuel for the gas cooker, combi boiler, and the boiler of ORC. The amounts of CO_2 and CO emissions are, as expected, decreased with the use of hydrogen. Here, a 20% of the blend consists of hydrogen. The hydrogen and natural gas requirements both for the household appliances and organic Rankine cycle are presented in Fig. 3.

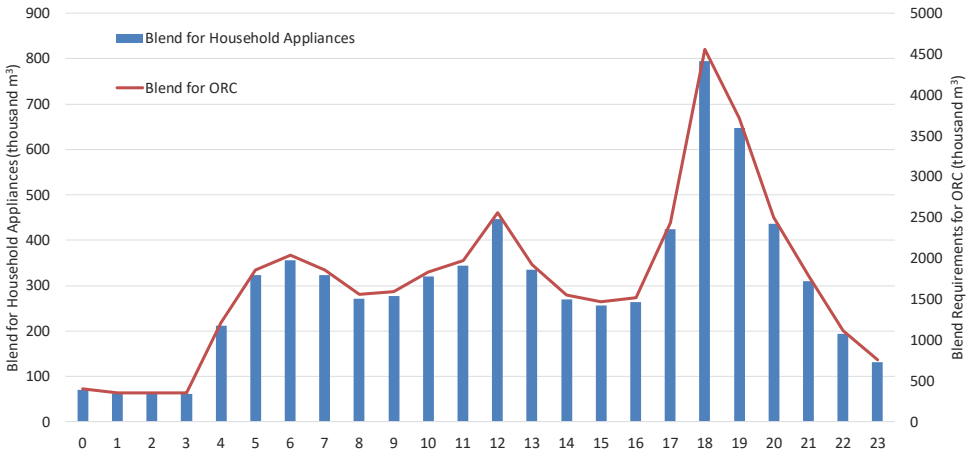

Fig. 3: Hourly hydrogen and natural gas requirements both for the household appliances and organic Rankine cycle.

CONCLUSIONS

In this particular study, a hydrogen and natural gas blend-based multigeneration system is studied in terms of energy, exergy, and the environment. The main findings obtained in this study are listed as follows:

- 41.27 million m³ hydrogen and natural gas blend, with a fraction of 20% hydrogen and 80% natural gas, is supplied to the boiler of the organic Rankine cycle.
- 7.2 million m³ blend with the same ratios is required for the household appliances of the selected community with 1000 houses.

ABSTRACT

There is today a strong effort in developing fuel cell / battery systems for ship propulsion to achieve zero-emission maritime transport, in accordance with UN sustainability goals and the Fit For 55 plan to achieve the climate goals agreed by the EU Council and the European Parliament. Critical for successful implementation of fuel cell / battery systems are system design and control during operation. Fuel cells and batteries have ideal operating ranges. Use outside of this range will cause degradation, impacting system lifecycle. Fuel cell / battery systems are used for transport today but applying such systems for maritime transport requires significant upscaling. Cars typically have a power of 100 to 300 kW, while ocean going ships require tens of MW of power to handle the loads required. To achieve such system capacity, systems are assembled with multiple fuel cells and batteries in stacks. A better understanding of the effect of such upscaling, and system dynamics with respect to load, is therefore required for successful implementation of fuel cell / battery systems for maritime transport. This paper discusses fuel cell types, methods and models applicable for this purpose.

Keywords: PEM fuel cell, Battery, Upscaling, Marine vessel hybrid system.

HYBRID FUEL-CELL/BATTERY DRIVEN SHIP

A hydrogen fuel cell is an electrochemical cell using hydrogen and oxygen as fuels to convert chemical energy to electrical energy. Commercial solutions for hydrogen-based transport using fuel cell systems, generally combined with batteries acting as an energy buffer, has existed for a couple of decades. The use in cars manufactured in series started in the late 2000s, and the first passenger-ship running on a hybrid FC/batteries system was put into service in 2008 [1]. With the national and global green transition, there is today a strong incentive for increasing the use of such technology in maritime transport. This technology transfer requires upscaling of both fuel cell and battery technology to cover the increase in power requirements [2], which for large ships can be several MW when in transit. The operational properties of individual battery and fuel-cell components are normally known. However, for an upscaled system such as a large ship with an integrated fuel cell as the main power generator, the system requires the consideration of fuel cell stacks and battery packs, but the properties of scaled systems with multiple elements are not necessarily proportional [3]. The energy / power requirements will vary with time, these load variations depend on such factors as ship schedules, speed/current, waterline (cargo), wind, and waves, making it challenging to predict system power and energy requirements. Poor predictability means that systems must have the capacity to deal with a large variability in load. This introduces a challenge with respect to systems engineering and systems control. Additionally, reliable and predictable upscaling of fuel cell technology remains a challenge, with respect to the system performance of a fuel cell which are characterized by durability, reliability and robustness [4]. So, uncertainty in systems performance, or degradation of system components, must also be considered in engineering. Relevant characteristics of ships and ship components are illustrated in Fig. 1.

The type of fuel cell and battery technology also impacts system performance. Oxide fuel cells provide high energy efficiency and fuel versatility but are unsuitable for rapidly varying loads [5]. Polymer Electrolyte Membrane (PEM) fuel cells, more suited to maritime application, are also limited with respect to fast current transients [6]. To accommodate for load transients on a PEM fuel cell and quick upstarts/shutdowns, a battery pack is integrated to minimize such transient behavior. Such a power splitting between a fuel cell and a battery requires a fuel cell-battery management strategy and system (FCBMS). Recent advances in autonomy, connectivity and machine learning have given rise to methods for predictive power management systems but has not yet been applied to large-scale ships in transit at sea. Also, recent health-conscious power management strategies have been considered for fuel cell-battery hybrid systems for on ground vehicles [7], however these advances do not properly account for the thermal dynamics which are strongly connected to fuel-cell/battery aging.

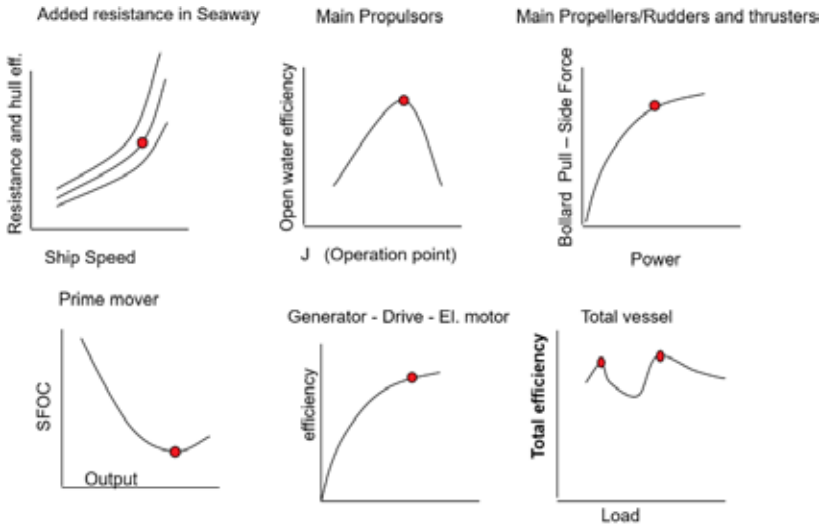

Fig. 1. Typical ship characteristics

For fuel cells, power output is constrained by compressor saturation limits. Exceeding these limits cause oxygen starvation, increase in temperature, fuel cell degradation, and reduced stack lifetime. Sufficient hydrogen and oxygen, provided by the compressor, must always be available at the cathode for the required power output to avoid oxygen / hydrogen starvation and subsequent stack degradation. It is well-known that load variations induce temperature changes in a fuel cell, and that temperature has an impact on both degradation (thermal degradation) of the membrane and on its performance. However, the temperature dynamics involve on a faster timescale than that of degradation. This imposes challenges on how to capture instantaneous effects of degradation on the fuel-cell/battery by implementing the thermal dynamical behavior. Most research in literature has not been focused on such instantaneous effects [8]. Ideally instantaneous effects of degradation should be described in terms of power requirements over time [9]. The performance of a PEM fuel cell can be classified into four processes, the membrane, catalyst layers, GDL/MPL and the channels. Each of these can further be described by the internal dynamics of the fuel cell including transport phenomena. In fact, in order to achieve realistic and detailed accounts of system degradation then atomic and system scale coupled models must be constructed [10]. For a PEM fuel cell ideal operating temperature is close to $80°C$, for which thermal degradation can be completely neglected. Therefore from this perspective, it is crucial to develop a temperature control strategy to avoid thermal cycling and induced stress on the fuel cell and other related components [10], [11]. For a battery its health indicators often use the charge capacity as a characteristic parameter which is a fixed value, while for a fuel cell the charge capacity is not fixed since it depends on the fuel supply. This induces issues on how to properly define the SOH of a fuel cell, in the literature health indicators that have been considered include voltage and impedance-based indicators. However, most research done has been for steady-state systems, thus for a dynamical system where load variations occur and change rapidly i.e., for actual operating conditions, estimating the SOH of a PEM fuel cell has not been considered [8].

The charge capacity for batteries fades over time. How the battery is used affects this degradation. Batteries have a minimum state of charge where further discharge will cause permanent damage [12], so this should be avoided. Further, depending on the cell chemistry, both high and low state of charge may deteriorate performance and shorten battery life. Subsequently, the state of charge of a battery should vary as little as possible around its ideal state of charge. Deviation from this state of charge increases battery degradation. On a ship simultaneously the SOH and SOC of both the fuel cell and battery must be estimated along with possibly other relevant states of their domain, this is referred to as multi-state joint estimation. This type of estimation is challenging, since there is often a coupling between states and even for a single battery, most multi-state joint estimation that has been described in the literature are for two-state joint estimation. There is also a challenge with respect to upscaling, in the sense of how state estimation algorithms developed for a single fuel-cell/battery can be generalized to a fuel cell stack respectively battery pack [13]. This issue strongly depends on the modeling complexity of the fuel cell stack/battery pack needed for the system-level estimation requirements, i.e., lumped vs distributed configurations.

Models exist for predicting battery lifetime, and capacity, as a function of state of charge history [3]. There is a comparison issue that needs to be addressed between modeling types, particularly towards upscaling, a proper analysis in literature comparing lumped models versus distributed models is lacking. For a PEM fuel cell, lumped parameter models are the most common ones explored in the literature, from static to dynamic, and in some cases they are represented as an electrical equivalent circuit [14]–[16]. However, to implement degradation into a dynamical

model, which strongly depend on the internal dynamics including mass, water and heat transport, then one needs to consider more spatial dimensions, i.e., distributed parameter models. The latter model types are more complex to work with from the computational and simulation aspect, in the sense that their state spaces are infinite dimensional and involve PDEs which are highly non-linear. They also come with a high number of parameters to estimate, and discretizing methods must be applied which pose numerical challenges [15]. In contrary to lumped models they are not naturally suited for control because of their computational complexity, and model order reduction techniques need to be applied. In literature distributed parameter models have also been considered, for example model order reduction techniques have been applied to a single PEMFC distributed parameter model, for which a model suitable for control and simulation was found [17].

It may be concluded that batteries have operational sweet spots or zones, while fuel cells have upper operational limits: Operating outside of these zones will cause component degeneration, impacting both system capacity and life cycle. To ensure staying within battery and fuel cell limits, process management requires intelligent systems control with predictive capability (or equivalent manual systems management). There must always be sufficient power to drive the vessel with respect to required loads, while the fuel-cell and battery systems should ideally operate within their ideal operating limits. Through model prediction, future energy demand, through the current sailing leg, needs to be estimated. Ideally the fuel cell / battery system should be regulated so that the combined power supply of both will provide the power needed at any time while still working within ideal component operating limits. For full power, electricity from both battery and fuel-cells can be directed to the ships electric drive system, but battery charge will run out in such a mode, so such operation is unsustainable. Further, if required, it should be possible to run the system at full capacity, overriding any possible limitation with respect to ideal operational limits. However, such operation will cause significant increase in component degradation, having a high impact on the lifetime of fuel cells and batteries. Subsequently, operational management of the fuel cell / battery system needs to cover not only the current sailing leg, but the entire life cycle of the system, where choices in systems engineering impact operational constraints. Constraints in optimization with respect to lifetime are subsequently maintenance / upgrading cost, ship/system lifetime expectancy, and fuel cell / battery energy density and available system space – impacting total possible capacity.

Further knowledge of system behavior is subsequently required for optimization, including such properties as fuel cell and battery degradation as a function of power load and time [9], battery discharge rate as a function of load [18], and also load capacity for system components as a function of degradation [19]. There may also be a question with respect to properties of scaled systems. Gains in energy efficiency, and time spent, may be gained by integrating dynamic models with the ships control systems for optimizing dynamic operational sequences such as ship accelerations – both building and reducing speed, and for ship maneuvering in general. A good analogy in drilling process control is optimization of drill pipe movement and starting of pumps for drilling fluid circulation [20], where automation must account for available power, operational constraints, and specific sequence requirements.

Finally, if optimal operation is to be achieved using continuous predictive models, enforcing limits, accounting for breach of limits, and always ensuring optimal combined use of fuel cell / battery system, then a certain degree of automation is needed. Automation / semi-automation using model prediction, enforcing constraints, and continuous model updating, has been applied in other domains, such as for control of petroleum drilling operations [18]. Technology transfer from such development is therefore highly relevant.

CONCLUSIONS

Designing hydrogen driven hybrid fuel cell battery power systems for ships requires systems upscaling from today's hydrogen powered systems to meet power demands. A better understanding of the effects of upscaling on individual battery and fuel cell components is required for systems design and control.
Degradation of battery and fuel cells as a function of load and other operating conditions impacts system lifecycle. Such effects must be understood and accounted for in systems control. Automated control can help optimize and prolong system lifetime.
Predicting operational loads as a function of weather, waves, ship routes and schedules enables improved systems control. Efforts should be made to improve such prediction, thereby improving operating reliability and system lifetimes.

THERMODYNAMIC ANALYSIS OF A NEW GEOTHERMAL ENERGY BASED INTEGRATED PLANT FOR COMPRESSED HYDROGEN PRODUCTION

[1*]Fatih Yilmaz, [1]Murat Ozturk
[1]Isparta University of Applied Sciences, Faculty of Technology, Department of Mechatronics Engineering, Isparta, TURKİYE

*Corresponding author e-mail: fatiyilmaz7@gmail.com

ABSTRACT:
The main aim of this newly designed geothermal energy-based combined plant is to conduct the thermodynamic performance investigation for clean and sustainable power, hydrogen, heating, cooling, and hot water. For this aim, the Kalina cycle, an ORC, a double effect cooling system, two thermoelectric generators, a hot water generator, and finally, a hydrogen generation and storage unit are thermally integrated with a geothermal source. Each subsystem is examined in detail from the thermodynamic point of view and parametric analyzes are carried out. According to the analysis findings, the energy and exergy efficiency of the whole system is determined as 39.63% and 36.14%.

Keywords: Energy, Hydrogen, Multigeneration, Geothermal.

INTRODUCTION

With the rapid increase in energy demand in the world, the creation of suitable energy options for countries has become an important issue. Therefore, various energy sources have started to be preferred. Consequently, multigeneration systems (MG) have become one of the most important main alternatives [1]. Other important alternatives are renewable energy sources and hydrogen energy. The use of hydrogen by producing it from renewable energy sources is also indispensable in the fight against global warming and environmental problems. Geothermal energy has an important position among renewable energy sources and recently many studies have been presented to obtain different useful outputs in combined systems.

Mehdikhani et al. [2] proposed the two geothermal wells based combined plant in terms of thermodynamic and exergoeconomic analysis. According to the results they obtained, they stated that the thermal efficiency is improved by 3.18% compared to similar studies. Koc et al. [3] examined a geothermal energy-based combined plant system in which the energy and exergy efficiency of the overall plant is determined as 60.14% and 58.37%, respectively. Li et al. [4] studied an innovative flash-binary geothermal energy-based MG plant for power, hydrogen, freshwater and cooling. Their modeled plant has optimum exergy efficiency is 46.44%. As a result of a short literature review, it is seen that many useful outputs such as power and hydrogen can be obtained with geothermal energy-supported MG systems. The main purpose of this designed study, thermodynamic analysis of geothermal energy supported plant that is generated power, hydrogen, heating, cooling, and hot water production is carried out. One of its innovative parts is the storage of hydrogen and the other is the use of TEG instead of a condenser. Moreover, a comprehensive parametric study is carried out to examine the effects of some system elements on efficiency.

SYSTEM DESIGN AND ANAYSIS

The newly designed geothermal energy-based MG system, mainly consists of a Kalina cycle, an ORC plant, a double effect absorption cooling system, two thermoelectric generators, a domestic hot water generation unit, and a hydrogen generation and storage system, as illustrated in Fig.1.
Before applying a comprehensive thermodynamic analysis to this designed study, the general mass, energy, exergy, and entropy equilibrium equations are applied to each component separately, as stated below, according to the first and second laws of thermodynamics [5-7]

$$\sum \dot{m}_i = \sum \dot{m}_e \quad (1)$$

$$\sum \dot{m}_i h_i + \sum \dot{Q}_i + \sum \dot{W}_i = \sum \dot{m}_e h_e + \sum \dot{Q}_e + \sum \dot{W}_e \quad (2)$$

$$\dot{S}_{gen} = \sum \dot{m}_e s_e - \sum \dot{m}_i s_i - \sum \frac{\dot{Q}_{cv}}{T} \quad (3)$$

$$\dot{E}x_{Des} = \sum \dot{m}_e \dot{e}x_e + \sum \dot{E}x_e^Q + \sum \dot{E}x_e^W - (\sum \dot{m}_i \dot{e}x_i + \sum \dot{E}x_i^Q + \sum \dot{E}x_i^W) \quad (4)$$

where i and e subscripts determine the inlet and exits of the component. $\dot{Q}$ and $\dot{W}$ display the heat power, power transfer rate, respectively. For overall plant, the performance ratio of the whole system should be specified as;

$$\eta_{WS} = \frac{\dot{W}_{net} + \dot{Q}_{cooling} + \dot{Q}_{heating} + \dot{Q}_{hotwater} + LHV_{H_2}\dot{m}_{H_2}}{\dot{m}_1 h_1 - \dot{m}_7 h_7} \quad (5)$$

$$\psi_{WS} = \frac{\dot{W}_{net} + \dot{E}x^{\dot{Q}}_{cooling} + \dot{E}x^{\dot{Q}}_{heating} + \dot{E}x^{\dot{Q}}_{hotwater} + ex_{H_2}\dot{m}_{H_2}}{\dot{m}_1 ex_1 - \dot{m}_7 ex_7} \quad (6)$$

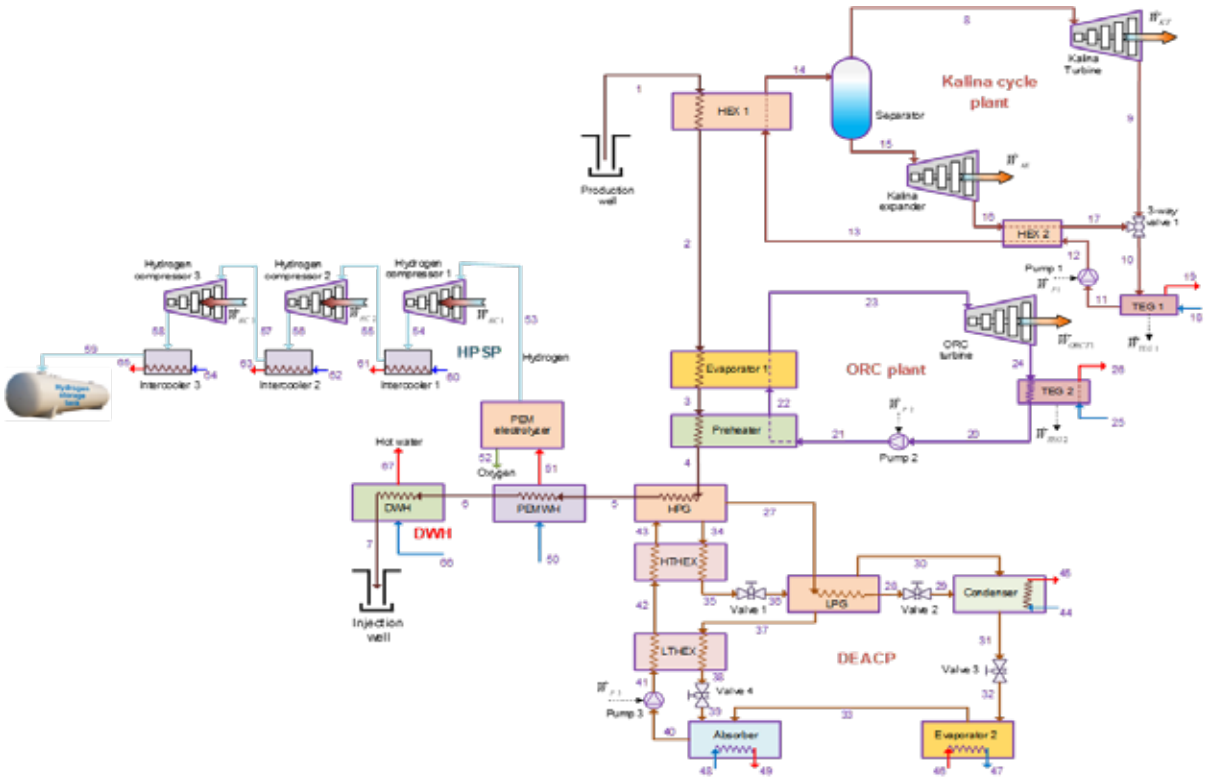

Fig. 1. Schematic illustration of geothermal MG plant

RESULTS AND DISCUSSION

In this proposed study, thermodynamic analysis is performed theoretically. There are some assumptions made and these are that the whole system is steady-state flowing, there is no temperature change between the system and the environment, kinetic and potential energy changes are neglected, and 25 ℃ ambient temperature and 101.325 kPa ambient pressure are assumed. As a result of the assumptions made, the results of the thermodynamic analysis findings are presented in Table 1 and Table 2 below. While Table 1 illustrates the useful outputs and consumed electrical power values in the system, Table 2 shows the energy and exergy efficiencies of the main subsystems.

Figs. 2 and 3 show the change of the reference temperature and the geothermal water temperature (T1) on the useful outputs obtained from the system. That is clearly seen that a positive effect of these two parameters on the system performance.

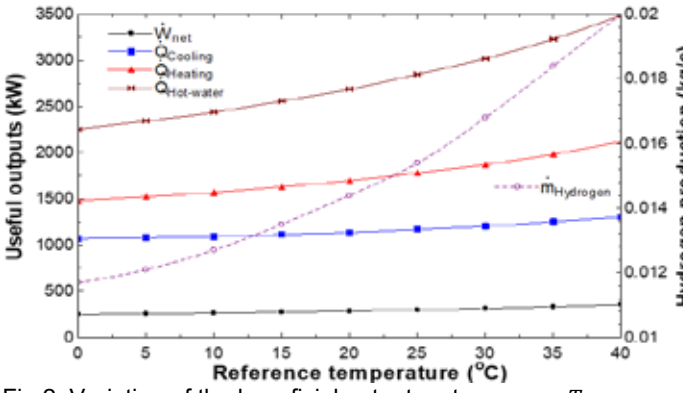

Fig.2. Variation of the beneficial outputs rates versus T_0

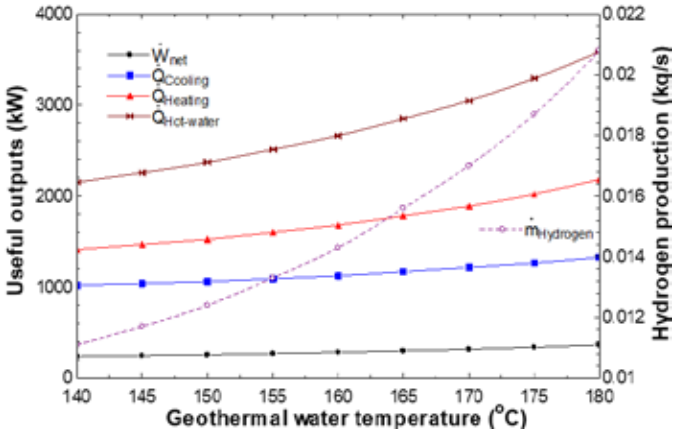

Fig.3. Variation of the beneficial outputs rates versus T_1

Figs. 4 and 5 display the increase in energy and exergy efficiency of the overall system and subsystems against different T1 temperatures. With the increase of the geothermal water outlet temperature from 140 ℃ to 180 ℃, the

useful outputs are obtained as the system reaches higher heights and the thermodynamic performance with flour increases.

CONCLUSION

The newly designed geothermal energy-based combined plant is proposed and analyzed for power, hydrogen, heating, cooling, and hot water. The proposed plant comprised a Kalina cycle, an ORC, a double-effect absorption cooling system, a domestic hot water generator, and hydrogen generation and storage. By applying a detailed thermodynamic analysis method, system efficiencies, namely energy and exergy efficiencies, are investigated for sub-systems and the whole system. It can highlight the most important points that come to the fore in the analysis results as follows;

- The power generation rate of the Kalina cycle and ORC are 358.2 kW and 160.4 kW. Also, TEG power generation rate is 182.62 kW. Furthermore, heating and cooling loads of this modeled plant are 1783 kW and 1169 kW, respectively. In conclusion, total hydrogen generation rate is 0.0156 kgs^{-1}
- The proposes MG plant's energy and exergy efficiency is computed as 39.63% and 36.14%, respectively.
- It is reported that with the goes up the reference and geothermal water temperature, the proposed system and subsystem performance clearly increase.

Table 1. Thermodynamic analysis results of the combined plant

Products	
Kalina turbine ($\dot{W}_{KT}$)	189.1 kW
Kalina expander ($\dot{W}_{KE}$)	169.1 kW
ORC turbine ($\dot{W}_{ORCT}$)	160.4 kW
TEG 1 ($\dot{W}_{TEG1}$)	70.82 kW
TEG 2 ($\dot{W}_{TEG2}$)	111.8 kW
Cooling ($\dot{Q}_{Cooling}$)	1169 kW
Heating ($\dot{Q}_{Heating}$)	1783 kW
Hot water ($\dot{Q}_{Hot_water}$)	2850 kW
Hydrogen ($\dot{m}_{H_2}$)	0.0156 kgs^{-1}
Oxygen ($\dot{m}_{O_2}$)	0.1232 kgs^{-1}
Consumptions	
Pump 1 ($\dot{W}_{P1}$)	17.76 kW
Pump 2 ($\dot{W}_{P2}$)	10.22 kW
Pump 3 ($\dot{W}_{P3}$)	30.88 kW
PEM electrolyzer ($\dot{W}_{PEM}$)	83.98 kW
Hydrogen compressor 1 ($\dot{W}_{HC1}$)	42.17 kW
Hydrogen compressor 2 ($\dot{W}_{HC2}$)	54.72 kW
Hydrogen compressor 3 ($\dot{W}_{HC3}$)	163.1 kW

Table 2. Energy and exergy efficiency of the main sub-plants

	Energy efficiency (%)	Exergy efficiency (%)
Kalina cycle plant	21.04	18.23
ORC plant	24.31	20.96
Double effect absorption cooling plant	18.28	10.24
Hydrogen production and storage plant	58.93	55.31
Domestic water heater	78.24	74.09
Overall plant	39.63	36.14

ABSTRACT:
The primary goal of this proposed work is to examine the solar energy-combined multigeneration model in order to produce heating, power, hydrogen, and clean water in a comprehensive way from the thermodynamic aspect. This plant consists of mainly five sub-unit that is heliostat field, supercritical Brayton cycle, transcritical Rankine cycle, multi-effect desalination unit, and PEM electrolyzer. Looking at analysis results, the amount of the hydrogen rate of this combined plant is 0.001179 kgs^{-1}. Also, the capacity of the electrical power is 1194 kW. To finish, the whole energetic and exergetic performance of the modeled plant is 44.63% and 13.74%, respectively.

Keywords: Energy, Exergy, Hydrogen, Thermodynamic, Solar

INTRODUCTION

Currently, to meet the energy demand in our global, fossil-based fuels have still widely usage proportion. That is, it is mean that environmental problems caused by fossil fuels have linearly increased. One of the main and important solve these complications, the widespread usage of non-fossil energy sources that are solar, wind, geothermal, biomass and etc., in almost every field. However, it can be stated that the production and use of hydrogen in clean and sustainable ways is another effective method. In this respect, renewable energy, especially solar, assisted multigeneration systems and obtaining hydrogen from them, has become a subject of interest and researched by many researchers in recent years.

Dincer and Zamfirescu [1] modeled a multigeneration plant that generates a number of outputs. Their modeled plant' exergy efficiency is determined between 55% and 65%. Yilmaz [2] evaluated a new solar heliostat supported multigeneration plant. The modeled plant energy and exergy performance is computed as 78.93% and 47.56%, respectively. El-Emam and Dincer [3] developed a combined plant driven by solar heliostat system. They performed a comprehensive thermodynamic evaluation and then the amount of the hydrogen rate is found as 1.25 kgh^{-1}. Izadi et al. [4] conducted a comprehensive optimization of the trigeneration system driven by a solar tower unit and a hydrogen generation unit. Further, in 2021, thermodynamic and environmental analysis as well multiobjective optimization of a multigeneration plant are conducted by Colakoglu and Durmayaz [5]. Their suggested plant's energy efficiency is modeled at 55.57%, in the light of analysis results. Again in 2021, the authors [6] designed and thermodynamically examined a solar-assisted trigeneration plant for the purpose of electricity, ammonia, and fresh water production. The whole exergy efficiency of their suggested system is 12.1%.

The key difference of this paper from other works is the use of environmentally friendly CO_2 fluid in sub-power generation cycles. The significant purpose of this study is to examine the thermodynamic analysis of power, heating, freshwater, and hydrogen production by integrating solar heliostat supported, supercritical Brayton cycle ($sCO_2 - BC$), and transcritical Rankine cycle ($tCO_2 - RC$) subsystems.

SYSTEM DESIGN AND ANALYSIS

In this research, solar heliostat-based $sCO_2 - BC$ and $tCO_2 - RC$ sub-power plants are integrated to generate power, hydrogen, freshwater, and heating, as illustrated in Fig.1.

Thermodynamic performance analysis is applied to this integrated system that is above-mentioned. For thermodynamic modeling, mass, energy, entropy, and exergy balance equations in their general form are written for each component and then modeled with the EES package program. This equilibrium equation can be expressed as [7–9]:

$$\sum \dot{m}_i = \sum \dot{m}_e \quad (1)$$

$$\sum \dot{m}_i h_i + \sum \dot{Q}_i + \sum \dot{W}_i = \sum \dot{m}_e h_e + \sum \dot{Q}_e + \sum \dot{W}_e \quad (2)$$

$$\dot{S}_{gen} = \sum \dot{m}_e s_e - \sum \dot{m}_i s_i - \sum \frac{\dot{Q}_{cv}}{T} \quad (3)$$

$$\dot{E}x_{Des} = \sum \dot{m}_e \dot{e}x_e + \sum \dot{E}x_e^Q + \sum \dot{E}x_e^W - (\sum \dot{m}_i \dot{e}x_i + \sum \dot{E}x_i^Q + \sum \dot{E}x_i^W) \quad (4)$$

where i and e subscripts determine the inlet and exits of the component. $\dot{Q}$ and $\dot{W}$ display the heat power, power transfer rate, respectively. For overall plant, the performance ratio of the whole system should be specified as;

$$\eta_{WS} = \frac{\dot{W}_{net} + \dot{Q}_{heating} + LHV\dot{m}_{H_2} + \dot{m}_{fw}h_{fw}}{\dot{Q}_{solar}} \quad (5)$$

$$\psi_{WS} = \frac{\dot{W}_{net} + \dot{Ex}_{Q_{heating}} + ex_{H_2}\dot{m}_{H_2} + \dot{m}_{fw}ex_{fw}}{\dot{Ex}_{Q_{solar}}} \quad (6)$$

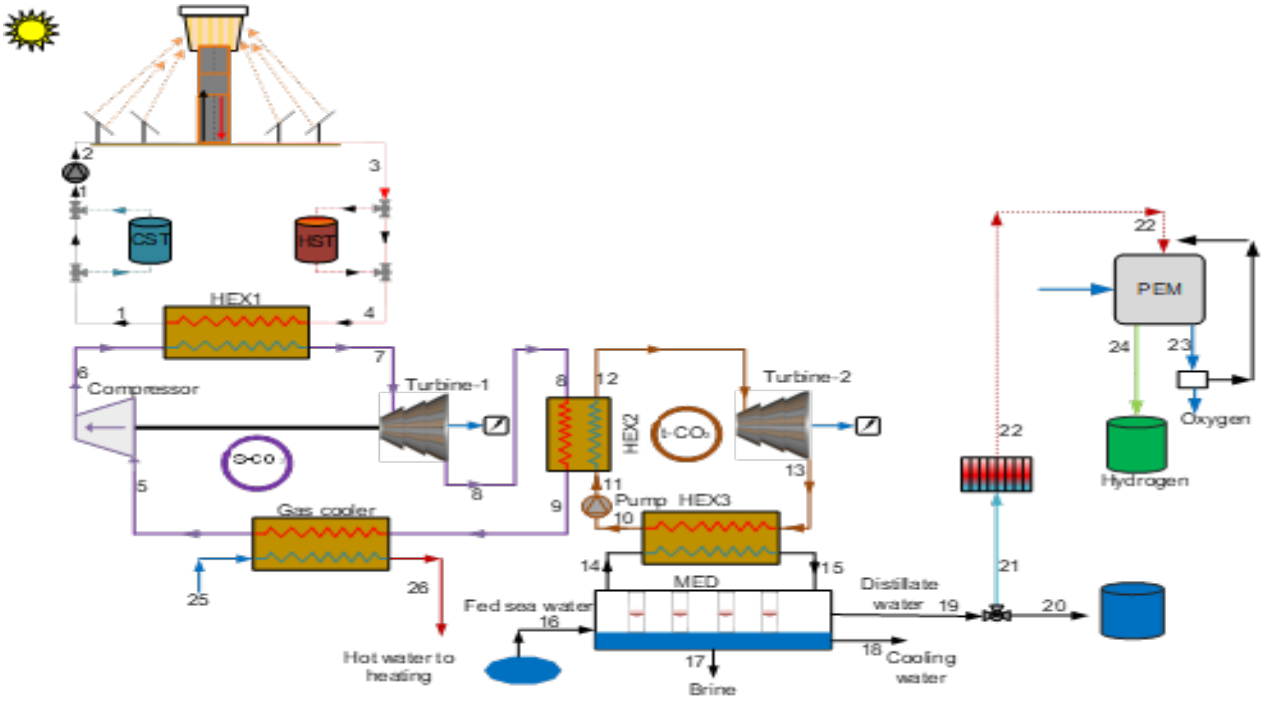

Fig. 1. Schematic representation of solar energy-based plant

RESULTS AND DISCUSSION

This examined work is carried out with a complete thermodynamic modeling of the solar multigeneration system that generates hydrogen, electricity, heating, and clean water production. The assumptions made to perform this analysis are presented in Table 1. In the light of Table 1, the analysis results applied are highlighted in Table 2.

Figure 2 shows the rise in useful output from the plant with the change of solar energy flux. Figure 3 plots the linear increase in energy and exergy performance of the total plant with increasing solar flux. Moreover, the effect of ambient temperature on the energy and exergy efficiency and total exergy destruction of the entire plant is presented in Figure 4.

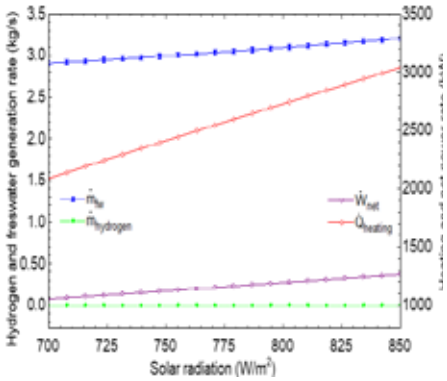

Fig.2. Effect of solar flux on the beneficial products from the suggested plant

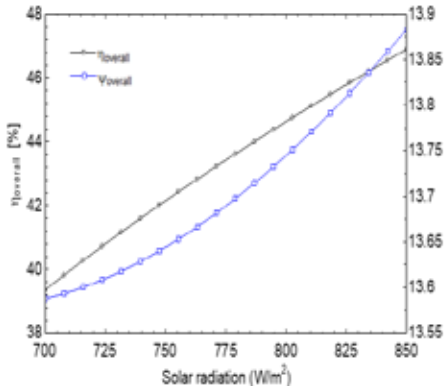

Fig.3. Impact of solar flux on the suggested plant's performance

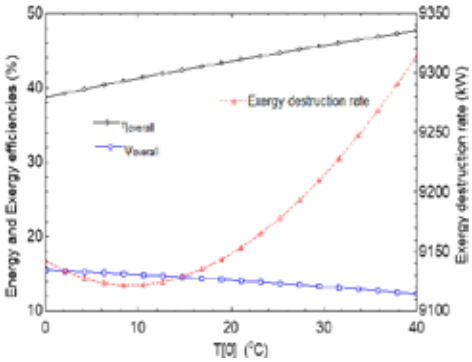

Fig.4. Performance and total exergy destruction rate versus reference temperature

Table 1. Assumptions for the thermodynamic modeling of the plant

Parameters	Unit	Value
Solar radiation	$\dot{W}/_{m^2}$	800
Heliostat are	m^2	11*11
Heliostat efficiency	%	76.5
Mass flow rate of solar cycle	kgs^{-1}	50
Solar cycle working fluid	-	Salt(68KCl_32MgCl2)
Compressor inlet pressure	kPa	$P_{critic} * 1.5$
Compressor pressure rate	-	2.5
Pump inlet pressure of RC	kPa	6300
Turbine inlet pressure of RC	kPa	9450
Desalination effect number	-	4
Sea water's salinity	ppm	42,000
Brine's salinity	ppm	47,000
Reference point temperature	℃	25
Reference point temperature	kPa	101.325

Table 2. Thermodynamic analysis results of the examined plant

Parameters		Value
Net power generation rate		1194, kW
Hydrogen generation capacity		0.001179, kgs^{-1}
Clean water generation capacity		3.095, kgs^{-1}
Heating capacity from hot water		2728, kW
$sCO_2 - BC$	Energy efficiency	14.7, %
	Exergy efficiency	41.69, %
$tCO_2 - RC$	Energy efficiency	6.41, %
	Exergy efficiency	30.78, %
Overall plant	Energy efficiency	44.63, %
	Exergy efficiency	13.74, %

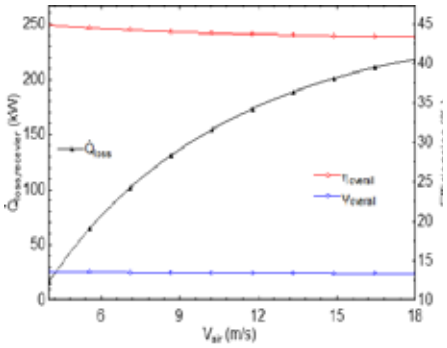

Fig.5. Performance and total heat loss rate versus air velocity

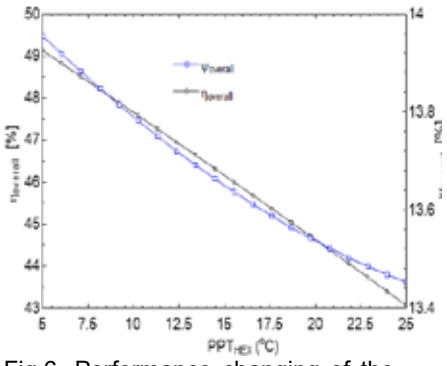

Fig.6. Performance changing of the overall plant versus different PPT_{HEX}

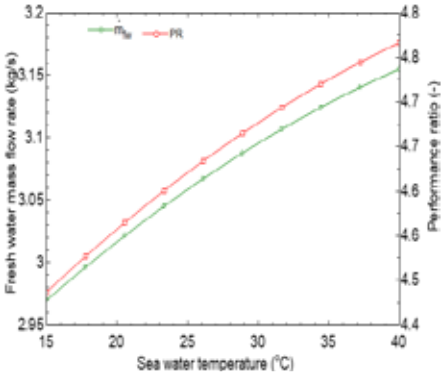

Fig.7. Impact of the seawater temperature on the performance rate of MED and amount of fresh water

Also, Figure 5 shows the impact of air velocity variation on overall system performance and heat loss. As the air velocity rises, the system performance decreases as the loss on the heliostat surface increases. The energy and exergy efficiency of the whole plant with the increase of pinch point temperature of HEX (PPT_{HEX}) is presented in Figure 6. In conclusion, increment in the seawater temperature give rise to an increase in the MED performance and fresh water generation rate, as shown in Fig. 7.

CONCLUSION

The proposed combined work that generates hydrogen, power, heating, and freshwater, is investigated and thermodynamically analyzed. For this aim, to examine energetic and exergetic performance and exergy destruction rate of the overall plant, parametric analysis is also applied. As a coming to the analysis results, some important points can be presented as below;

- The power and hydrogen generation capacity of this designed model is 1194 kW and 0.001179 kgs^{-1}. In addition, 3.095 kgs^{-1} of clean water was produced in this system.
- The total energetic and exergetic performance is calculated as 44.63% and 13.74%.
- With the increase of solar flux, the valuable productions obtained from the plant and the efficiency of the whole system increased.
- It is noted that with the increase of air velocity, the thermal loss on the heliostat surface increased and there is a low decrease in system performance due to this.

ABSTRACT

Post-2030 decarbonization targets, enable energy storage as a key element in the energy mix of future sustainable energy systems in Europe. Storage is supported by the high penetration of renewable energy sources (RES) in the European energy landscape. One of the most efficient, zero emission fuels is hydrogen produced by RES via electrolysis. Hydrogen production and storage is combined with fuel cells and batteries to comprise an integrated Power-to-Power (P2P) system. Such systems offer efficient, reliable, and cost-effective energy delivery that is quick in release and of high density, aspects that are necessary to counter the RES power intermittency. Stochastic RES profiles, dynamic response of sub-components, and multiple decisions inside a constantly changing environment are major challenges in P2P systems' operation. The Energy Management Strategy (EMS) developed in this work and employed in the control framework of the P2P systems ensures their efficient operation. The EMS supervises the optimal distribution of power production and consumption. A series of applications of pilot P2P systems with different characteristics showcase the system's performance, resilience and replicability potential through certain key performance indicators (KPIs).

Keywords: Energy storage, Green hydrogen, Control, Renewable energy, Energy management

INTRODUCTION

Electricity generation, in general, is heavily dependent on fossil fuel generators that burn diesel, gas, or heavy fuel oil. Such fuels are extremely pollutant, expensive and uncertain due to high greenhouse gas emissions and challenges regarding transportation and availability [1]. Governments around the world are investing in infrastructure to provide an efficient, cost-effective, and cleaner alternative to electricity generation. Power generation through RES such as solar, wind, hydroelectric, and biomass is a viable solution to this task. The highly unpredictable and intermittent nature of RES power generation systems requires that the produced energy is converted and stored, like hydrogen or electricity in battery banks. Green hydrogen-based power-to-power systems integrated with fuel cells (FC), electrolyzers (EL), and batteries (BAT) provide medium to long-term storage capabilities by exploiting the available RES [2]. This work describes the formulation of a generalized control strategy that was built in parallel with the formulation of a decision-making algorithm in the form of operating rules that constitute an energy management strategy. This algorithm, namely finite state machine or finite state automata, integrates a propositional-based rationale that seeks to determine the status of each plant's subsystem and lead in the transition to a new status in compliance with the operational standards of the integrated framework [3]. This technique provides a robust and easily expandable systemic approach to the energy management of P2P systems in comparison to the widely used heuristic approaches. This approach is replicated to be implemented in different case studies and highlight its advantages. The main objectives and contributions of this study are the:

- Formulation of a generic control strategy based on the developed EMS.
- Operation analysis and comparison of performance among the case studies.
- Showcase the replicability of the EMS and overall system design.

SYSTEM DESCRIPTION AND METHODOLOGY

Three different motivating cases which are located in the north and south of Europe are selected, two are islanded microgrids and the third one is at a remote location at the edge of the electrical network [4]. The power supply subsystems are illustrated in Fig. 1. The primary energy source is local renewable systems from various sources (solar, wind, biomass). Moreover, the short-term load demands and energy storage is governed by batteries. Finally, hydrogen energy storage ensures the P2P system's long-term ability to satisfy load demands (days/weeks/months). Hydrogen is produced at 30 bars by electrolysis without any further compression stage. Low-pressure hydrogen storage comes with higher round-the-year efficiency, longer durability, improved reliability, and lower maintenance. The main characteristics of the subsystems and the overall configuration are given in Table 1. In this study, the operation of the hybrid energy storage system is realized with the use of Hybrid Automata (HA) which is described in detail in [3]. The interaction

between discrete and continuous operating dynamics motivates the use of HA which appears as a suitable formulation for the realization of a systemic EMS. The system requirements are transformed into propositional-based logic realizing a set of operating rules. The dynamics exhibited in such a system are predominantly of two kinds: a) specific actions such as start-ups and shutdowns of the FC and b) continuous dynamics (state of charge (SOC) of BAT). The application of the aforementioned systematic methodology to the power distribution between the subsystems is targeted within this work. To this end, the developed EMS is employed to achieve this objective using linear system-level models. The general objectives of the P2P energy storage system are:

- Optimal exploitation of RES power regarding load satisfaction and energy stored.
- Safe operation within the safety limits of every subsystem
- Preservation of battery life expectancy

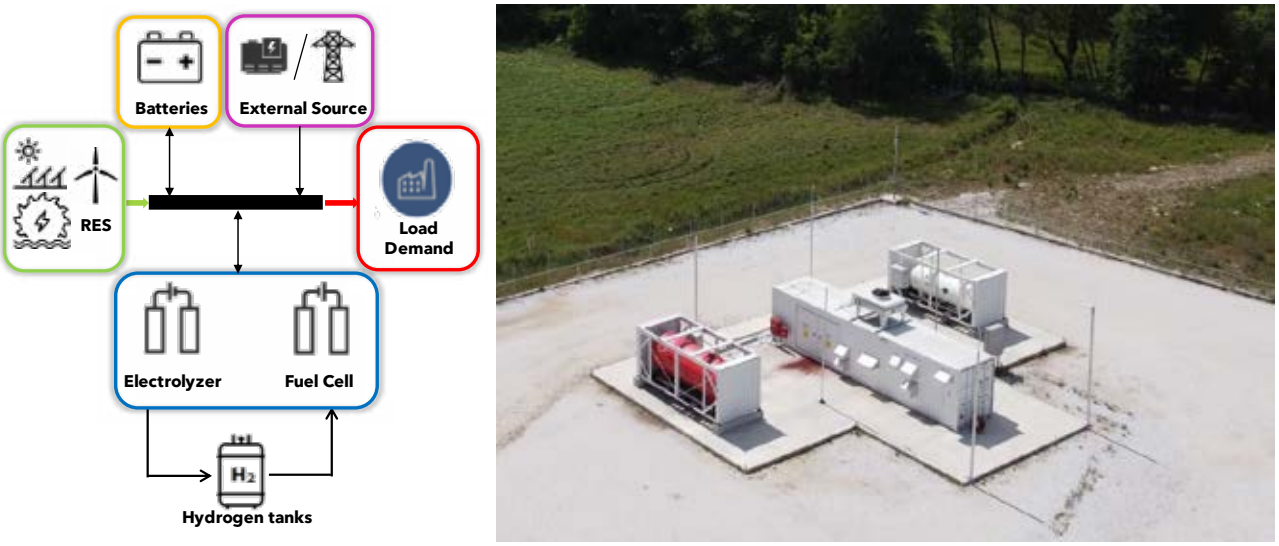

Fig. 1. (left) General layout of the P2P system, (right) Pilot demonstration of the P2P system [4]

Table 1. Main characteristics of the case studies

	Case 1	Case 2	Case 3
Remoteness	Off-grid	Micro-grid	Off-grid
Load	Residential	Residential, fish industry	Residential
RES	Solar (170kW)	Solar (85kW), Wind (225kW)	Solar (40kW), Biomass (50kW)
Storage	Hydrogen (1800kWh) Battery (600kWh)	Hydrogen (3700kWh) Battery (550kWh)	Hydrogen (500kWh) Battery (30kWh)
Fuel Cell	Proton Exchange Membrane (50kW)	Proton Exchange Membrane (100kW)	Proton Exchange Membrane (50kW)
Electrolyzer	Alkaline (50kW)	PEM (55kW)	Alkaline (25kW)

In this study, the battery, the fuel cell, the available RES in each site, and the external power (EXT) source are considered energy sources. Whether the energy that is produced by the RES is adequate to cover the load or another power source (FC, BAT, EXT) is necessary, it is defined by the size of the load demand. Therefore, the operation of the individual subsystems is determined by the energetic surplus or deficit between load and RES production occurring in each time step. When there is a RES surplus, the excess energy is stored. Depending on the level of fulfillment of the hydrogen tanks and battery banks, the battery is charged first up to the desired SOC, and then the electrolyzer will operate to produce and store hydrogen. If there is still a surplus of energy after both the tanks and batteries are full, then the energy is curtailed. When there is a RES deficit, the amount of energy to cover the remaining load comes from one of the power sources. First, the battery covers the load until it reaches its lower SOC limit and then the FC takes over the load demand. In case the system's stored energy is depleted then the external power source operates as backup.

RESULTS AND DISCUSSION

Each examined case integrates different RES technologies, exhibits variable load demands depending on the location, and incorporates the same control strategy with some minor adjustments. A set of metrics, or performance indicators, allows the assessment of the effects that each technology has on the integrated case. Each control formulation and its application to each case study is examined using these KPIs, which are defined as ratios of the cumulative energy (kWh) of each subsystem divided by the total RES surplus (kWh) or total demand (kWh) for a year. The first three metrics depict the conversion of the available RES surplus energy. Excess energy can either be stored or curtailed. Battery utilization is favored against hydrogen, resulting in a big difference between the converted surplus to hydrogen energy storage percentage and the electricity storage percentage. However, when a larger hydrogen storage unit is employed in combination with greater RES production, hydrogen storage is favored. The rest of the metrics refer to the distribution of the total load demand among the subsystems. The satisfaction of the load is mainly met by RES in all three cases, while the battery's involvement is governed by its capacity. When analyzing the overall performance, the KPI that best reflects the ability of the system to be resilient and emission-free is the "Total load satisfied by EXT". It is within the goals of the EMS to minimize the utilization of EXT. Overall, the issues that arise from the simulation of the three case studies are the large amounts of curtailed RES energy and the need for EXT intervention to cover the load. These issues can be dealt with in the designing process of the P2P plant by optimizing the storage capacities of both electricity and hydrogen storage. Larger hydrogen tanks or the addition of more battery stacks or both are the solutions to utilize as much RES energy as possible and fully curtail the use of fossil fuels.

Table 2. KPI comparison of the case studies

KPI	Equation	Case 1	Case 2	Case 3
RES surplus to electricity	$\frac{\text{RES surplus energy to battery}}{\text{RES surplus energy}}$	41%	15%	17.6%
RES surplus to hydrogen	$\frac{\text{RES surplus energy to battery}}{\text{RES surplus energy}}$	10%	18.8%	58.2%
RES surplus to curtailment	$\frac{\text{RES surplus energy to battery}}{\text{RES surplus energy}}$	49%	66.2%	24.2%
Total load by FC	$\frac{\text{Fuel cell energy to load}}{\text{Total load}}$	4.7%	4.6%	5.8%
Total load by EXT	$\frac{\text{External source energy to load}}{\text{Total load}}$	4.5%	0.8%	4.4%
Total load by BAT	$\frac{\text{Battery energy to load}}{\text{Total load}}$	43.6%	25.7%	4.2%
Total load by RES	$\frac{\text{RES energy to load}}{\text{Total load}}$	47.2%	68.9%	55.6%
Total load by BIO	$\frac{\text{Biomass energy to load}}{\text{Total load}}$	-	-	30%

CONCLUSIONS

This work developed and implemented a supervisory control algorithm based on the formulated generic EMS. The same EMS was implemented in different case studies with varying conditions and contexts, showing the replicability and performance that can be achieved. Future work will include the incorporation of additional and multiple energy sources and the integration of a greater number of subsystems.

ABSTRACT

This study presents a concept of a renewable energy system based on hydrogen generation by coupling of an electrolyser to a tidal generator. The proposed energy conversion system has two main energy requirements. The first one is for the electrolyser and the other is for the reverse osmosis unit. High-fidelity CFD simulations are performed on whether the preliminary designed turbine would provide sufficient power in OpenFOAM open-source package. Results show the importance of detailed design to understand the hydrodynamics characteristics of tidal turbines. Considering the maximum C_p at 3.5 TSR, the output power calculated as $44.67\ kWh$. The selected turbine's parameters do not meet the required power. In this case, the preliminary turbine design should be updated by increasing the swept area of it.

Keywords: Tidal power, Hydrogen storage, CFD, Reverse osmosis

INTRODUCTION

Tides are very long waves that move back and forth in the same direction in response to the forces of the moon and sun. Tidal energy is a type of renewable energy most prevalent along ocean coasts. Therefore, countries with this type of coastal area are interested in utilizing and improving the efficiency of tidal energy. There are three leading technologies, namely tidal turbines [18], barrages and lagoons based on their physical configurations that utilize tidal energy. Lopez and his colleagues [10] investigated the hydrokinetic energy conversion systems in detail and their current status in terms of energy conversion schemes and structural installation. As with all renewable energy conversion systems, tidal energy devices should be divided into three stages: design, operation, and end use. In design stage, requirements have to be defined carefully to be able to decide the size of tidal energy convergence system. Then, the system layout is prepared according to the direction of flow, mass flow rate and so on. In operation, tidal devices generally work back and forth in the same direction regarding the tides' directions [14]. The stored energy in the form of pumped, compressed air or in batteries is directly consumed by the user in end-use stage. Tidal turbines are classified in two main categories according to their rotor configuration, horizontally and vertically. Both of them have advantages and disadvantages concerning design simplicity, generator coupling, floating equipment, noise emission, skewed flow, knowledgebase, performance, control, which are clearly described by [10].

DESIGN OF THE ENERGY CONVERSION SYSTEM

Fig. 1 (a) shows a concept of a renewable energy system based on hydrogen generation by coupling an electrolyser to a tidal generator in the first line. This type of system can be used to store hydrogen and operate a polymer electrolyte membrane (PEM) fuel cell to provide power at times when renewable energy cannot meet the load demand and to compensates for the power oscillations of the production units. The other line of the system occurs the freshwater from the seawater with the help of Reverse Osmosis (RO) unit [6]. The tidal turbine powers the high-pressure pump which moves and pressurizes water from the sea to the RO unit. An electrolysis unit is a system that utilizes electricity to break water into hydrogen and oxygen. Produced hydrogen is directly stored in an undersea storage unit. The hydrogen storage system is designed to be underwater in order to take advantage of the tidal turbine operating beneath the free surface and thereby keep away from most of the significant effects of storms and waves. The storage system has a buoyant balloon suspended in deep-sea water and connected by an anchor [12]. Freshwater supply has always been critical to sustainability. In this context, the generated tidal power is used to generate freshwater by utilizing the coastal area within the scope of this study. Studies [2],[11] showed that RO is one of the best desalination methods which can be coupled with tidal energy. In the RO process, the pressurized seawater passes through a semipermeable membrane which, separates freshwater from the seawater.

System Energy Requirement

The proposed energy conversion system has two main energy requirements. The first one is for the electrolyser and the other is for the RO unit. There are many analyzes [1],[13] that show the energy consumption of a RO unit. According to [4], an energy efficient RO unit's consumption is assumed to be $2.4\ kWh$ for $1\ m^3$ fresh water.

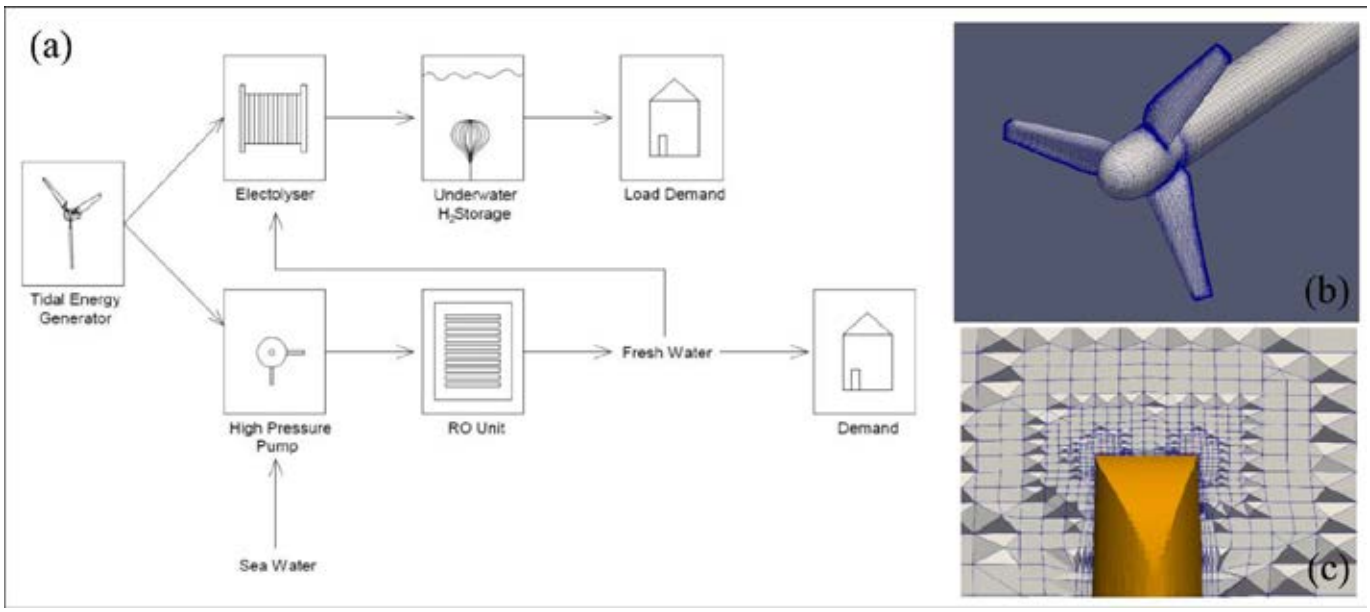

Fig. 1. Tidal energy conversion scheme (a), mesh structure on the turbine geometry (b) and detailed view of mesh layers in boundary layer at tip of the blade (c)

1 kg of hydrogen is ideally produced from 8.9 liters of water by supplying $39\ kWh$ of electricity at $25℃$ and 1 atmosphere pressure. Typical electrolyser units are being used with an efficiency of between approximately 56% and 80% which corresponds to between $70\ kWh$ and $50\ kWh$. The required power for the selected Proton Exchange Membrane (PEM) type electrolyser is $55\ kWh$ to produce 1 kg of hydrogen gas [9],[8]. The rest of the fresh water after the electrolyzes process is consumed by the community.

Considering the real state of a wind turbine, there are environmental and structural effects such as biofouling around the turbine, turbine's hydro-elastic behavior and so on that consume the produced power. Therefore, an additional 10% margin is considered, and the turbine's total energy is estimated as $63.14\ kWh$.

PRELIMINARY DESIGN OF THE HORIZONTAL AXIS TIDAL TURBINE

In this study, the steady flow condition is assumed to design and implement the horizontal axis tidal turbine energy conversion system. An approach is presented to determine of the tidal turbine dimensions with respect to the load demand. Firstly, the required power is determined and then an initial tidal turbine [6] is selected to carry out CFD analysis which computes the torque (Q) and output power (P_{out}) relatively. CFD simulations are performed by changing the rotational speed (ω) of the tidal turbine, which give the results of C_p in equation (1). The curve of the tip speed ratio (TSR) versus C_p is drawn to determine the maximum power of the characteristic tidal turbine and corresponding TSR value. The output power is directly related to the design parameters of a tidal turbine such as diameter of the rotor area, number of blades, section profiles of blades, sections' twist angle, hub geometry and so on. It has a dominant importance to determine the diameter of the rotor area among other parameters. In the second stage of the design, it is checked whether the output power provides the required power of the energy conversion system. The rotor diameter decreased or increased depending on the result from the CFD within the scope of this study.

Power coefficient is defined as follows;

$$C_p = \frac{P_{out}}{P_{in}} = \frac{Q\omega}{\frac{1}{2}\rho A V_{in}^3} \quad (1)$$

Here, ρ is the density of water, A is the blade swept area, V_{in} is the inlet velocity, Q is the turbine torque, ω is the turbine angular velocity (rad/s).

The mean flow velocity of tides is assumed as $2\,m/s$. In the preliminary design of the horizontal axis turbine, the maximum C_p is considered to be 0.4 before the high-fidelity CFD simulations. Then, the initial radius of the swept area is calculated as $3.5\ m$.

Turbine Geometry

There are different types of tidal turbines based on the number of blades and section geometry. Three blade and S814 section type tidal turbine investigated experimentally [16] in Emerson Cavitation Tunnel is selected to produce the power. The model scale turbine has $0.4m$ diameter utilized instead of using the full scale one in this study. There is a critical phenomenon that should be pointed out about the scale effect of the tidal turbine. Song and his colleagues [15] have carried out numerical analysis on both model and full scale to show the difference in terms of C_p. They presented that there is a slight difference on C_p curve between 1 and 5 TSR.

CFD SIMULATION AND VALIDATION

In this work, the viscous flow around the tidal turbine is solved with the open-source software, OpenFOAM. Three dimensional, incompressible, unsteady RANS equations as momentum equations are solved by the method of finite volume discretization. The other governing equation is the conservation of mass in the problem. The first-order implicit (Euler) scheme is applied to discretize the unsteady term in Navier-Stokes equations. PIMPLE Algorithm, a combination of PISO (Pressure Implicit Split Operator) and SIMPLE (Semi Implicit Methods Pressure Linked Equations) algorithms, is used to solve the pressure-velocity coupling. Inlet, bottom, top and side boundaries are located 10 times diameter (D) of the turbine away from the turbine model and the outlet boundary is placed 20 times D downstream direction. The snappyHexMesh utility is executed to create a three-dimensional mesh. The number of mesh is around 2.5 M and the average $y+$ value of turbine blades is 12.6. (see Fig. 1 (a) and (b))

RESULTS AND DISCUSSION

CFD simulations have been performed by changing the rotational speed (ω) of the tidal turbine. The curve of the tip speed ratio (TSR) versus C_p was obtained to determine the maximum power of the characteristic tidal turbine and corresponding TSR value. The maximum C_p is 0.283 achieved at around 3.5 TSR, which shows good agreement with the experimental data provided by [16]. The power into turbine P_{in} is $157.85\ kWh$ on full scale condition. Considering the maximum C_p at 3.5 TSR, the output power calculated as $44.67\ kWh$. It should be noted that the selected turbine's parameters do not meet the required power. In this case, the preliminary turbine design should be updated by increasing the swept area of it.

Pressure distribution around the turbine has been shown in Fig. 3 at 3.5 TSR. Tip vortex formation starts from TSR3 and then grows gradually up to TSR4.

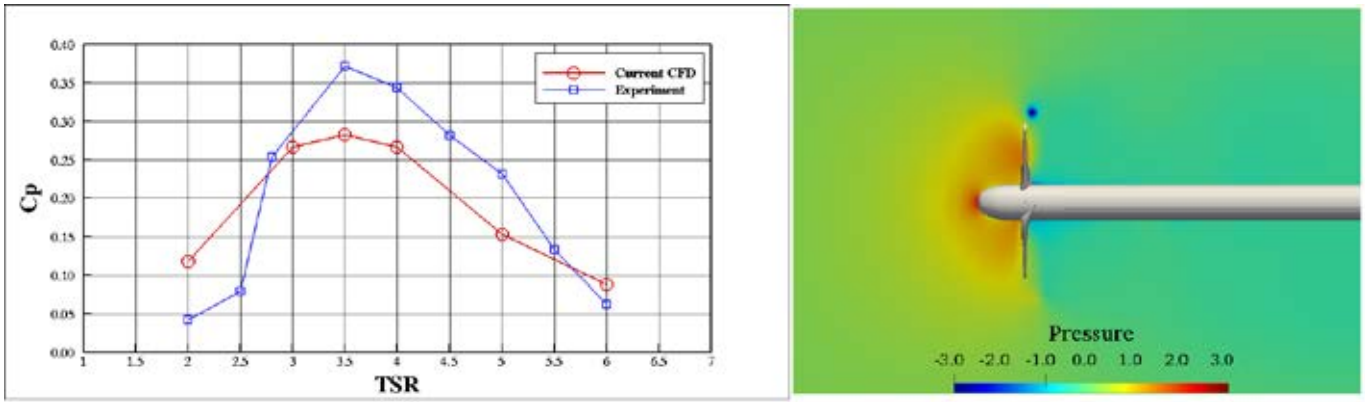

Fig. 3. Variation of C_p with TSR and pressure distribution at 3.5 TSR

CONCLUSIONS

Performing CFD simulations play a critical role to understand the hydrodynamics characteristics of tidal turbines. This study shows the miscalculation points at the preliminary design stage. The maximum C_p at 3.5 TSR, the output power calculated as $44.67\ kWh$. The output power of the designed horizontal axis tidal turbine at the preliminary design stage does not meet the required power according to the high-fidelity CFD simulations. Therefore, the swept area of the tidal turbine should be increased to generate enough torque.

DEEP LEARNING-BASED BINARY CLASSIFICATION OF ISLANDING CONDITIONS IN A HYDROGEN ENERGY-BASED DISTRIBUTED GENERATION SYSTEM

[1] *Alper Yılmaz,* [2*] *Gökay Bayrak*

ABSTRACT

This paper presents a deep long short-term memory (DLSTM) with a binary-label classifier method proposed for binary classification of islanding and non-islanding events in a hydrogen energy-based distributed generator (DG) system. Deep learning (DL)-based method eliminated the lack of performance of conventional intelligent islanding detection methods that uses feature extraction, feature selection, and event classification. Besides, the proposed method has provided the need for a processing-intensive filtering process to reduce noise from the signal. The proposed islanding detection method has a 98.33% accuracy rate under no-noise, and 97.66% high-level noise conditions. In the proposed method, the non-detection zone (NDZ) is almost zero, and the detection time is under the defined IEEE 929-2000 standards. Experimental and simulative data results show that the LSTM-based islanding detection method outperforms the algorithms in recent studies in terms of noise immunity and accuracy.

Keywords: Hydrogen energy, Islanding detection, Long-short-term memory, Deep learning, Microgrid.

INTRODUCTION

The use of distributed generators (DGs) is becoming more common worldwide and hydrogen energy (HE) is the most promising renewable energy source for DGs with their advantages [1]. The adoption of Fuel Cell (FC) technology can eliminate the weather dependence on renewable energy resources (RES) such as wind farms and, photovoltaic (PV) systems [2]. Besides, the rapid advancement of FC technology has increased the popularity of grid-connected FC systems. The rapidly growing number of grid-connected FC systems must meet some electrical connection standards. As a result, connecting FC systems to the main grid is a major concern for DGs [1]. One of these criteria and the most important is islanding detection. Islanding as defined by IEEE standards [3]: The condition in which a distribution system becomes is electrically isolated from the grid yet continues to be energized by one or more local DG through the associated point of common coupling (PCC). Detecting unplanned islanding conditions in FCs improves system stability and allows consumption-side equipment to operate more consistently for longer periods [4].

Islanding detection methods can be classified as remote, local, and intelligent methods. However, local methods have several drawbacks, including difficulty in determining a threshold value, uncertainty due to operating conditions, and susceptibility to noise [5]. Also, they contain a large non-detection zone (NDZ) [6]. NDZ is low in remote methods, but the cost is quite high [6]. To eliminate the drawbacks of conventional methods, intelligent methods including signal analysis and classifier are proposed [6]. Previous research divided automatic islanding identification into three stages: signal processing [7], feature selection [8], and event classification [9]. In the signal analysis step, all methods have a heavy computation burden and are affected by noise. Besides, the feature filtering optimization process is time-consuming and tedious. Deep learning (DL) methods have automatic feature extraction capability, eliminate human involvement, it has closed-loop feedback. These methods can automatically extract t features without the need for any conventional signal analysis method.

In this study, the DL-based islanding detection method using long short-term memory (LSTM) is proposed for binary classification of islanding and minor disturbances such as sags, swells, and frequency deviations in a hydrogen energy-based DG system. Besides, high penetration of PV and wind energy in the micro-grid with hydrogen energy-based DG is examined in the scenarios. The motivation for using LSTM in this model is to extract the dependencies between each row of features from the network model. Deep LSTM (DLSTM) is used for feature extraction and classification, unlike the conventional three-stage process. The proposed islanding detection method has a 98.33% accuracy rate under no-noise, and 97.66% high-level noise conditions. In the proposed method, the NDZ is almost zero, and the detection time is under the IEEE standards.

DATA GENERATION AND TEST SYSTEM

Islanding conditions with different real/reactive power mismatches and minor disturbances are generated using the MATLAB/SIMULINK model in Ref. [9] for hydrogen energy-based DG connected microgrid. The fundamental frequency and the sampling frequency are selected 50 Hz, and 10 kHz, respectively. Besides, the number of cycles for each

sample is selected 10 cycles.1000 samples are generated for each event for the training proposed model. The number of training sets reached 7000 samples. Generated test samples for islanding and non-islanding classes are shown in Table 1.

Table 1. Generated test samples for islanding and non-islanding classes using a simulated test system [9]

Class	Events	Number of Test Samples
C1	Islanding in different power mismatches (at the PCC of the Hydrogen energy-based DG)	300
C2	Voltage sag (switching on loads and switching off capacitor banks)	100
	Voltage swell (switching offloads and switching on capacitor banks)	100

DLSTM-BASED ISLANDING DETECTION METHOD

The proposed DL-based model is shown in Fig. 1. LSTM models are a type of recurrent neural network (RNN) to overcome the vanishing gradient problem. LSTM models are formed by sequential use of the LSTM units [10]. Models using multiple LSTM layers are called deep LSTM (DLSTM). In the proposed method, there is a dropout layer, which can be used once or several times between layers to prevent overfitting problems. At the output of the LSTM layers, there is a traditional neural network layer containing an activation function for classification. This layer is called a fully connected (FC) layer. FC layer uses the features extracted from the previous layers. As a result of this, it is possible to say that the DLSTM model includes feature extraction in itself. In islanding and minor disturbances classification, we used a softmax layer with a softmax activation function at the end of FC layers. The softmax means the probability of the input sample. That is, the class with the highest probability will be determined as the output. Utilizing the softmax activation function given by

$$P(y = j\,|x) = \frac{e^{x^T w_j}}{\sum_{k=1}^{K} e^{x^T w_k}} \tag{1}$$

where, x represents the input vector, and w is the weight matrix.

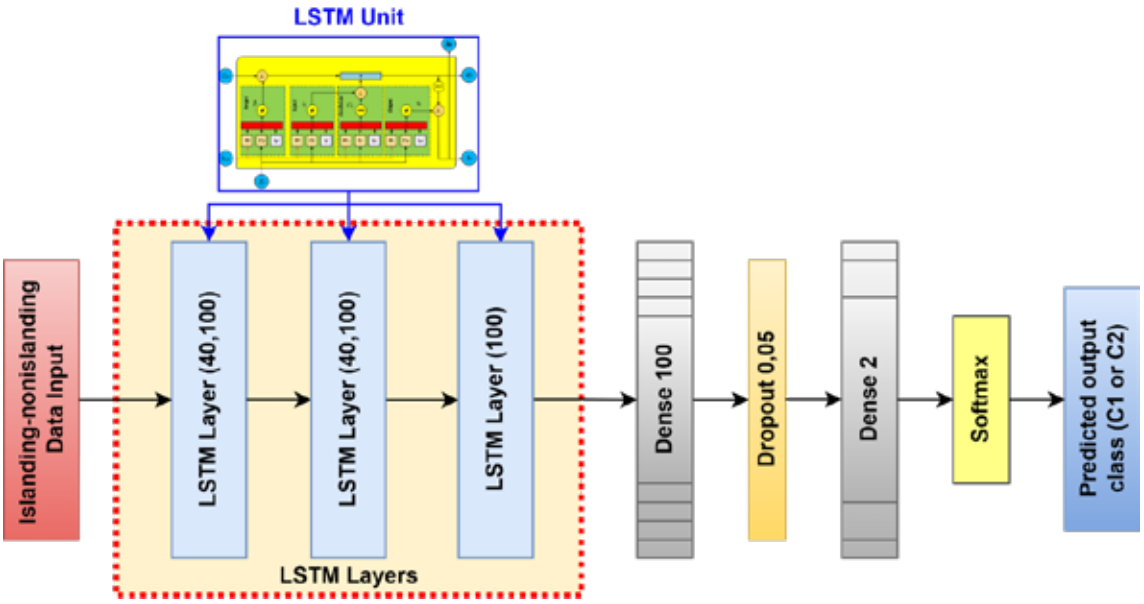

Fig. 1. Proposed DL-based islanding detection model

RESULTS

The classification test results of the proposed method have shown in Table 2. Accuracy performance is very high for test data containing noise at different signal-to-noise ratio (SNR) values and covering all scenarios. The proposed approach classifies islanding conditions caused by CB opened and minor disturbances caused by the presence of drivers with industrial equipment, short circuit faults, motor starting, RES disconnection, and, loads/capacitors switching in microgrids.

Table 2. Classification results for DLSTM

Class	Number of test samples	Corrections	Accuracy rate (%)
C1	300	294	98.0
C2	700	687	98.14

The performance comparison of DLSTM and convolutional neural network (CNN)-based method at different noise levels is given in Table 3. DLSTM provides better performance than CNN in accuracy and noise immunity. LSTM is to extract the dependencies between each row of features from the model. With this advantage, the proposed model shows performance superiority in automatic feature extraction.

Table 3. Comparison with CNN

	Accuracy rate (%)		
Model	**Under no-noise**	**Under low level noise (SNR:40 dB)**	**Under high level noise (SNR:30 dB)**
CNN	98.37	97.89	96.47
Proposed DLSTM	98.33	98.01	97.66

CONCLUSIONS

In this study, the LSTM-based DL method is proposed for binary classification of islanding and minor disturbances in hydrogen energy-based DG-connected microgrid. DLSTM eliminated the lack of performance of conventional intelligent islanding detection methods. The LSTM-based method is analyzed under different load conditions on the simulated test system. The accuracy results are also compared with the CNN-based method. DLSTM has 98.33% accuracy under no-noise, and 97.66% high-level noise conditions. The NDZ is almost zero, and the detection time is under the IEEE standards for DLSTM with binary classifier.

THD MINIMIZATION OF VEHICLE-TO-GRID (V2G) IN FUEL CELL EVs WITH A DEVELOPED ELLIPTIC IIR FILTER

[1*]Gökay Bayrak, [2]Alper Yılmaz

ABSTRACT

The popularity of fuel cell electric vehicles (FCEVs) and plug-in electric vehicles (PEVs) is a key factor in addressing the electricity demand. With vehicle-to-grid (V2G) applications, these vehicles can act as distributed generators. Total harmonic distortion (THD) in the connection of electric vehicle charge stations (EVCSs) capable with V2G technology with the grid should be fulfilling the values specified by international electrical standards. Although V2G topologies are improved, the use of a suitable filter is necessary to improve the power quality (PQ) of the system. Since analog filters bring additional losses to power losses caused by inverter and converter, software-based digital filters are also needed. Due to the implementation of the infinite impulse response (IIR) filter includes fewer parameters, it requires less memory and has less computational complexity. In this study, a low-pass elliptical IIR filter design is realized in real-time with the converter using LabVIEW infrastructure. When imbalances occur in the grid voltage, reducing bandwidth using phase locked loop (PLL) will not be enough to keep the system stable. This problem solved by adding a proposed low-pass elliptical IIR filter to the system.The results obtained by using the filter are presented in the paper and the THD value was obtained as 0.82% for converter capable V2G.

Keywords: Vehicle-to-grid (V2G), Fuel cell electric vehicles (FCEVs), IIR filter design, THD minimization, Power quality

INTRODUCTION

Today, limited fossil fuel sustainability, environmental concerns, and increasing energy demand are universal issues that are widely addressed to find appropriate solutions. Fuel cell electric vehicles (FCEVs) and plug-in electric vehicles (PEVs) with vehicle-to-grid (V2G) support stand out in solving these problems [1,2]. Here, it is an important criterion to connect the electric vehicle charging stations (EVCS) with V2G technology to the grid following the grid code requirements. Besides, V2G topologies have improved, and a proper filter is required to increase the system's power quality (PQ) and THD minimization.

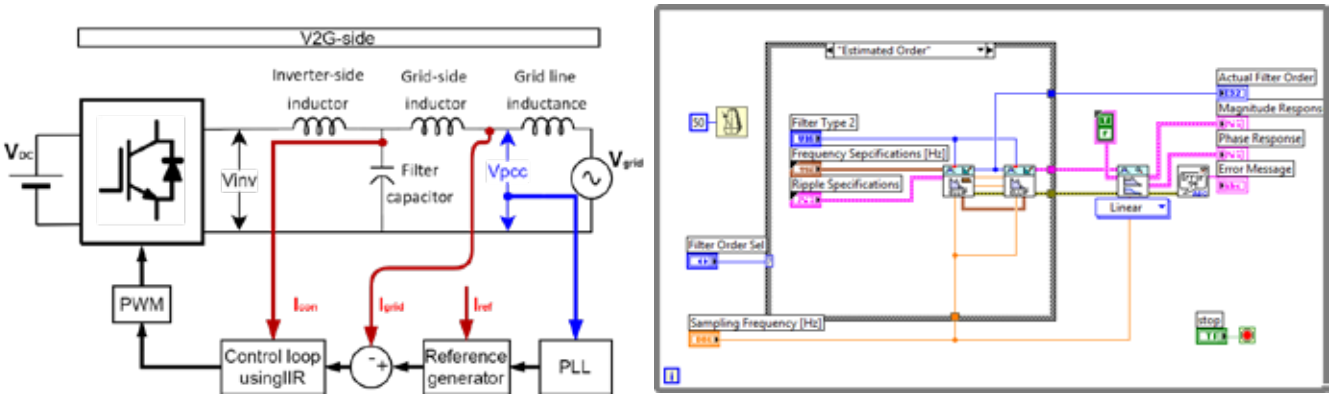
A digital filter used in converters is a method or algorithm that works on digitized analog signals, converting the input signal to the desired output signal. Among the main design purposes of the filters, which have a wide application area, are to separate the interfering signals from each other, to increase the signal quality by reducing the noise in the signal, and to recover the distorted signal. In the frequency selective filters, desired filter properties are defined in the frequency region in terms of desired amplitude and phase response. In the filter design filter, we determine the desired frequency response characteristics, and the response coefficients to provide the causal finite impulse response (FIR) [3] or infinite impulse response (IIR) filter [4] most closely. Digital filter design depends on the nature of the problem and the characteristics of the desired frequency response.Due to the implementation of the IIR filter includes fewer parameters, it requires less memory and has less computational complexity. Because of its advantages, the IIR filter is used in this study.

In a study on this subject [5], an adaptive IIR digital filter design has been implemented for inverter output. In this way, it is aimed to prevent harmonic distortions in the output voltage. In another study using a narrow band in IIR filter design [6], harmonic distortions in the output current and voltage were tried to be prevented. Especially by developing different control methods for LCL filters, is aimed to reduce the effects of DG systems on grid power quality and preventing total harmonic distortion (THD). Some of these studies [7, 8] performed digital IIR filter designs to increase the stability of the inverter and DC / DC converter. Through IIR filter design, both the grid and the converter system are operated stable, and the power system quality is between the defined threshold values by the international grid codes. Today, the design of FIR and IIR digital filters can be carried out by a large number of computer software programs. Thus, designing an accurate digital filter with a high-efficiency converter is a significant issue for PV-based distributed generators to avoid power quality disturbances (PQDs).

In this study, elliptical IIR filter design is realized using LabVIEW infrastructure for THD minimization on the V2G side. The results obtained by using the filter are presented in the paper and the THD value was obtained as 0.82%. In this

way, a high-efficiency converter structure with a low THD value has been obtained following the values determined by the grid code.

THEORETICAL BACKGROUND



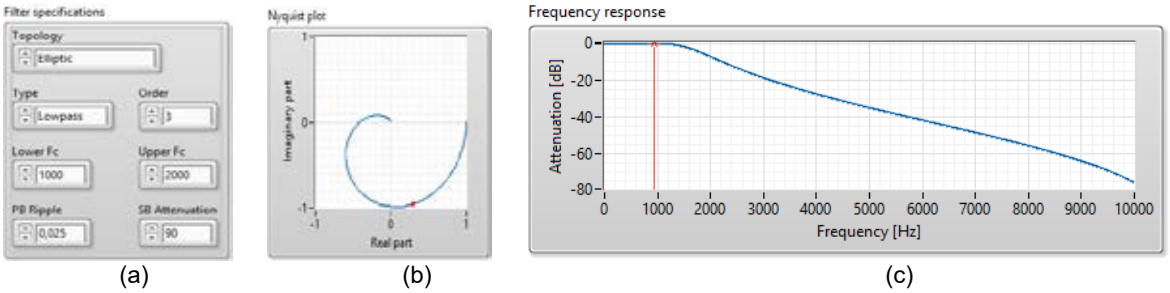
Describe the problem/system being studied and the methodology applied. Avoid footnotes at the bottom of the page within the frame. In many converter applications, the digital filter is designed in the frequency domain. To define the frequency response in the digital filter, it is necessary to define the phase response, target magnitude response, and the allowable deviation for them. Stopband edge frequencies, passband gain, passband edge frequencies, maximum passband ripple, and minimum stopband attenuation are the selected parameters in our filter design. Considering these parameters, the z transform of an IIR filter is defined as:

$$H(z) = \frac{\sum_{k=0}^{N} b_k z^{-k}}{1+\sum_{i=1}^{M} a_i z^{-i}} = K \frac{\prod_{k=1}^{N}(1-z_k z^{-1})}{\prod_{k=1}^{M}(1-p_k z^{-1})} \quad (1)$$

where z_k and p_k are the roots of the H(z).

PROPOSED METHOD

A general schematic of the developed IIR filter and phase-locked-loop (PLL) structure is shown in Fig. 1 (a). In the loop filter design of PLL, fast locking of the obtained phase angle to the phase angle of the grid and showing a good filtering characteristic is very important for the dynamic performance of the system. In ideal conditions, the high bandwidth of the filter enables the amplitude and phase angle of the grid voltage to be determined quickly and accurately and high order harmonics of the grid voltage. In case of failure, the stable operation of the PLL is provided by reducing the bandwidth, but in this case, the synchronization time increases. When imbalances occur in the grid voltage, reducing the bandwidth cannot stabilize the system. This problem can be solved by adding a low-pass IIR filter to the system. The changes that occur with the addition of a low pass filter improve the stability of the system, while significantly reducing the dynamic response of the system. The signal acquired was then processed in digital IIR filter design software developed with LabVIEW filter tools shown in Fig. 1 (b).



(a) (b)

Fig. 1. (a) Block diagram of the proposed method and, (b)developed software for designed IIR filter in LabVIEW environment

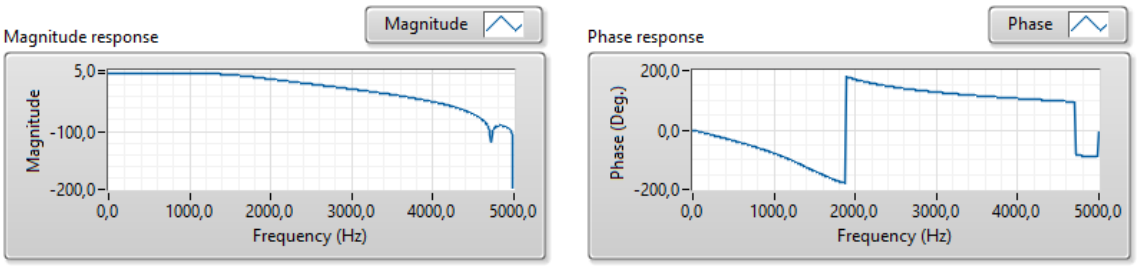
RESULTS

As shown in Fig. 2a, 3rd order low-pass elliptical IIR filter design was realized by selecting the lower cut frequency 1 kHz, uppercut frequency 2 kHz, switching frequency 10 kHz, SB Attenuation 90, and PB ripple 0.025. The Nyquist plot and frequency response of the proposed IIR filter is also indicated in Fig. 2a and Fig 2b, respectively.

(a) (b) (c)

Fig. 2. (a) 3rd order low-pass elliptic filter specifications, (b) Nyquist plot, (c) frequency response

The amplitude and phase responses of the proposed filter are also shown in Figures 3a and 3b. 3rd order low-pass elliptical IIR filter design is observed in the figures, and the proposed filter has a stable response. Thanks to LabVIEW filter tools and other software developments, it is aimed to filter the inverter output voltage and comply with the grid connection conditions required by international standards (IEEE 519 and 1547, IEC 61000-3-2, and IEC 61000-3-12). Especially disturbing signals and electrical noise caused by harmonic distortions caused by inverter and converter are largely eliminated by the developed 3rd order low-pass elliptical IIR filter.



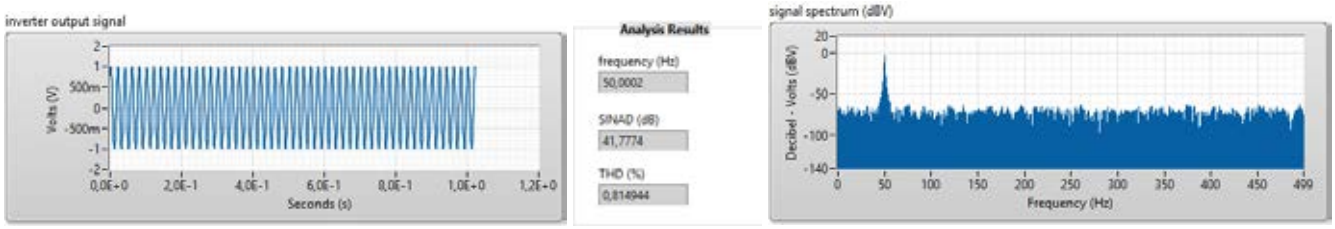


Fig. 3. (a) Magnitude, (b) Phase response of proposed filter

As can be seen from Figures 4a, 4b, and 4c, the THD value is calculated as approximately 0.82% according to the waveform at the inverter output with a single phase 50 Hz frequency. Considering that the allowable THD value should be less than 5%, it is seen that the result obtained is a quality output close to pure sinus. This shows that the developed filter can be used for V2G applications. The developed filter is software-based and provides great convenience both in terms of development and in terms of allowing the search for suitable solutions by easily testing different types of filters.

(a) (b) (c)

Fig. 4. (a) Inverter output signal, (b) THD result, (c) signal spectrum

CONCLUSIONS

In this study, a low-pass elliptical IIR filter design is realized with the V2G converter using LabVIEW infrastructure. The results obtained by using the filter are presented in the paper and the THD value was obtained as 0.82% for a converter. In this way, a low THD value is obtained for the V2G converter under the values determined by the grid code.

ABSTRACT

In this study, an analysis of the use of photovoltaic (PV) and fuel cell (FC) systems as a combined (hybrid) system is presented. unified system; It consists of a PV panel, electrolysis unit, hydrogen tank, and fuel cell. The electrical energy supplied from the PV panel is used for hydrogen production in the electrolysis unit. The stored hydrogen then drives the fuel cell, providing a regular supply of electricity. Fuel cell stack efficiency was found to be 65% in Antalya region and 58% in Sinop region.

Keywords: Photovoltaic, Fuel cell

INTRODUCTION

The use, transportation, and storage of energy, which is the most important factor in a sustainable environment, society, and economy, must also be sustainable. However, the depletion of fossil energy resources, environmental problems due to energy consumption, greenhouse gas emissions and global warming, the increase in foreign dependency on energy and economy, and the rapid decrease in natural and local resources cause the social and economic order to change rapidly. Due to their low environmental impact, PV hybrid systems using fuel cells as energy storage devices are one of the most promising renewable energy sources.

Renewable sources of vitality, for example, photovoltaic and wind, do not transmit a constant power, but due to their complementarity, their combination provides more uninterrupted electrical output.[1] The reason for the hybrid power system is to provide as much energy as possible from renewable energy sources to guarantee the load demand. The increase in power demand and the growth in fuel prices are among the solar energy sources that we need to develop alternative energy technologies.[1]

Variable renewable energy (RE) and power conditioning units such as hydrogen, alkaline water electrolyzer, storage hydrogen tank, solar and wind PEM fuel cell (PEMFC) can be used to store its energy [2].

METHODS

Hydrogen, the lightest element in the world, was created technologically for its storage. Hydrogen is a very efficient and clean fuel. Hybrid energy systems design mainly depends on the performance of the individual system. To predict performance, individual components must be modeled first.

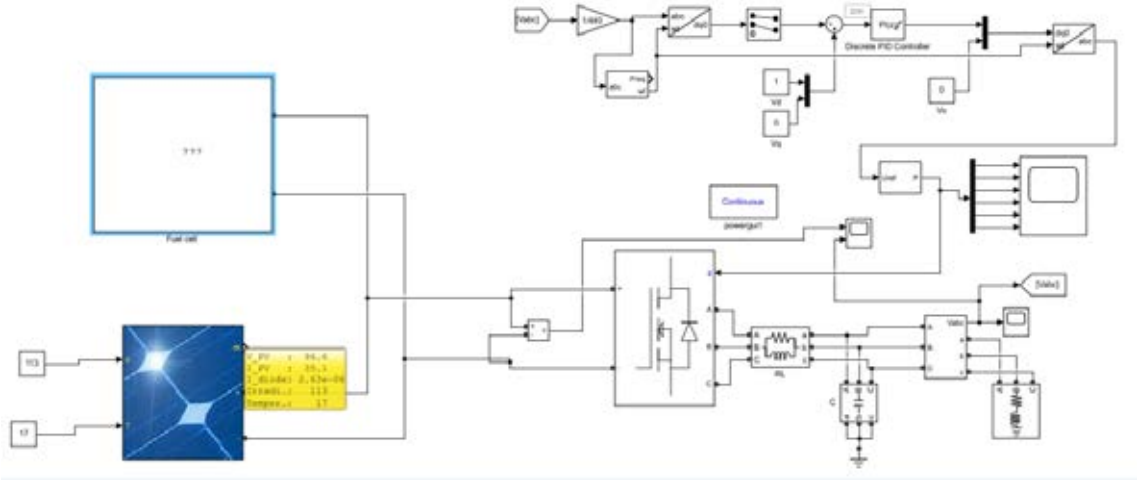

Fig. 1. Photovoltaic (PV) and fuel cell (FC) hydrid model

In Fig. 1, the photovoltaic (PV) and fuel cell (FC) hydride model is simulated in Matlab/Simulink environment. By running Matlab simulation, the voltages and fuel cell usage depending on the varying amount of radiation were investigated in the cities of Antalya and Sinop in April, on the same day and time, using the same panel and cell.

Fig. 2. Antalya Radiation Values [3]

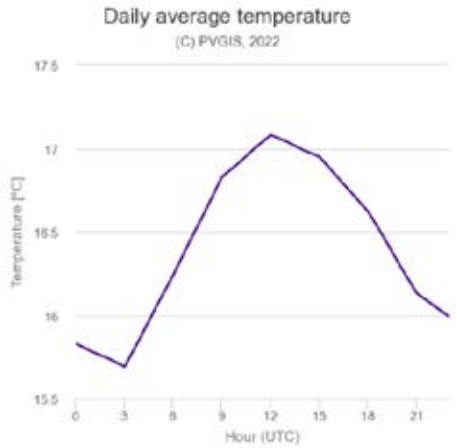

Fig. 3. Antalya Temperature Values in April 2022 [3]

Fig. 4. Sinop Radiation Values [3]

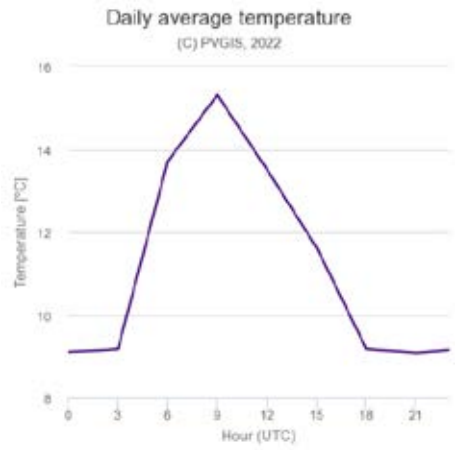

Fig. 5. Antalya Temperature Values in April 2022 [3]

The model given in Fig.1 consists of a photovoltaic and a dc-dc converter activated by the fuel cell. Power from the DC link is supplied to the electrical grid via the converter. A fuel cell works like a battery by converting a chemical reaction into electricity. The dependence of operating continuity on the supplied hydrogen and oxygen separates the fuel cell from the battery. The operation of the fuel cell depends on the chemical reaction of hydrogen with oxygen. In this study, a module was created by using a 6 kW 45V DC PEMFC and 10 serial and 40 parallel solar panel modules. The dc voltages produced were converted to ac voltages using the inventor. In the case of insufficient sunlight, the voltage was generated from the insulating cell by the electrolysis reaction.

By using the created module, the radiation and temperature values of April in two cities were taken and run on Matlab simulation. In the simulation, the voltages and the changes in the fuel cell depending on the radiation values falling on the solar panel were read.

RESULTS AND DISCUSSION

When the created module is run with simulation, the voltage values obtained for the cities of Antalya and Sinop are shown in Fig.6 and Fig.7. The radiation value measured in April in Antalya is 218.69 kWh/m^2, and the radiation value measured in Sinop in April is 159.99 kWh/m^2. Taking these values as a reference, when the photovoltaic and fuel cell hybrid generation system was operated for 0.45 seconds using Matlab simulation, it was observed that the voltage values formed in April in the two cities were very close to each other.

However, when we look at the fuel cell usage values shown in Fig.8 and Fig.9 in the Matlab simulation made concerning the April radiation data of Antalya and Sinop cities, the fuel cell of the hybrid module in Sinop city needs to work much more to produce almost the same voltage. Figures 8 and 9 also show A: Fuel flow (increase); B: The

usage percentages of hydrogen and oxygen are shown (Fixed after a certain period of time); A: Hydrogen and oxygen flow rates of the stack are shown (increase over time); D: Shows the efficiency of the stack (Minimum decreases are observed over time).

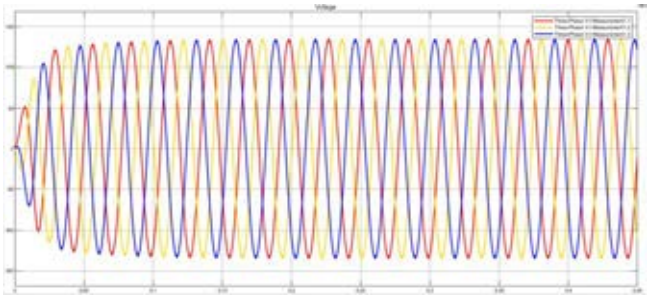

Fig. 6. Antalya April Produced Voltages (Voltage-seconds)

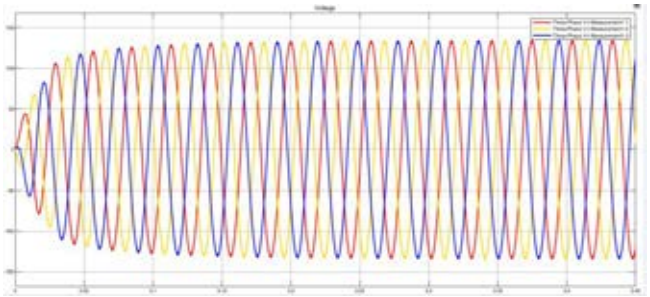

Fig. 7. Sinop April Produced Voltages (Voltage-seconds)

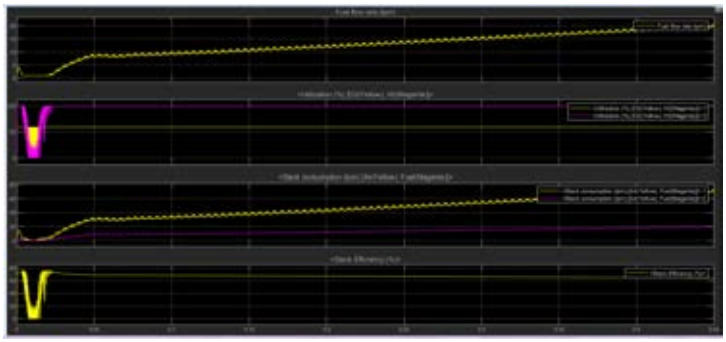

Fig. 8. Antalya April Fuel Cell Usage

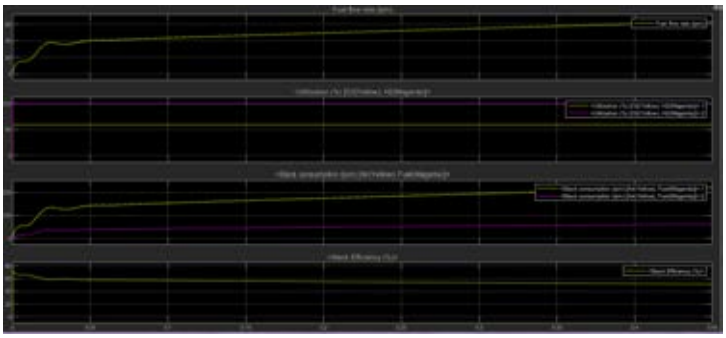

Fig. 9. Sinop April Fuel Cell Usage

In this study, the use of fuel cells was investigated to produce approximately the same voltage in the determined period by using the hydride module created in two cities with different temperatures and radiation values. It has been observed that the need for the use of fuel cells is much less to reach the desired voltage in a city with a high radiation value.

CONCLUSIONS

The photovoltaic and fuel cell hybrid power system powered by Matlab Simulation works flexibly by utilizing maximum solar energy and optimum energy from the fuel cell. The studies conducted using the information of two different cities in the south and north were quite close to each other. This result shows that the system from north to south can be used in Turkey.

ABSTRACT

The effects of hydrogen enrichment with natural gas have been experimentally investigated in an industrial burner for heat production. The hydrogen content was varied from 0%, 30%, and 50% by vol in the fuel blend (hydrogen + natural gas) to examine the burner's performance, combustion, and emission characteristics. The emission characteristics were analysed by using a flue gas analyser and verified with a mass spectrometer. The experiments were performed on HEC (High Efficiency Combustion) range – TMG fully condensing industrial heater. The experimental study shows that flame thermal runaway occurs in the burner when deploying higher amount of hydrogen (i.e. ≥30% by vol.) in the blend and combustion instability increases. The required fuel flow rate for hydrogen blend increased to achieve the same power output as for natural gas. The most important influence of using hydrogen blend in combustion for industrial burner is the reduction of both CO and NOx. The study shows that CO, NO and NOx are reduced up to two times and more for 30% by vol. hydrogen blend with natural gas. The study also shows that the higher amount of hydrogen blend (i.e. ≥50% by vol.) will require a significant amount of modification to the burner's control.

Keywords: Industrial burner, Hydrogen, Emission,Combustion instability, Flames

INTRODUCTION

Hydrogen has been identified as one of the new, low (or zero) carbon solutions that will be critical for many countries' transitions to net zero [1]. Stringent regulations on emissions from industrial heat production and applications have motivated researchers and engineers of various low emission technologies, including decarbonised industry, carbon capture, and flexi-fuel systems allowing the use of carbon-free fuel such as ammonia and hydrogen. Ultra-lean and low emission (ULLE) combustion has traditionally been one of the most common technology used to reduce emissions from industrial burners. The HEC (High Efficiency Combustion) fully condensing industrial heater (gas fired warm air heaters) provides 101% efficiency on high fire and 109%+ on low fire [2]. Such industrial heaters range from 12 to 1000 kW. This ULLE combustion is reliant on a highly controlled mixing of mixture composition (i.e. air and fuel) to achieve ultra-lean premixed combustion. This premixed combustion supports reducing the flame temperature and ultimately reducing the NOx formation. The control system of this heater ensures that the combustion does not promote an unnecessary level of unburnt hydrocarbons, carbon monoxide, and combustion instabilities. It is important to note that these burners face other challenges when deploying hydrogen blend fuel – e.g. higher burning velocities, higher flame temperature, flashbacks etc. These challenges require careful design optimization via heater's control system. The properties of hydrogen and natural gas (methane) are outlined in Table 1.

Table 1. Characteristics of hydrogen and natural gas (methane)

	Hydrogen	Natural gas (methane)
Density	0.084 kg/m^3 (much lighter than air 1.225 kg/m^3)	0.651 kg/m^3
Energy of Combustion	141.8 MJ/kg	55.5 MJ/kg
Flame temperature	2045 °C	1957 °C
Flammability limits (ϕ*)	0.1 – 7.1	0.4 – 1.6
Ignition temperature	585 °C	800 °C
Flame velocity	1.85 m/s	0.38 m/s

* equivalence ratio is defined as the ratio of the stoichiometric air-to-fuel ratio to the actual air-to-fuel ratio

The effects of constant velocity and constant residence time scaling on the local NOx emissions and flame characteristics of complex partial premixed hydrogen burners have been previously investigated [3]. Additionally, the

conversion of natural gas jet flame burners to hydrogen was also studied [4] and found that to retain the same heat release in burners as with CH_4, H_2 would require an approximately three fold increase in jet velocity [4]. Moreover, an experimental study on potential natural gas/hydrogen blends as fuel for industrial heat treatment furnaces was investigated and both technological and economical aspects were considered with the possibility of CO_2 reduction [5]. However, there is a gap in the literature for the study on hydrogen blend fuel with natural gas in an industrial burner for heating application which has not been done for emission aspect, where the aim is to meet same power output as natural gas while lowering the emission. This study aims to address this gap by conducting an experimental study on hydrogen enriched natural gas combustion in industrial burner.

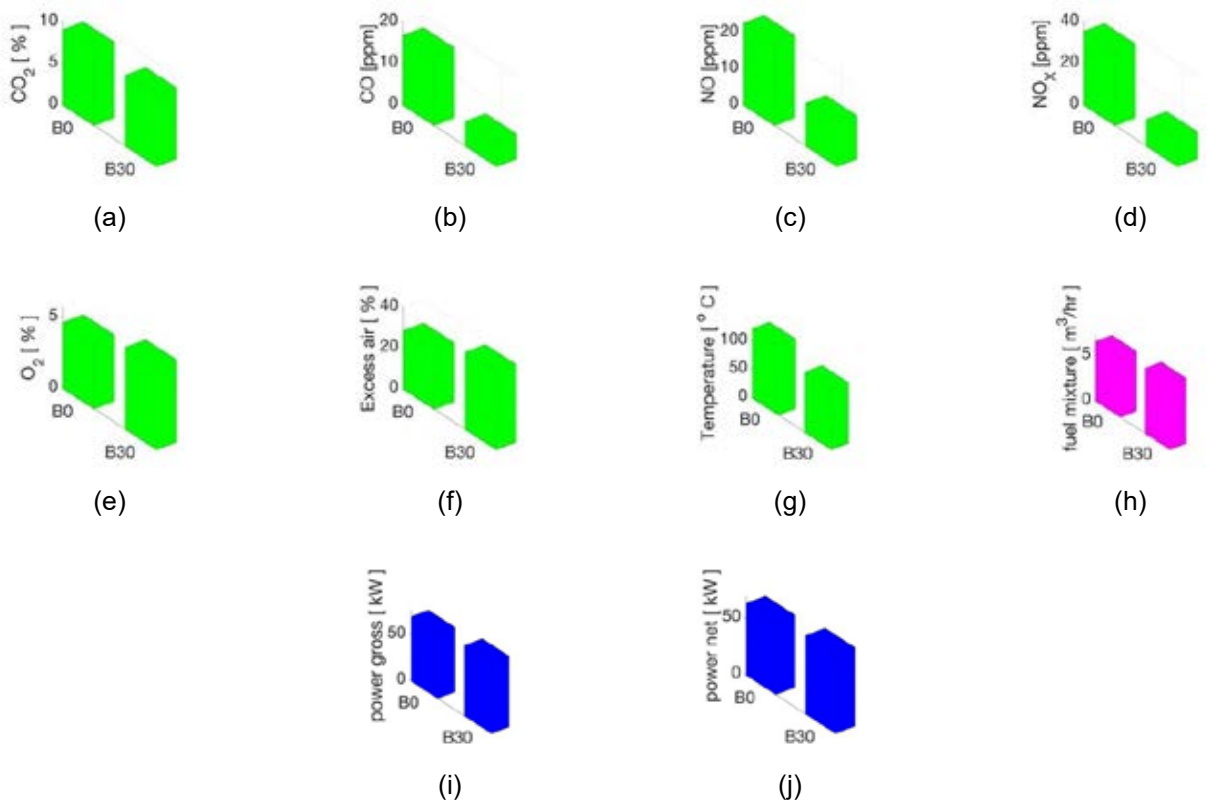

Fig. 1. The emissions ((a), (b), (c), (d), (e), (f), (g)) and performance ((h), (i), (j)) characteristics of TMG module burner for B0 and B30 blend cases

EXPERIMENTAL SETUP

The experiments were carried out using the TMG range of fully condensing gas module burner unit from BMM Heaters Ltd. The various hydrogen blends were obtained and supplied from Air Products UK. The accuracy of such hydrogen blend with natural gas was %mole = $\pm$0.5 and calculated calorific values were recorded for power output and required fuel flow rate calculations. The composition of the combustion products was measured using a flue gas analyser which then further verified with the ESS quadrupole mass spectrometer [6]. The mass spectrometer measures mass-to-charge ratio (m/z) of gas-phase ions. It has three main components: an ion source, a mass analyser, and a detector. The ion source converts analyte molecules into gas-phase ions, the mass analyser separates the ionised analytes according to their m/z, and the detector records the number of ions at each m/z value. An advantage of mass spectrometers over other analytical instruments is that it affords a high degree of accuracy and sensitivity. The various missions were captured using ESS quadrupole mass spectrometer. Here B0, B30, and B50 case represent hydrogen contents in blend fuel of 0%, 30%, and 50% by vol. respectively.

RESULTS AND DISCUSSION

The emissions, combustion, and performance characteristics of the TMG module burner have been captured, calculated, and shown in fig 1. The emissions characteristics includes CO_2 (%), CO (ppm), NO (ppm), NOx (ppm) and O2 (%) are show in fig 1 (a), (b), (c). (d) and (e) respectively. The combustion characteristic includes excess air (%) and flue temperature (^oC) are shown in fig 1 (f) and (g) respectively. And finally, the performance characteristics including fuel mixture inflow (m^3/hr), power gross (kW) and power net (kW) are shown in fig 1(h), (i) and (j)

respectively. It can be seen from fig 1(b) that the CO (ppm) for B30 case is significantly lower compared to B0 case due to that the fuel contains 30% less carbon content in the combustible mixture to start with. Both NO and NOx levels are expressively lower in 30% hydrogen blend case (i.e. B30) compared to pure natural gas (i.e. B0). The ultra-lean combustion was successfully obtained for the hydrogen blend case using the burner's control unit by allowing more excess air (please see fig 1(e) and 1(f)), which further supports the reduction in combustion flue temperature (please see fig 1(g)). It is worth noting that the flow rate for hydrogen blend case mixture was higher compared to that of natural gas case to achieve the same power output. This finding is in consistent with experimental study from [4]. The performance characteristics of TMG module burner show that more comparative (if not higher) power output results can be obtained for hydrogen blend cases without any modification to the existing burner. Both the gross and net power output for 30% hydrogen blend cases were more advanced than natural gas. It is important to mention that much higher hydrogen blend cases (i.e. $\geq 50\%$ by vol.) impose combustion instability, thermal runaway, and flashbacks. A more control optimization for burner is required for flame initiation and self-sustained combustion. The higher mass diffusivity of hydrogen coupled with a higher mixture inflow rate tends to move combustible mixture away from the ignition point – leaving misfire and unsuccessful combustion. Hence the hydrogen blends with 50% by vol. results are not shown here because TMG module burner's control system was modified to accommodate higher hydrogen blend fuel to achieve the same performance output.

CONCLUSIONS

The current study presents an experimental investigation on hydrogen enriched natural gas combustion in an industrial burner for heat production applications. The TMG module burner from BMM heaters was used for the experiments. And emissions data were captured using a flue gas analyser and further verified with an ESS quadrupole mass spectrometer. The experimental study shows very promising results for accommodating hydrogen blend fuel for an industrial burner application. A recent report [7] on hydrogen blending and the gas commercial framework suggests that interim use of hydrogen blend is required before the commercial gas network is ready for 100% hydrogen. Moreover, this report shows that hydrogen blend up to 20% by vol. in the gas commercial framework can be demonstrated in the upcoming near future (early 2023) and the industrial burner market requires to be ready for such change. The main findings are listed below:

- B30 case shows two to three times reduction in CO, NO, and NOx emission as compared with 100% natural gas case.
- Consistent and comparative (if not more) power output can be achieved with a 30% hydrogen blend case without any modification to the existing burner.
- An ultra-lean and low emission combustion can be successfully initiated and self-sustained with a 30% hydrogen blend.
- The TMG module burner is well-suited and supports the UK government's plan for blending up to 20% hydrogen by vol into the existing gas network.

ABSTRACT

Electrodialysis (ED) is an efficient process that desalinates brackish and saline water under the influence of the electrical field. The ions that present inside a solution moves through ion exchange membranes to the adjacent compartments called concentrate compartment. The main purpose of the ED process is to desalinate brackish water; besides this, a valuable energy carrier gas, hydrogen is generated at the cathode side of the ED cell in this study. However, due to the internal recirculation of the electrolyte solution from anode to cathode compartment, hydrogen gas reacts with oxygen gas and reforms water. In this study, the potential of hydrogen gas generation in an ED system while treating saline/brackish water, is experimentally investigated. The ion removal efficiencies are 68% and 67% for combined and separated processes, respectively. The hydrogen production rates of the ED system are 2.42 and 3.28 mL/h.cm^2 for combined and separated processes, respectively.

Keywords: Cogeneration, Energy Carrier, Hydrogen, Ion-exchange Membrane, Seawater

INTRODUCTION

Water and energy are the most essential needs of the humanity. The energy and water demand increase by the increasing world population and urbanization, however the earth has limited natural sources. Available fresh water sources are getting polluted by human applications and getting depleted due to the insufficient precipitation triggered by the climate change. The main cause of the climate change is the increase of the burning of the carbon-based fossil fuels to generate energy. Also, the fossil fuels are getting depleted day by day thus, the usage of the alternative energy sources should be expanded for a more sustainable life. In this case, hydrogen gas, which is a crucial energy carrier, is an important alternative fuel. Recently, integrated processes that produce hydrogen gas from saline water has gained importance. Tufa et al. [1] have integrated reverse electrodialysis and alkaline polymer electrolyte water electrolysis to produce hydrogen gas. They have reported maximum hydrogen production rate as 50 mL/h.cm^2. Similar research has been conducted by Zhang et al. [2] by using serial reverse electrodialysis stacks for hydrogen production. They have reported the maximum hydrogen production rate of 2.652 mL/h.cm^2. On the other hand, in conventional electrodialysis process, hydrogen gas is also produced during desalination process of the saline water on the cathode electrode of the ED cell, however, mostly the catholyte solution recycled to the anode compartment. By this way, the pH, electrical conductivity, and the total dissolved solids concentration of the electrolyte solution remain same in the ED cell. However, this prevents collection of the hydrogen gas. In this study, the hydrogen gas that is generated in a conventional electrodialysis process has been collected by separating anolyte and catholyte solutions. The effects of the separated electrolyte solutions on the ED desalination efficiency and hydrogen production rate are examined.

MATERIALS AND METHODS

The conventional electrodialysis (ED) process has been set up as given in Fig. 1. The ED cell was supplied from PCCELL company from Germany (GmbH, 2021) [3]. The system was composed of three solution containers for the electrolyte, dilute, and concentrate solutions. Two peristaltic pumps with three mounted apparatus to circulate the solutions have been used. Electricity was supplied to the ED system by using Gamry Potentiostat “Interface 1000 E model 12016”, and two reference electrodes have been used to conduct the electrochemical analysis. During the running of ED process, hydrogen gas is generated at the cathode compartment. A volumetric cylinder has been used to collect the generated hydrogen gas. The hydrogen production rate was calculated according to the area of the electrodes. The area of the electrodes was 64 cm^2. The ED system is tested in batch mode and solutions are circulated until desired conductivity levels of the solutions are obtained.

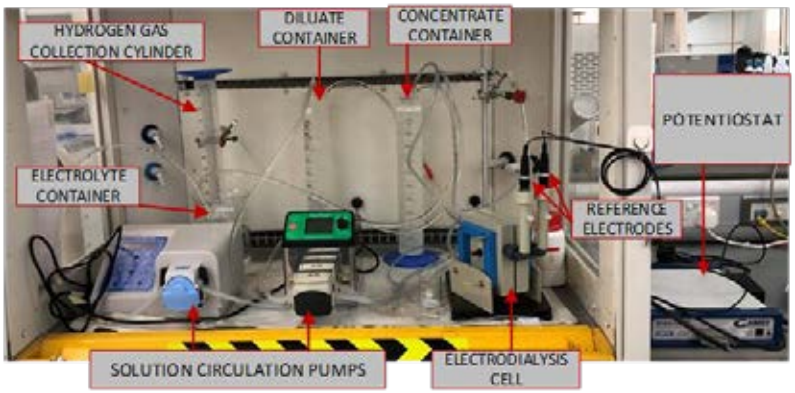

Fig. 1. Electrodialysis system setup.

Hydrogen gas has been collected during electrodialysis process in two different ways. First, anolyte and catholyte compartments have been separated. A graduated cylinder with gas vent has been utilized to collect H_2 gas. The tip of a curved piped was placed inside the cylinder from its open end as shown in Fig. 2. The effluent of the cathode compartment has been returned to the catholyte vessel by using this pipe. Here, the solution was pumped back to the cathode compartment while the hydrogen gas was rising inside the cylinder. The amount of the collected hydrogen gas was recorded in every 5 minutes.

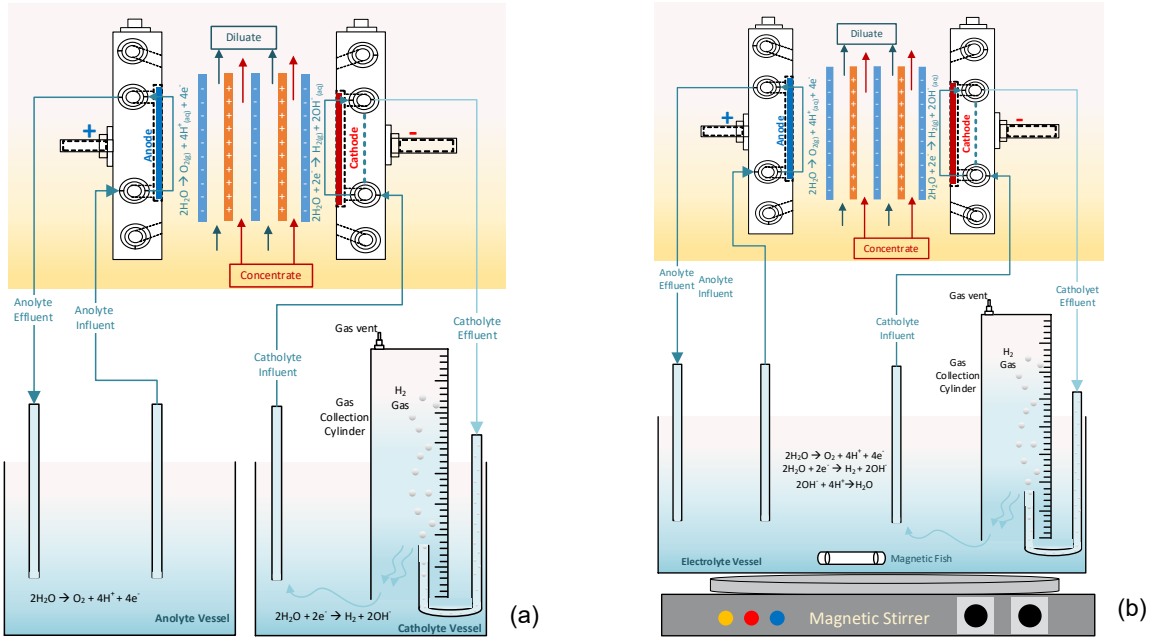

Fig. 2. Schematic representation of hydrogen gas collection alternatives. (a) Hydrogen gas is collected at separated catholyte vessel and (b) hydrogen gas is collected at combined anolyte and catholyte vessel.

RESULTS AND DISCUSSION

The saline waters with 21 and 14 mS/cm initial conductivity values are desalinated by using the ED process at batch mode. The results reflect that when the initial conductivity value of the saline water is higher, the resistance is getting lower and more current could pass through the ED system. The ion removal rates of the ED system can be compared by the slopes of the lines given in Fig. 3. (a) and (b). It is obvious that the ion removal rate is at its peak when the initial conductivity value of the saline water is 21 mS/cm. In addition, the ED process is run in two different modes (separated and combined anolyte and catholyte). The desalination time is adjusted as 60 min for 500 mL saline water to make comparison. The conductivity values of the dilute solutions reach to 7 and 4.3 mS/cm with separated and combined electrolyte solutions, respectively as given in Fig. 3. (a) and (b). The average power consumption of the ED cell is calculated as 4 kWh/m^3 according to Ohm's law. Nassrullah et al. [4] have reported energy requirement for seawater desalination as 2.58-8.5 kWh/m^3 by using different kinds of treatment processes and the required energy increases with increasing total dissolved solids (TDS) concentrations. The current densities of the ED cell show slight changes between 6.9 – 8.08 mA/cm^2 for separated electrolyte and 4.8-5.6 mA/cm^2 for the combined electrolyte solutions due to the change in the conductivity of the solutions (Fig. 3. (c)). Finally, the hydrogen production rates of

the ED process have been calculated as 3.28 and 2.42 mL/h.cm^2 for separated and combined electrolyte solutions, respectively. Since, the main problem of the application of ED process for desalination of high salinity waters is the power consumption and energy cost, the recovery of the energy as the hydrogen gas will lead to increase of the ED process for waters with high salinity.

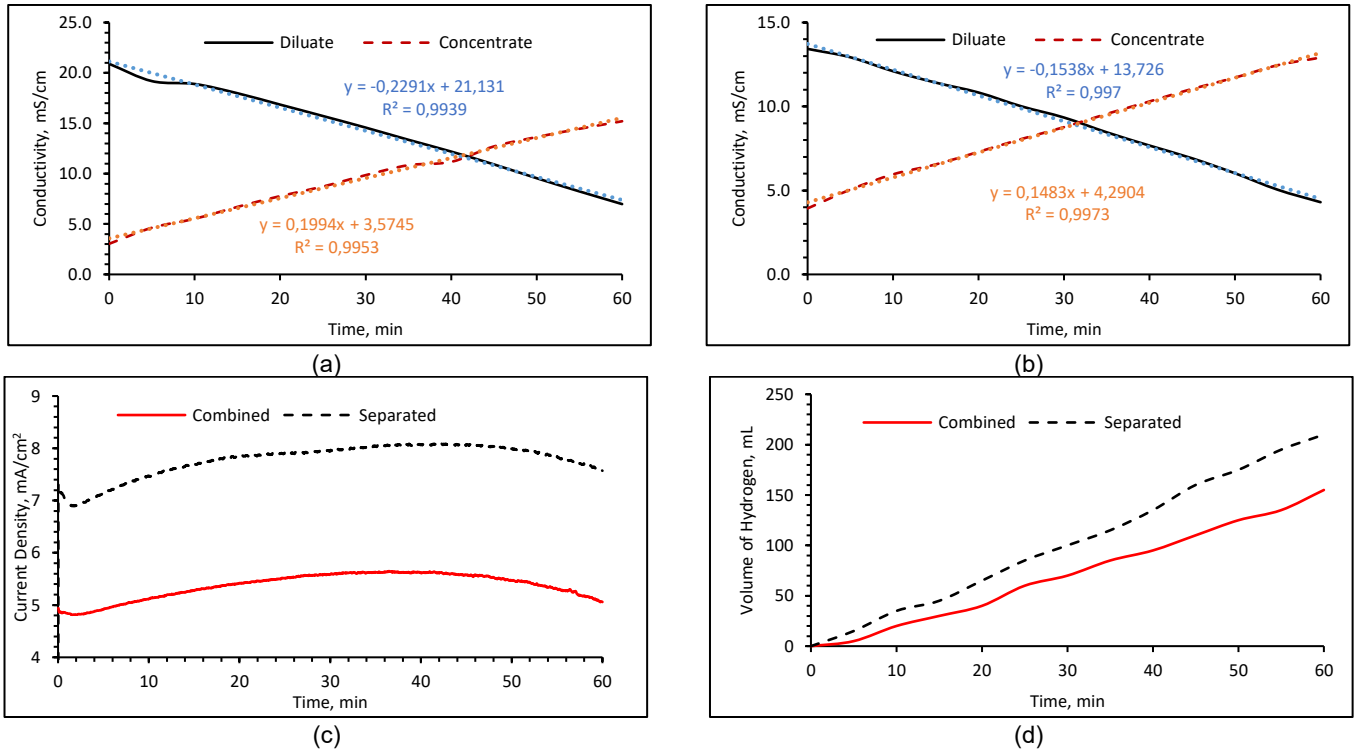

Fig. 3. Results of the desalination of the saline water by using the ED process (a) conductivity vs time graph “separated anolyte and catholyte”, (b) conductivity vs time graph “combined anolyte and catholyte”, (c) current density vs time graph, (d) volume of the hydrogen gas vs time graph.

CONCLUSIONS

The applicability of the recovery of the hydrogen gas generated during the desalination of saline waters by using the ED process is investigated. It is by separation of the anolyte and catholyte solutions in the ED process, the generated hydrogen gas can be collected from the ED system. The ion removal efficiencies are 68% and 67% for combined and separated processes, respectively. The hydrogen production rates of the ED system are 2.42 and 3.28 mL/h.cm^2 for combined and separated processes, respectively. The recovery of the hydrogen gas from the ED process may increase the ED applications for high salinity waters such as sea water.

ABSTRACT

Energy storage becomes a more critical issue for humanity to maintain a sustainable integration of renewable-based energy resources with the demand side. As an energy carrier, hydrogen can provide a large amount of energy storage with minimal loss over long periods. The current work focuses on designing and modeling a hybrid renewable energy-based system comprised of Photovoltaic (PV) cells, a battery bank, a PEM Electrolyzer for hydrogen generation, a compressor, and a pressurized hydrogen tank to meet the electricity demand of an off-grid house in Izmir. In the proposed system, solar energy was utilized to produce electricity through PV arrays. The produced energy was either used in the PEM electrolyzer for Hydrogen (H_2) production or stored in the batteries to meet the required energy during low solar radiation or nighttime. An energy management strategy was developed for the proposed hybrid system using the MATLAB software for carrying out the above-mentioned purposes. For the system component modeling, a one-dimensional mathematical approach was applied to investigate the dynamic behavior of the integrated system. The hydrogen generated by the electrolyzer was pressurized with a compressor and stored in pressure tanks at a pressure of 350 bar.

Keywords: PV, PEM electrolyzer, Energy management, Hydrogen storage.

INTRODUCTION

The dramatic increase in energy demand and the adverse environmental effect of fossil fuels in recent years have led some countries to meet their energy needs using alternative clean energy resources. Renewable energy resources such as wind, solar and geothermal are inexhaustible and harmless to the environment. In addition, these sources are intermittent and discontinuous energy sources due to hourly, daily, and seasonal differences. For this reason, it is necessary to store the energy to ensure the continuity of the energy obtained from these sources. When the demand is low, the energy produced is stored and used when the demand is high, allowing the existing resources to be used more effectively. Renewable energy coupled with energy storage will supply better system dependability, making it appropriate for off-grid applications as well [1]. Hydrogen produced by water electrolysis combined with solar energy creates an appealing energy pathway that can balance the intermittent nature of renewable energy resources as a storage medium and an energy carrier for electricity generation [2]. Previous research has mostly focused on improving solar electrolyzer technology for hydrogen generation, progressing hydrogen storage technology, lowering costs, assessing and optimizing off-grid hydrogen production, and hydrogen safety concerns. Toghyani et al. [3] investigated the performance of a hydrogen refueling system consisting of an integrated PEM electrolyzer with PV cells and a compressor to raise the hydrogen pressure. Nasser et al. [4] examined the use of wind turbines and PV cells in a hybrid renewable energy system for hydrogen generation and storage in various climatic conditions of five different Egyptian cities from a techno-economic perspective.

MATERIALS AND METHODS

Fig.1 shows the schematic representation of the PV-based hydrogen generation and storage system. After the power produced by the set of PV arrays supplies the dwelling's electricity needs, the remaining power is passed to the electrolyzer, decomposes water, and generates hydrogen and oxygen. When sufficient power cannot be supplied from the PV panels, lithium-ion batteries are used to meet the electricity needs of the house and to power the electrolyzer. The hydrogen produced by the PEM electrolyzer is sent to the compressor, the pressure is increased, and high-pressure hydrogen is stored in the tank. The design parameters of the integrated system used in this study are given in Table 1. Fig. 2 shows the annual solar radiation and electrical load profile for the province of İzmir.

RESULTS AND DISCUSSION

Mathematical modeling of the hybrid system consisting of PV solar panels, battery, PEM electrolyzer, compressor, and hydrogen storage tank was made in MATLAB software. Modeling of PV solar panel is taken from Ref. [5] work, and battery modeling is from Ref. [6] study. In addition, PEM electrolyzer modeling is taken from Ref. [7] study, and hydrogen storage tank from Ref. [8] study. ABSTRACT
In this study, a novel multigeneration energy system based Brayton cycle is designed to generate power, compressed hydrogen, heating, drying and fresh water. The multigeneration system consists of the Brayton cycle, regenerative Rankine cycle, s-CO_2 power cycle, t-CO_2 power cycle, hydrogen production and compression plant, fresh water production plant and drying plant. In the evaluation part, energy and exergy analyses have been performed with a parametric analysis. The overall power production capacity of the system has been found as 13029 kW, and hydrogen production rate is 0.0624 kg/s. According to the thermodynamic analysis results, the overall energy and exergy efficiencies of the plant are 55.62% and 51.28%.

Keywords: Hydrogen production, Brayton cycle, Multigeneration, Thermodynamic analysis, Energy, Exergy, Efficiency

INTRODUCTION
During past several decades, there have been increasing environmental concerns and energy supply issues where bring out a necessity for more efficient, more cost effective and more environmentally-sound solutions implemented in various sectors. There are numerous researchers concentrating on tri-generation or multigeneration systems because of their high efficiencies compared to single generation systems, recently [1]. Santiago et al. [2] have performed a thermodynamic analysis and optimization of a tri-generation system. The products are cooling, heating and power which are used in a medium-sized hospital. They have compared different combinations of the tri-generation system and as a result, they have found the best energy efficiency at 81% while exergy efficiency is 42%. Kerme et al. [3] have designed a solar energy-based poly-generation system. Numerous configurations and combinations in various viewpoints of the system have been evaluated. The results of the study reveal that solar thermal collector and desalination unit are two main exergy destruction sources. Also, they have found that the overall energetic improvement potential of the system is 64.8%.

In this study, a novel multigeneration system is designed using the Brayton cycle as a prime source of the system and producing power, compressed hydrogen, heating, drying and fresh water. The energy and exergy analyses supported by parametric analyses are performed in order to determine the system performance and how some parameters affect the system performance.

SYSTEM DESCRIPTION
In this multigeneration energy system design, the Brayton cycle, regenerative Rankine cycle, s-CO_2 power cycle, t-CO_2 cycle, hydrogen production and compression plant, multi-effect desalination unit and drying plant are used. Compressed air and fuel mix in the combustion chamber and drive the gas turbine to produce power. Then the heat energy of the turbine is transferred into the heat exchanger (HEX) 1. Here, the regenerative Rankine cycle produces power by using heat energy. The waste heat energy of the regenerative Rankine cycle goes to HEX 2 with stream 5. In this part of the multigeneration system, s-CO_2 and t-CO_2 power cycles produce power by using heat energy. On the other part of the system, sea water enters the multi-effect desalination unit with stream 30. Here brine is separated, produced fresh water is sent to either tank or PEM electrolyzer with stream 36. PEM electrolyzer separates the water into oxygen and hydrogen, and hydrogen is sent to hydrogen compressors' series. Then, compressed hydrogen is stored in the tank. Finally, air enters HEX 5 to gain heat energy and the hot air can be used in drying applications. The related design and working parameters of the multigeneration plant are presented in Table 1.

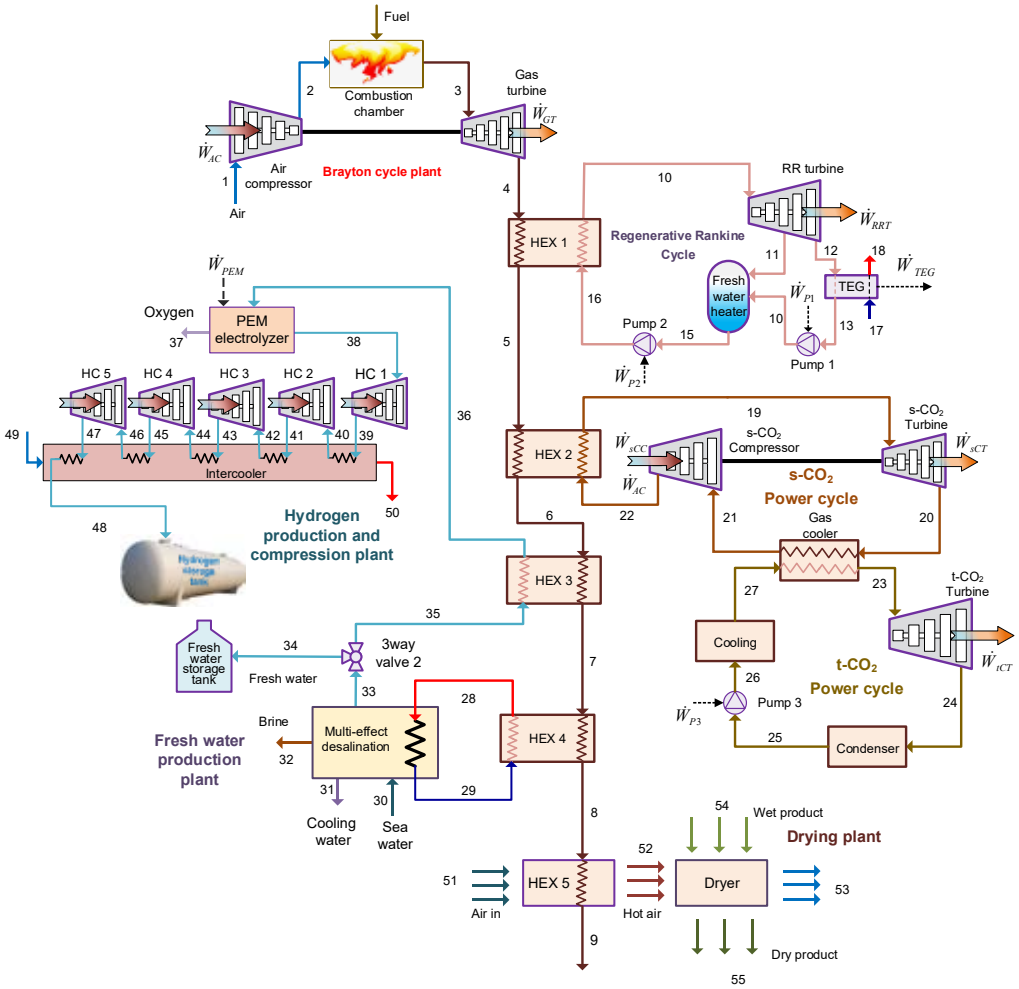

Figure 1. The schematic representation of the modeled multigeneration system

Table 1: Design and working parameters of the multigenerational plant.

Descriptions	**Values**
Ambient temperature, T_o	25°C
Ambient pressure, P_o	101.3 kPa
Isentropic efficiency of turbines	88%
Isentropic efficiency of pumps and compressors	85%
Combustion chamber temperature	890°C
Gas turbine inlet pressure	1500 kPa
RR turbine inlet temperature	356°C
RR turbine inlet pressure	4500 kPa
s-CO_2 turbine inlet temperature	237°C
s-CO_2 turbine inlet pressure	20000 kPa
t-CO_2 turbine inlet temperature	88°C
t-CO_2 turbine inlet pressure	20000 kPa
Mass flow of inlet air	23.5 kg/s

ANALYSIS

In this part, the thermodynamic analysis used to determine the system performance is described briefly. Calculations are made via EES software to determine energy and exergy efficiencies with exergy destruction rates of sub-plants and the overall plant. The general assumptions accepted for the calculations are listed as follows:

- A steady-state mechanism is assumed for the system units.
- The HEXs, pumps, and turbines are adiabatic.
- The changes in kinetic and potential exergetic terms are negligible.
- The reference temperature and pressure are constant (i.e., T_o=25°C and P_o=101.3 kPa)
- The ideal gas characteristics are chosen for air to make an assessment.
- The pressure losses are negligible.

To perform the thermodynamic assessment, the general mass, energy, entropy, and exergy balance equalities can be written as

$$\sum \dot{m}_i = \sum \dot{m}_e \quad (1)$$

$$\sum \dot{m}_i h_i + \sum \dot{Q}_i + \sum \dot{W}_i = \sum \dot{m}_e h_e + \sum \dot{Q}_e + \sum \dot{W}_e \quad (2)$$

$$\sum \dot{m}_i s_i + \sum \left(\frac{\dot{Q}}{T}\right)_i + \dot{S}_{gen} = \sum \dot{m}_e s_e + \sum \left(\frac{\dot{Q}}{T}\right)_e \quad (3)$$

$$\sum \dot{m}_i ex_i + \sum \dot{E}x_i^Q + \sum \dot{E}x_i^W = \sum \dot{m}_e ex_e + \sum \dot{E}x_e^Q + \sum \dot{E}x_e^W + \dot{E}x_d \quad (4)$$

where i and e show inlet and exit conditions, respectively, $\dot{Q}$ represents heat transfer rate, $\dot{W}$ is the work rate, s and h show entropy, and enthalpy, respectively, $\dot{m}$ is the mass flow rate, $\dot{S}_{gen}$ and $\dot{E}x_d$ show entropy generation and exergy destruction rate, respectively.

RESULTS AND DISCUSSION

The designed multigeneration plant has the capacity of producing 13029 kW power, 5132 kW heating, 4194 kW drying and hydrogen and fresh water production rates are 0.0624 kg/s and 16.53 kg/s. Thermodynamic analyses also reveal that energy and exergy efficiencies of sub-plants and the overall plant which are listed in Table 2. Also, parametric analyses show that as reference temperature increases from 0 °C to 40 °C, both energy and exergy efficiencies of sub-plants and the multigeneration plant increase. Another parameter investigated in this study is the air mass flow rate of the Brayton cycle altered from 21 kg/s to 25 kg/s. As air mass flow rate increases energy and exergy efficiencies of sub-plants and the overall plant increase.

Table 2. Energy and exergy efficiencies of sub-plants and the overall plant

Overall plant and sub-plants	η	ψ
Brayton cycle plant	0.4831	0.4498
Regenerative Rankine cycle	0.3283	0.2871
s-CO_2 power cycle	0.1718	0.1485
t-CO_2 power cycle	0.1325	0.1032
Fresh water production plant	0.4546	0.3893
Hydrogen production and compression plant	0.6938	0.6527
Drying plant	0.7416	0.6946
Overall plant	0.5662	0.5128

CONCLUSIONS

In this study, a novel Brayton cycle-based multigeneration system is designed and analyzed both thermodynamically and parametrically. The results of this study show that the overall energy and exergy efficiencies of the system are 55.62% and 51.28%. An increase in the reference temperature or the air mass flow rate has a positive impact on the hydrogen generation rate. Some key results of the study can be listed as follows:

- The lowest exergy efficiencies occur in t-CO_2 and s-CO_2 power cycles with 10.32% and 14.85%.
- The highest energy and exergy efficiencies belong to the drying plant with 74.16% and 69.46%.
- As the reference temperature goes up from 0 °C to 40 °C, the exergy efficiency of the overall plant increases from 48.07% to 53.31%.
- As the air mass flow rate increases from 21 kg/s to 25 kg/s, the overall exergy efficiency improves from 47.60% to 53.62%.

ABSTRACT

In this study, a novel compressed air energy storage-based combined plant for hydrogen production and other utilities is designed. Wind turbines and solar photovoltaic modules are the main drivers of the plant to compress the air. The multigeneration system is able to produce power, hydrogen, heating, and cooling. In the design step, each flow is enumerated and assigned thermodynamic balance equations. In order to evaluate the system performance, energy and exergy analyses are used. Then parametric analyses were performed in order to see the effects of the reference temperature and the charge-discharge pressure ratio. The study results show that the overall energy and exergy efficiencies of the multigeneration plant are 27.52% and 24.83%.

Keywords: Compressed air energy storage, Hydrogen production, Multigeneration, Energy, Exergy

INTRODUCTION

The increase in the world's population and the demand for more energy result in the depletion of fossil fuel reserves and environmental problems [1]. In order to overcome such problems, renewable energy sources such as solar, wind, biomass, and geothermal have been used in recent years [2]. Although solar and wind are good alternatives to meet the energy demand, their unstable and intermittent nature causes problems in their widespread use. One of the best ways to overcome such challenges is to use energy storage systems [3]. Ji et al. proposed a new hybrid wind-solar compressed air energy storage system. They have also integrated the organic Rankine cycle (ORC). Energy, exergy, and parametric sensitivity analyzes were performed for the proposed system. They showed that an increase in ambient temperature has a negative effect on system performance, while an increase in turbine inlet temperature has a positive effect [4]. Another study by Alirahmi et al. proposes an integrated system that offers a combination of compressed air energy storage with solar heliostat and multi-effect thermal vapor compression desalination units providing power and clean water. By performing energy, exergy, and exergoeconomic analyzes for the whole system, round-trip efficiency and total cost rate were calculated as 48.7% and 3056 $/hr, under the optimum conditions, respectively [5]. Another study emphasizing that the energy sector can be converted from fossil fuel to renewable energy sources and that energy can be used effectively with compressed air energy storage (CAES) systems was conducted by Xia et al. [6]. The literature clearly shows the importance of stored energy from intermittent renewable sources such as wind and sun. This proposed system is a new integrated system that air energy storage for electricity and hydrogen production from renewable energy sources. This study aims to evaluate the performance of the air storage system associated with power and hydrogen production from solar and wind from a thermodynamic point of view.

SYSTEM DEFINITION

The air heated by the energy obtained from the sun (PV modules) and the wind is passed through a three-stage compressor and sent to the air cave, and the compressed air storage cycle is completed (streams 1-7). The air entering the HEX 2 by stream 8 is included in the power production process. The air out of the Hex 2 passes through the high-mid-low heaters, and then the high-medium-low pressure air generates power in the turbines, respectively. The oil from stream 41 is used in the single-acting absorption refrigeration cycle to create a cooling effect. On the other hand, the water heated in HEX1 is sent to the PEM electrolyzer by stream 59. Here, water is decomposed into oxygen and hydrogen. While the oxygen is sent to be used in the health sector, the hydrogen is sent to the hydrogen liquefaction facility to liquefy. Some of the produced hydrogen passed through the heat exchangers is sent to the storage tank. The remainder is passed through the helium turbo expander to generate power. Thus, the integrated system cycle is completed.

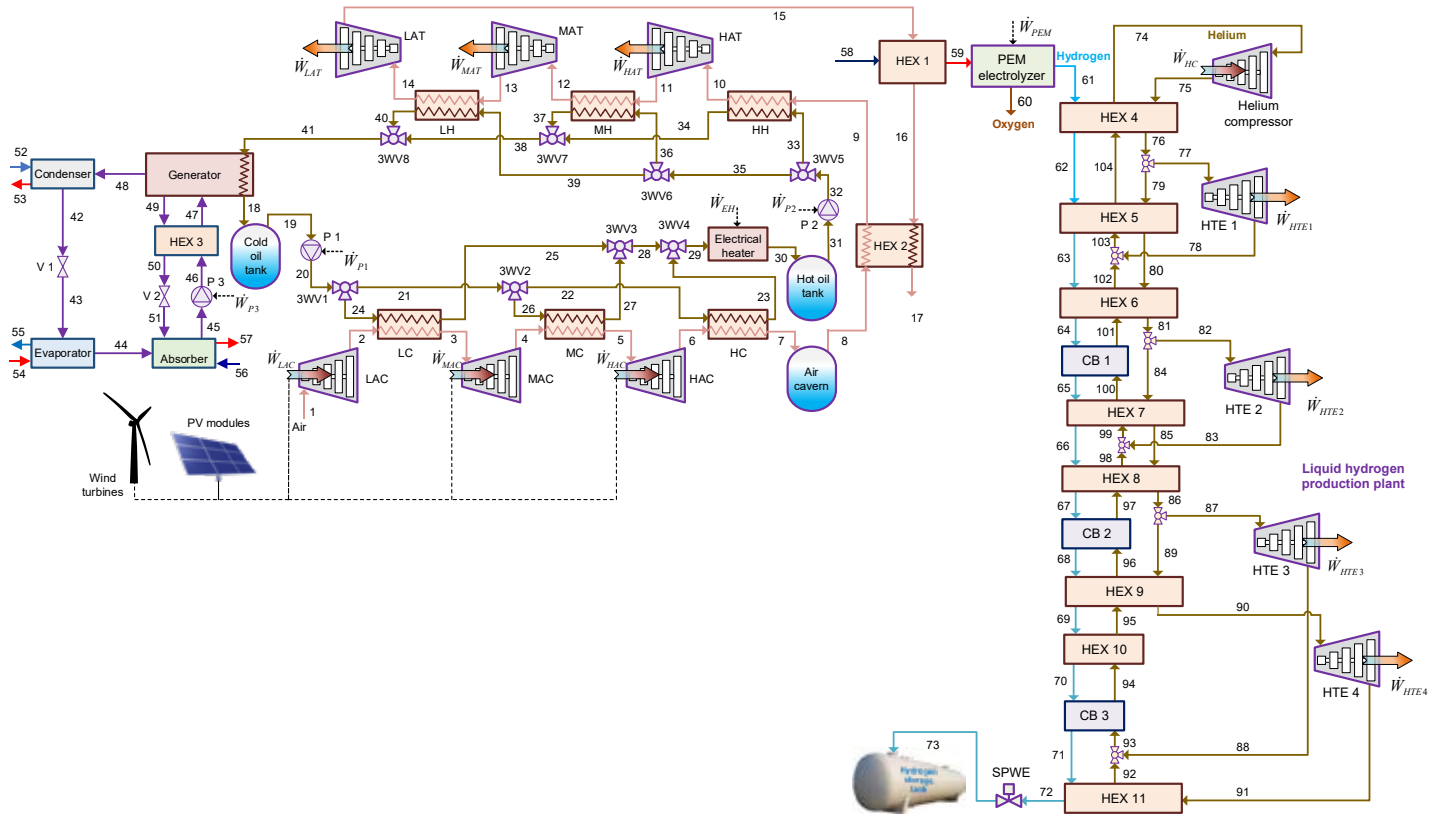

Fig. 1. Schematic diagram of the combined plant for compressed hydrogen production

THERMODYNAMIC ANALYSIS

In this subpart, the thermodynamical assessment utilized to determine the plant's effectiveness is defined briefly. View-points are analyzed using the Engineering Equation Solver (EES) program to determine energetic and exergetic performances with exergy destruction rates of the combined plant and its sub-plants. The general assumptions can be defined with:

- Steady-state and steady-flow mechanisms are assumed.
- The HEXs, compressors, pumps, and turbines are adiabatic.
- Kinetic and potential energy and exergy terms are neglected.
- The reference temperature and pressure are taken as 25°C and 101.3 kPa, respectively.
- The ideal gas characteristics are chosen for air to make an assessment.
- The pressure losses for connections and components are negligible.

To perform the thermodynamical analysis, the general mass, energy, entropy, and exergy balance equalities are written as given below;

$$\sum \dot{m}_i = \sum \dot{m}_e \tag{1}$$

$$\sum \dot{m}_i h_i + \sum \dot{Q}_i + \sum \dot{W}_i = \sum \dot{m}_e h_e + \sum \dot{Q}_e + \sum \dot{W}_e \tag{2}$$

$$\sum \dot{m}_i s_i + \sum \left(\frac{\dot{Q}}{T}\right)_i + \dot{S}_{gen} = \sum \dot{m}_e s_e + \sum \left(\frac{\dot{Q}}{T}\right)_e \tag{3}$$

$$\sum \dot{m}_i ex_i + \sum \dot{E}x_i^Q + \sum \dot{E}x_i^W = \sum \dot{m}_e ex_e + \sum \dot{E}x_e^Q + \sum \dot{E}x_e^W + \dot{E}x_D \tag{4}$$

where i and e give the inlet and exit conditions, respectively, $\dot{Q}$ shows the heat transfer rate, $\dot{W}$ illustrates the work rate, s and h are the specific entropy and enthalpy, respectively, $\dot{m}$ shows the mass flow rate, $\dot{S}_{gen}$ and $\dot{E}x_D$ are the entropy generation and exergy destruction rate, respectively.

RESULTS AND DISCUSSION

In this part of the study, the thermodynamic and parametric analysis results are presented. According to the findings, the multigeneration plant's overall energy and exergy efficiency are 27.52% and 24.83. Energy and exergy efficiencies of other sub-plants are listed in Table 1.

Table 1. Energy and exergy efficiencies of the multigeneration plant and its sub-systems

Overall plant and its sub-plants	η	ψ	$\dot{E}x_D$ (kW)
Compressed air storage plant	0.4554	0.4187	13839
Power production plant	0.3474	0.3196	8721
Hydrogen production and liquefaction plant	0.5827	0.5154	794
Cooling plant	0.2306	0.1935	1023
Overall plant	0.2752	0.2483	24377

On the other hand, the heating, cooling, and hydrogen amounts are 1921 kW, 1183 kW, and 0.0513 kg/s, respectively. Parametric analyses reveal that as the reference temperature increases from 0 to 50 °C, the energy efficiencies of sub-plants, except for the cooling plant, increase. For this increase in the reference temperature, the overall energy efficiency goes up from 26.31% to 28.78%. As focused on the exergy efficiencies, a similar trend with the energy efficiency can be seen. The overall exergy efficiency increases from 23.51% to 26.23% as the reference temperature increases.

Additionally, an increase in the reference temperature from 0 to 50 °C has a positive impact on the hydrogen production such that it improves from 0.0474 kg/s to 0.0555 kg/s while the exergy destruction rate of the multigeneration plant decreases. The second parameter investigated in this study is the charge-discharge pressure ratio from 1.2 to 2. When the charge-discharge ratio increases from 1.2 to 2, the energy efficiencies of sub-systems and the multigeneration system improve. Similarly, the exergy efficiencies of sub-plants and the overall plant increase as the charge-discharge pressure ratio increases. This parameter change increases the overall exergy efficiency from 24.24% to 25.63%.

CONCLUSIONS

In this study, a novel design is done with a multigenerational aim using compressed air storage. Thermodynamic and parametric analyses are performed to evaluate the multigeneration system's efficiencies. According to the results, the hydrogen production and liquefaction plant operate with the best efficiency among other sub-systems. Other concluding remarks are as follows:

- The highest exergy destruction rate occurs in the compressed air storage plant with 13839 kW.
- The energy and exergy efficiencies of the power production plant are 34.74% and 31.96%.
- The increase in the reference temperature positively impacts the sub-plants efficiencies except for the cooling plant.
- The overall energy and exergy efficiencies improve as the charge-discharge pressure ratio increases from 1.2 to 2.

ABSTRACT

Fuel cell vehicles' low environmental impacts, current technological advancements, and commercial manufacturing have opened the path to their employment in a variety of areas. The usage of fuel cell technology in marine transport has increased as the International Maritime Organization's (IMO) environmental regulations have been tightened. A simulation of a fuel cell propulsion system for use on boats is constructed in this study. A fuel cell, a metal hydride hydrogen tank, a battery pack, and an electric motor are represented as part of the system. The speed-power curve of the hull is obtained for the design draft using a computational fluid dynamics tool. The field data from the ongoing project are used to verify this system model.

Keywords: PEMFC, System Simulation, Recreational Boat, Fuel Cell Vehicles, CFD

INTRODUCTION

The marine transportation volume is growing at a rapid pace with the advancement of technology and the growth of the population. The number of ships in the oceans and, accordingly, the pollution in the seas have increased significantly. Shipping accounts for 3% of worldwide CO_2 emissions, according to the International Maritime Organization (IMO), with that percentage anticipated to climb up to 6% by 2050 [1]. As a result, ship transportation regulations have been strengthened. Following the tightening of regulations, efforts have been undertaken to reduce emissions in maritime transportation. One of them is to use fuel cells to meet the shipboard power requirements.

Because of the high cost of the fuel cell systems, it is important to understand the performance of the fuel cell vehicle with an accurate model. There are several studies on the fuel cell maritime vehicle system model. Honn-Choi et al. [2] developed and installed a hybrid proton exchange membrane fuel cell (PEMFC)/battery system for a 20-meter tourist boat with an output power of approximately 85 kW and a speed of 6.6-7.8 knots. Rivarolo et al. [3] compared the energy efficiency, CO_2 emissions, and other fuels for the fuel cell system to be used in a ferry. Software was created at the University of Genoa to study the design and cost of a 200-passenger capacity ferry operating on the artificial lake of Itaipu. Boudjabar and Khooban [4] suggested a zero-emission hybrid fuel cell/battery/cold-ironing system and used real data from a ferry to examine hull design and energy resources. Balestra and Schjolber [5] created a simulation tool that evaluates a user-selected configuration in a battery and fuel cell power plant for marine applications that can produce the electricity required by the energy management system realistically. Dall'Armi et al. [6] carried out simulations using different types of compressed hydrogen storage tanks (Type 1,3,4) to analyze the peak shaving point of the low temperature (LT)-PEMFC/battery system used for propulsion of a small-sized RoRo vehicle and passenger ferry.

In this study, the mathematical model of a 5.6-meters recreational boat with a hybrid PEMFC/battery system was modeled using the MATLAB/Simulink software in an ongoing project. The required engine power equation was deployed to the simulation as a velocity-power curve by curve fitting method using the gathered results from the computational fluid dynamics (CFD) tool. The batteries supply the boat's primary propulsion power. The fuel cell is used to charge the batteries as a range-extender. A Horizon H1000XP PEMFC with 1 kW rated power output and two pouch-type lithium-ion batteries with 3.3 kWh energy capacity produced by Farasis were selected. Two different configurations of the boat's propulsion system were evaluated at various service speeds, acceleration times, and ranges to find an optimized service speed versus energy consumption.

MATHEMATICAL MODEL AND SYSTEM DESCRIPTION

Assumptions

- Acceleration and deceleration rates were considered equal.
- The overall delivered efficiency (losses such as propeller and electric motor) was assumed to be 50%.

- The Froude number was assumed to be at most 0.4, due to the displacement type boat, even keel, and calm water condition.
- The batteries were operated between 20 - 80% state of charge (SoC).
- The electric motor efficiency was assumed to be 90%.
- The DC/DC converter efficiency was assumed to be 95%.
- The SoC of batteries and the battery efficiency were initially accepted as 100% and 92%, respectively.
- It was assumed that the fuel cell is constantly operating at its most efficient power point (500 W - 56.82%).
- The fuel cell was added to the system as a range extender.

The mathematical modeling of the ship was conducted in MATLAB/Simulink environment. The model includes three subsystems, which are a fuel cell model, a vehicle dynamic model, and a battery model. The design parameters of the battery, fuel cell, and boat are given in Table 1.

Table 1. Design Parameters of the Boat

Battery Parameters	***Values***	***Fuel cell Parameters***	***Values***	***Boat Parameters***	***Values***
Nominal Voltage	51.1 [V]	Voltage	30 [V]	Length	5.6 [m]
Rated energy	3.3 [kWh]	Current	0- 33.5 [A]	Beam	1.76 [m]
Weight	18 [kg]	Weight	7 [kg]	Hull Weight	500 [kg]
Energy Density	183 [Wh/kg]	Number of Cell	50 [-]	Design Draft	0.475 [m]
Cell Configurations	14S2P	Rated Power	1,100 [W]	Design Service Speed	5.5 [knot]
Dimensions (W x H x L)	168 mm x 248 mm x 200 mm	Max. Efficiency	0.56	Length of Water Line	5.1 [m]

Fuel Cell Subsystem

The fuel cell model was deployed as a subsystem to Simulink by integrating the data from the manufacturer's datasheet to the simulation environment as 1-D lookup tables for the H1000XP fuel cell [7]. The net power of the fuel cell system was calculated as follows,

$$P_{net} = P_{fc} - P_{BoP} \quad (1)$$

where P_{fc} is the fuel cell power and P_{BoP} is the power of the balance of plant components. MyH2 7000 was chosen as the onboard storage tank (produced by H2planet), which has more energy storage capacity per unit weight than the battery [8]. The specifications of the metal hydride (MH) tank are given in Table 2.

Table 2. Specifications of the MyH2 7000 [8]

Weight (kg)	**External Volume (liters)**	**Refilling Pressure (bar)**	**Max. Pressure (bar)**	**Storage Capacity (liters)**	**Energy Consumption (Wh/kg)**
47	16.7	5-12	30	7,000	218.67

Vehicle Dynamic Subsystem

The boat's power requirements are given as inputs to the model. The third order speed-power curve equation was obtained based on the design draft of the boat on a particular route (8.8 km, Urla-Izmir) using the results of the CFD at different service speeds corresponding to Froude numbers between 0.25 to 0.4.

The boat was designed to carry safely a total of 1,500 kg with four passengers. According to the Froude number of 0.4, which is critical for the boat's effective cruising, the boat's service speed was selected as 1.769 m/s [9]. Using multiple speeds (1.769, 1.9455, 2.122, 2.2985, 2.475, 2.6515, 2.828 m/s) and varied fixed acceleration values, the best cruising speed and acceleration time with the least amount of travel time and energy usage were obtained using multi-criteria decision-making method with TOPSIS (Technique for Order of Preference by Similarity to Ideal Solution). Ten associated academicians and boat owners were interviewed about the weighting criteria utilized in this procedure, and the average of their responses was obtained as 0.73 for energy usage and 0.27 for cruising time.

Battery Model Subsystem

In the model, the batteries are planned to provide the main propulsion power. The characteristics of the batteries to be used are given in Table 1. Battery current and power are calculated by Equations (2) and (3).

$$I_{battery} = {V_{OCV} - \sqrt{V_{OCV}^2 - 4 \cdot R_{int} \cdot P_{load}}}\Big/{2 \cdot R_{int}} \quad (2)$$

$$P_{battery} = I_{battery} \cdot V_{OCV} \quad (3)$$

where V_{OCV} is the open-circuit voltage (V), R_{int} is the internal resistance of the battery, and P_{load} is the power required by the electric motor.

RESULTS AND DISCUSSION

After applying the curve fitting tool of MATLAB, the power equation was obtained as:

$$P = 83.573 \cdot V^4 - 137.54 \cdot V^3 - 26.365 \cdot V^2 + 185.72 \cdot V \quad (3)$$

TOPSIS multi-criteria decision-making method was applied to find an optimum value for speed by using a weighting factor between acceleration time and service time. Some of the findings were given in Table 3 to give a better understanding. It can be seen that scenarios with high service speeds have worst ranks in the TOPSIS ranking according to the specified weight factors of 0.73 for energy usage and 0.27 for cruising time. The results in Table 3 were derived based on the boat's only one round (roundtrip) on the selected route. Except for the first two instances when the service speed is low, a short acceleration time has a negative impact on the TOPSIS result since it generates higher energy consumption and has a limited effect on the entire cruise duration.

Table 3. Pre-Design Calculations for the Ship Power and Energy Requirements

Service Speed [m/s]	Power @ Service Speed [W]	Acceleration Time [s]	Total Time [s]	Required Energy [kWh]	Rank from TOPSIS
1.8	303	30	5049	0.4218	1
		5010	10029	0.3072	1210
1.9	446	30	4594	0.5640	906
		4560	9124	0.3391	1013
2.1	656	30	4214	0.7560	1654
		4180	8364	0.3905	802
2.3	950	30	3893	1.0152	2090
		3860	7723	0.4642	945
2.5	1349	30	3617	1.3377	2420
		3580	7167	0.5634	1259
2.7	1874	30	3379	1.7341	2639
		3340	6689	0.6908	1553
2.8	2549.	30	3170	2.2106	2753
		3140	6290	0.8513	1838

The significant constraint of a boat design is the weight consideration. The desired passenger capacity of the boat has been planned as four passengers. The load capacity that the boat can carry in the design draft was found to be 1,500 kilograms. In the absence of a fuel cell, MH tanks, and batteries, the total weight of the lightship and equipment was calculated as 1,164 kilograms. Accordingly, the weight limitation for the fuel cell and batteries was determined as 336 kilograms. In Figure 1, the cost and range of the vehicle for different situations were given. The battery-only (with 18 batteries), fuel cell-only (with 7 MH tanks), and 6 different hybrid systems as Case 1 (15 batteries and 1 MH tank), Case 2 (12 batteries and 2 MH tanks), Case 3 (10 batteries and 3 MH tanks), Case 4 (7 batteries and 4 MH tanks), Case 5 (5 batteries and 5 MH tanks) and Case 6 (2 batteries and 6 MH tanks) were determined according to weight limitations. When the system is dimensioned according to the weight limitations, it can be seen that the fuel cell-only case yields the longest range. In the cost analysis, the battery-only case gave the lowest cost. In hybrid cases, it can be seen that while the MH tank number increases, the range of the boat increases. In this case, the fuel cell-only situation is the most advantageous case. It was shown that the best case among hybrid systems is Case 6.

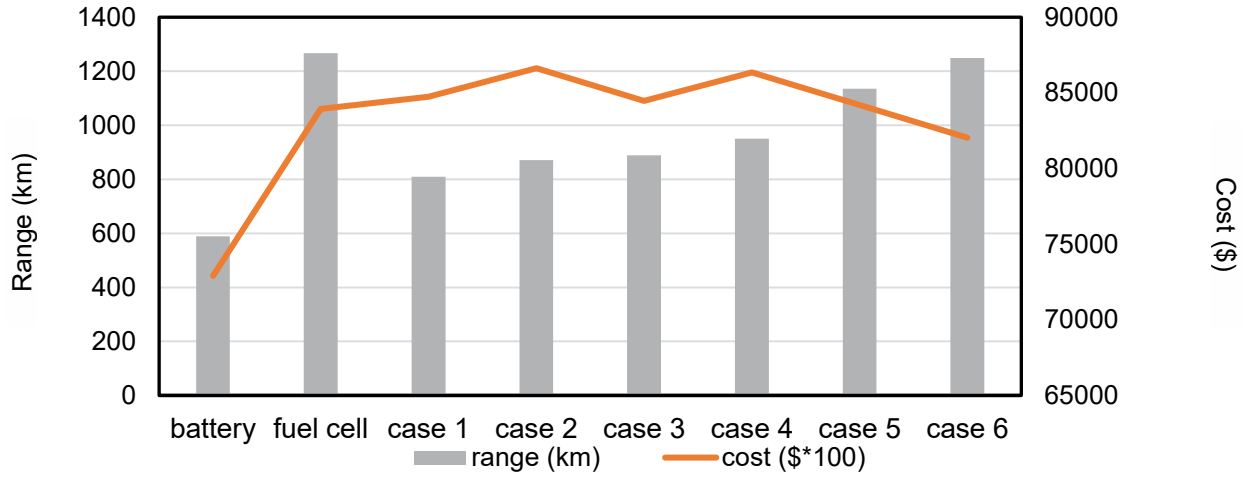

Fig. 1. Range and cost analysis for different cases

CONCLUSION

In this study, using the CFD method, a speed-power curve was obtained for four different service speeds of the boat at the design draft. By using this curve, the power values required by the boat were obtained on the route determined. Service times and total energy consumption were calculated by using different acceleration time values for the same cruise speed and the same acceleration time values for different service speeds. The best acceleration time (30 s) and service speed (1.769 m/s) values were determined with the multi-criteria decision-making method with TOPSIS using the obtained cruise times and energy consumption amounts. These values were simulated for different scenarios in the system model created with MATLAB/Simulink. Considering the weight constraint, range and cost analyzes were carried out. As a result, it was observed that only the fuel cell situation gave the longest range, and the cost of Case 6 was found minimum.

ABSTRACT

In this study, a mathematical model is developed for an integrated downdraft biomass gasifier and solid oxide fuel cell (SOFC) system. The models for the SOFC as well as the other components are developed in Matlab environment. Regarding the mathematical modelling, energy and exergy analyses are conducted to assess the system's performance. Then thermo-economic analysis is performed in order to find the electricity production cost. After that, a multi-objective optimization study using TOPSIS method is conducted in order to find the optimum operating conditions.

Keywords: *Thermo-economic analysis, Biomass Gasifier, Solid Oxide Fuel Cells, Multi-Objective Optimization*

INTRODUCTION

Recently, energy demand has increased as a result of the increasing population and developing technology. In the coming years, it is predicted that fossil energy resources will be insufficient compared to the population. This situation has created the need for alternative energy resources. One of these resources is biomass, which is made up primarily of carbon-based materials and organic chemical combinations. Some examples of biomass can be listed as rice husk, wood chips, agricultural waste, and municipal solid waste [1]. One of the methods used to convert biomass into usable energy is gasification. Gasification is one of the processes for turning biomass into useable energy. Biomass is fed into the gasifier with air, oxygen, or steam, and then transformed into syngas via a thermochemical process. Updraft and downdraft gasifiers are the most typical fixed bed gasifiers. As both the biomass and the air move downstream in the downdraft gasifier, the biomass is fed from above and the syngas generated leaves from the bottom. The biomass is still fed from above in an updraft gasifier, but the biomass moves downwards, the supplied air goes upwards, and the produced syngas leaves from the top of the gasifier. The gasification process is divided into four steps. In the downdraft gasifier, the biomass is first fed to the dryer (>150°C) in order to reduce its moisture content. Then, in the pyrolysis step (between 200°C and 500°C), dry biomass is separated into components such as coal, and. During the oxidation process (between 700°C and 1500°C), carbon dioxide and water are produced as a result of the reactions with oxygen. The reduction process takes place in the absence of oxygen, under high temperatures (between 650°C and 900°C) and syngas is formed [2].

Solid oxide fuel cells (SOFCs) are thermochemical systems that operate at high temperatures (800-1000℃). Solid oxide fuel cells are made up of two electrodes which are separated by a ceramic electrolyte. The oxygen fed from the cathode chamber is reduced to the oxygen ion. In the anode chamber, on the other hand, hydrogen combines with the oxygen ions coming from the cathode chamber and electrons from the external load, and water is released [3].

Evaluations of integrated systems on an economic basis can be evaluated by calculating some economic indicators such as the cost of useful products over the active life of the facility and the payback period. Thermo-economic and techno-economic analysis methods are generally used in the cost analysis of these systems. In this study, energy and exergy analyses are conducted to find the state properties and the component's irreversibilities, respectively. After that, thermoeconomic analysis is used to calculate the operating cost of the system and to make economic improvements in the system. Finally, a multi-objective optimization (using TOPSIS method) is used to find the optimum operating parameters of the integrated system.

MATERIAL AND METHOD

In this study, thermo-economic analysis of a hybrid system as shown in Fig. 1, which consists of a downdraft biomass gasifier, a SOFC, an afterburner, and heat exchangers was investigated. Firstly, energy balance equation (Eq. (1)) is applied in order to find the state properties. Then, exergy balance equation (Eq. (2)) is used to find the flow exergies of each states and irreversibilities of system's components. After applying the energy and exergy balances, the cost of exergy flows for each

component k^{th} is calculated. The general equation used for thermo-economic analysis is written as Eq. (3) shown below. Details of the equations used for economic analysis can be found in the literature [4]. By means of these equations, the effect of the gasifier temperature and power produced by the SOFC on the cost of the electricity produced was examined and a parametric study was carried out via MATLAB.

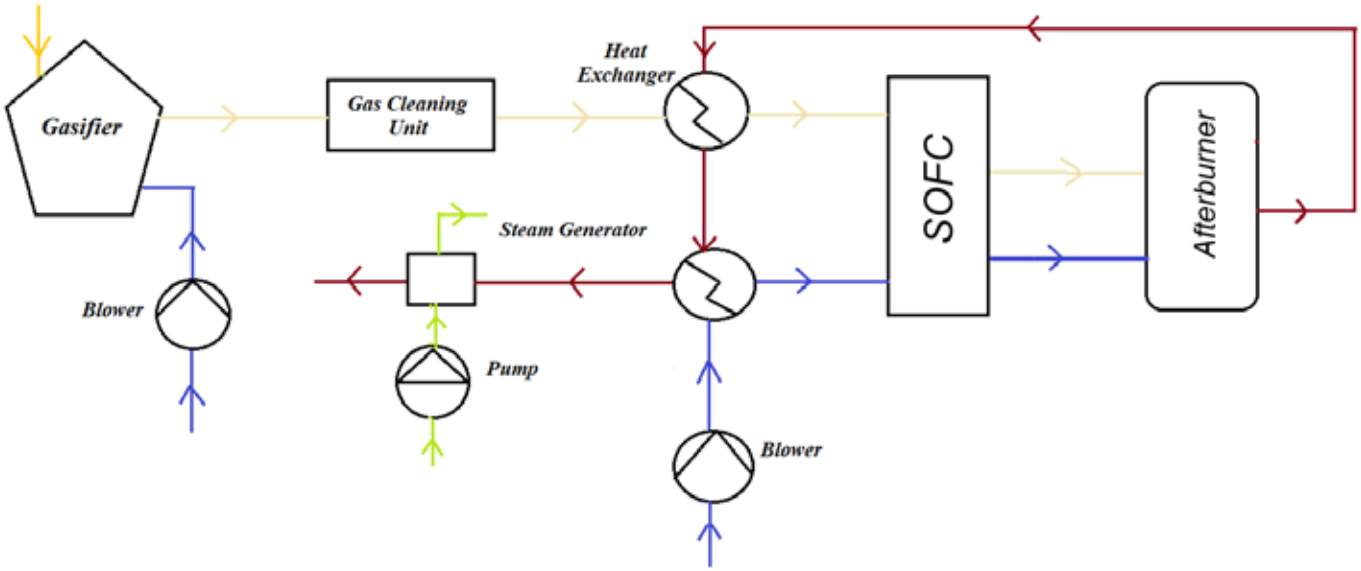

Fig. 1. The schematic of the integrated down-draft biomass gasifier and SOFC system

$$0 = \dot{Q} - \dot{W} + \sum_i(\dot{n}_i \cdot \bar{h}_i) - \sum_e(\dot{n}_e \cdot \bar{h}_e) \quad (1)$$

$$0 = \dot{E}x_Q - \dot{E}x_W + \sum_i \dot{n}_i \cdot (\bar{e}_{f,i}{}^{PH} + \bar{e}_{f,i}{}^{CH}) - \sum_e(\bar{e}_{f,i}{}^{PH} + \bar{e}_{f,i}{}^{CH}) - \dot{E}x_D \quad (2)$$

$$\sum \dot{C}_{out,\ k} + \dot{C}_{W,\ k} = \sum \dot{C}_{in,k} + \dot{C}_{q,\ k} + \dot{Z}_k \quad (3)$$

After finding the thermodynamic and thermo-economic performance parameters, an optimization study using TOPSIS method is carried out to find the optimal operating conditions for the system studied. The main equations used this method are presented as follows.

$$r_{i,j} = \frac{a_{i,j}}{\sqrt{\sum_{k=1}^{m} a_{k,j}{}^2}} \quad (4)$$

$$S_i{}^+ = \sqrt{\sum_{j=1}^{n}(v_{i,j} - v_j{}^+)^2} \quad (5)$$

$$S_i{}^- = \sqrt{\sum_{j=1}^{n}(v_{i,j} - v_j{}^-)^2} \quad (6)$$

$$C_i{}^* = \frac{S_i{}^-}{(S_i{}^+ - S_i{}^-)} \quad (7)$$

Regarding the optimization study, the range for operating parameters are given as follows. The aim of optimization study is to maximize the exergy efficiency and the fuel utilization efficiency and to minimize the cost of produced electricity.

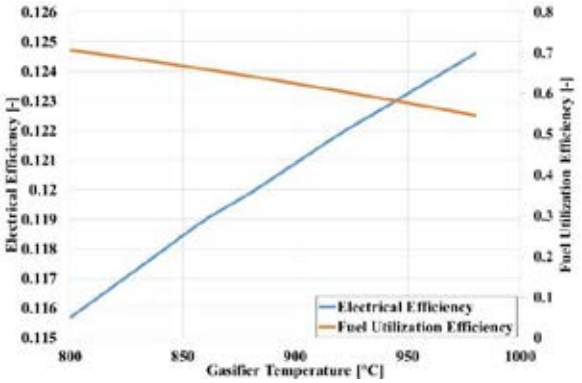
Table 1. Parameter ranges for the optimization study

Parameter Name	Range
Gasifier Temperature	800°C - 940°C
SOFC Power	10 kW – 100 kW

RESULTS AND DISCUSSION

In this section, the results derived from the study are presented and discussed. Fig. 2 shows that the effect of gasifier temperature on the electrical efficiency and fuel utilization. As the gasifier temperature increases, the electrical efficiency increases. This trend mainly due to the slightly increase of net power output of the integrated system. On the other hand, when the gasifier temperature increases, the fuel utilization efficiency decreases due to the decrease

of useful heat from the steam. In addition, it can be observed that if the gasifier temperature increases from 800°C to 980°C, the electrical efficiency decreased by 7.69%; whereas FUE decreased by 22.5%.



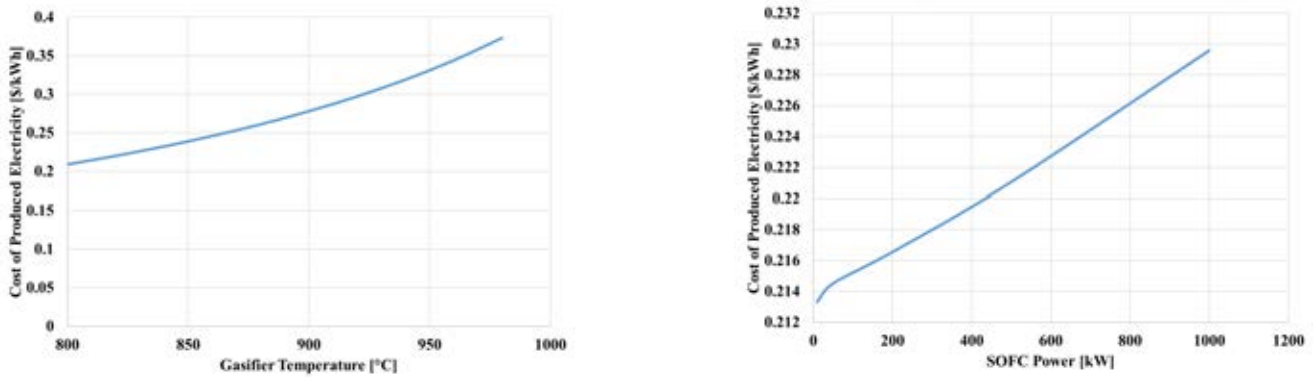


Fig. 2. The effect of gasifier temperature on the electrical efficiency (left axis), and fuel utilization efficiency (right axis).

Fig. 3(a) illustrates the effect of gasifier temperature on the cost of produced electricity of the system. As the gasifier temperature increases, the cost of power produced increases. Fig. 3(b) shows the effect of number of SOFC stack on the electricity cost. As the number of stack increases, the electricity cost increases. However, it should be noted that this parameter could be optimized in order to increase the system's performance and decrease the cost.

(a) (b)

Fig. 3. (a) The effect of gasifier temperature on the cost of produced electricity of the system. (b) The effect of the number of SOFC stack on the cost of produced electricity.

Table 2 shows that the results for optimization study. For the analysis, the weighting factor for the performance parameters are taken as 25% for the exergy efficiency, 25% for the fuel utilization efficiency, and 50% for the cost of power produced.

Table 2. Results of the optimization study

Gasifier Temperature (°C)	Power of SOFC (kW)	Exergy Efficiency	Fuel Utilization Efficiency	Cost of Power Produced ($/kWh)	Rank
800	99	0.225536	0.411	0.171	1
800	92	0.225567	0.398	0.170	2
800	95	0.225341	0.395	0.175	3

CONCLUSION

In this study, thermodynamic and thermo-economic analyses of a biomass gasifier integrated with solid oxide fuel cell was conducted in order to assess the performance in terms of thermodynamic and economic point of view. Then, a multi-objective optimization using TOPSIS method was performed to indicate the optimum operating parameters. The results derived from the study conducted are listed as follows.

- As the gasifier temperature increases, electrical efficiency increases. However, the fuel utilization efficiency decreases.

- As the gasifier temperature increases, the cost of electricity increases.
- In order to assess the system's performance in terms of environmental point of view, as the gasifier temperature increases, the rate of CO_2 impact keeps stable.
- As the number of stack increases, the electricity produced cost increases. However, this parameter should be optimized in order to reduce the electricity cost.
- The optimization study results show that when the gasifier temperature 800°C, the SOFC power is 99 kW, the exergy efficiency, the FUE, and the cost of power produced are found as 22.55%, 41.1%, and 0.171 $/kWh, respectively.

ABSTRACT

In this study, exergetic sustainability indicators of solar methane cracking for hydrogen production have been analysed. For this purpose, solar methane cracking system is considered a cleaner process for production of hydrogen fuel from natural gas. To evaluate the system comprehensively, a detailed exergy analysis is performed, and indicators based on exergetic sustainability are defined and calculated. The system has an exergy efficiency of 53% and a recoverable exergy ratio of 34%. Further improvements to the system can lead to enhanced sustainability.

Keywords: Exergetic sustainability indicators, Turquoise hydrogen, Thermodynamic modelling, Methanol, DME

INTRODUCTION

Hydrogen is a clean fuel, but the production process plays a crucial role in determining the level of environmental impact [1]. Currently hydrogen is produced from natural gas using steam reforming. An alternate pathway for cleaner hydrogen production is methane cracking. At high temperatures methane can be decomposed into pure hydrogen and solid carbon black. The process produces carbon black instead of CO/CO_2 as a by-product and the hydrogen produced is termed as 'turquoise hydrogen'. The carbon black is easier to manage and has several applications in other industries [2]. Nevertheless, carbon utilization can lead to CO_2 emissions. Therefore, it needs to be ensured that the CO_2 is captured and utilized.

Hydrogen due to its low energy density is difficult to transport or store, therefore it is suggested to convert it to other suitable energy carriers such as methanol and dimethyl ether (DME). This study proposes an integrated system for hydrogen production from natural gas, along with cleaner utilization of carbon product and conversion of hydrogen into a suitable energy carrier. The systems performance is studied by calculating indicators for exergetic based sustainability.

SYSTEM DESCRIPTION

An integrated system was designed to utilize the products of methane cracking in fuel cells. Concentrated solar power is used to provide the high temperatures required for methane cracking. Hydrogen and carbon black are used in a hydrogen fuel cell and direct carbon fuel cell (DCFC) respectively to generate electricity. The DCFC produces a pure CO_2 waste exhaust stream that is further utilized to produce fuels. CO_2 hydrogenation subsystem uses CO_2 from the DCFC and hydrogen to produce methanol and DME in a single step. The sources of this system are methane, solar energy, air to provide electricity, methanol and DME. The proposed process is summarized in Fig. 1.

ANALYSIS

The overall system was modelled on Aspen Plus® to obtain the thermodynamic properties of the streams. An exergy analysis is performed, and the input and output exergy flows were determined. Exergetic sustainability indicators were calculated using equations from the literature [3-4]. The following main indicators were computed for the proposed system:

$$Exergy\ efficiency\ (EE) = \frac{Useful\ exergy\ output}{Total\ exergy\ input} \quad (1)$$

Where the useful exergy outputs are determined based on the desired outputs from the overall system which are electricity, DME and methanol.

$$Waste\ exegy\ ratio\ (WER) = \frac{Total\ waste\ exergy\ output}{Total\ exergy\ input} \quad (2)$$

Where total waste exergy output includes all exergy outputs from the overall system to reference environment except the desired output. This also includes the total exergy destruction.

$$Exergy\ destruction\ ratio\ (EDR) = \frac{Total\ exergy\ destruction}{Total\ exergy\ inputs} \quad (3)$$

The total exergy destruction is calculated using the exergy balance.

$$Exergy\ recoverability\ \text{ratio}\ (ERR) = \frac{Total\ recoverable\ exergy\ output}{Total\ exergy\ inputs} \quad (4)$$

Exergy flows from the waste exergy outputs that can be reused for the same system are considered as recoverable exergy outputs.

$$Environmental\ effect\ \text{ratio}\ (EEF) = \frac{Waste\ exergy\ ratio}{Exergetic\ efficiency} \quad (5)$$

$$Exergetic\ sustainabilty\ index\ (ESI) = \frac{Exergetic\ efficiency}{Waste\ exergy\ ratio} \quad (6)$$

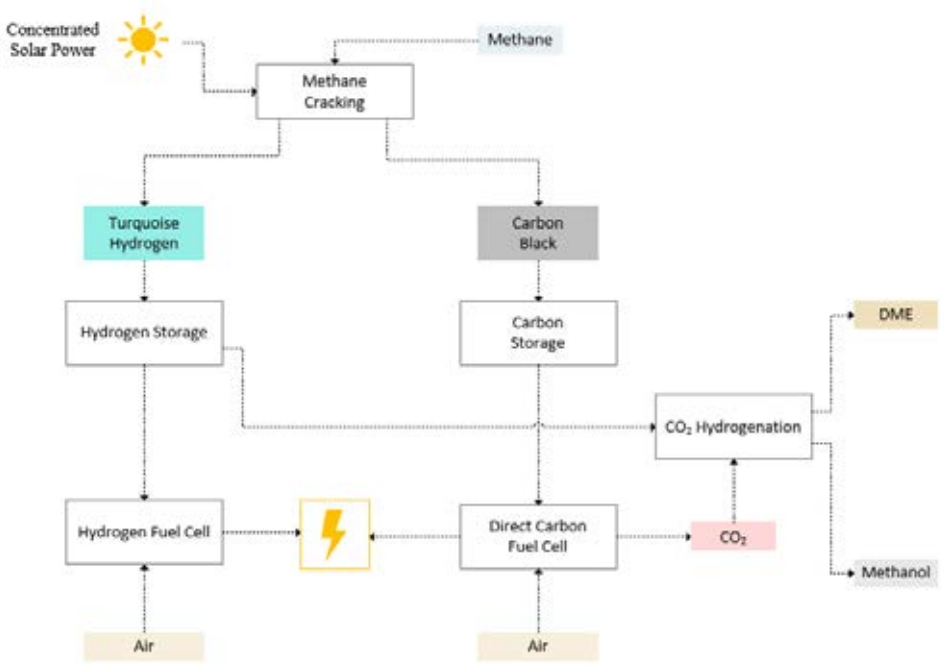

Fig. 1. Block flow diagram of the proposed integrated system

RESULTS AND DISCUSSION

The exergy flows of all streams in the process were obtained using the Aspen plus simulation. Exergy balances were performed over each unit and the overall system exergy inputs and outputs were determined. The exergetic sustainability indicators were calculated and the results are presented in Table 1. The exergy efficiency of the overall system is 53%. The system has an ESI greater than 1 and a high EEF. This system can be further improved by recovering the waste exergy outputs to increase its sustainability.

Table 1. Results of the exergy analysis

Exergetic sustainability indicator	Value
Exergy efficiency (EE)	0.53
Waste exergy ratio (WER)	0.47
Exergy recoverability ratio (ERR)	0.30
Exergy destruction ratio (EDR)	0.09
Environmental effect factor (EEF)	0.89
Exergetic sustainability index (ESI)	1.12

CONCLUSIONS

An integrated system for solar methane cracking is proposed and evaluated using exergetic sustainability indicators. The system has an exergy efficiency of 53% and ESI of 1.11. it was also noted that the exergy recoverability ratio is high indicating that system can be further improved. The addition of other technologies can recover waste exergy outputs to decrease the level of environmental impact and achieve higher overall efficiencies. Future work includes evaluating each subsystem to determine the areas that need improvement and comparisons with other alternate utilization pathways for produced hydrogen and carbon.

ABSTRACT

The objective of the proposed study is to examine the performance of an integrated hydrogen generation system based on solar energy. For this purpose, CO_2, a natural fluid that does not harm the environment, was used as the working fluid. The system is comprised of the Photovoltaic/thermal (PV/T) panels, a pump, a condenser, a turbine, a Proton Exchange Membrane Electrolysis Cell (PEM-EC), and hydrogen and oxygen storage tanks. MATLAB and EES software programs are utilized to perform the performance assessment of the system. According to the analysis made on data for 17th August of İzmir, the net power generation from the PVT panels was calculated as 2696 W, the net power generation from the transcritical C02 Rankine cycle was 73.03 W, and the hydrogen production was 0.514 g/h.

Keywords: PV/T, CO2, Transcritical CO_2, Hydrogen, PEM electrolyzer,

INTRODUCTION

Because of the significant growth in population and industrial development, global energy demand continues to rise. Fossil fuels are the most widely used energy resource on the planet. These traditional energy resources have serious negative environmental consequences, such as global warming, greenhouse impact, and air pollution. As a result, replacing fossil fuels with sustainable fuels like hydrogen is unavoidable if our ecosystem is to remain clean and green. Hydrogen as an energy carrier facilitates sustainable energy systems. Hydrogen fuel has several benefits over fossil fuels, comprising a reduced carbon footprint. As a result, efforts to develop and deploy sustainable energy and fuel technologies are underway [1]. One of the most prevalent hydrogen generating techniques is the PEM-EC [2]. The PEM-EC consumes electrical energy to break water molecules into hydrogen and oxygen gas [2]. The quantity of electrical input to the PEM-EC has a nearly linear relationship with the amount of hydrogen produced [3]. Consequently, the presence of a stable and sustainable energy supply to meet the PEM-EC's electricity demand is required. In order to produce hydrogen by the green method, this energy resource must also be renewable and environmentally friendly. Because of its abundance, solar energy is the most potential renewable energy resource. It must, however, be turned into power or heat. PV/T systems are the most common combined solar systems. Thermal collectors and PV modules combine to produce both thermal and electrical energy in this system. In recent years, energy production technologies using sCO_2 based on solar energy have attracted the attention of important research. The sCO_2 power generation cycles use environmentally friendly and non-toxic CO_2 as the working fluid. Also, the thermophysical characteristic of CO_2 presents sharp changes near the critical state, which diminishes the compression power consumption and consequently promotes its cycle efficiency. Integrated PV/T modules with transcritical CO_2 Rankine cycle is a promising way of energy production with solar energy. These systems convert low-grade thermal energy into electricity. Salari and Hakkari-Fard [1] investigated the performance of a PV/T-ORC system coupled with a PEM-EC and developed a combined numerical/theoretical model of the system. The performance of a combined PVT-ORC system was theoretically explored by Tourkov and Schaefer [4]. The effects of numerous design parameters on PVT-ORC performance, for instance, ORC configuration, ORC working fluid, and working fluid mass flow rate, were explored in this study. Hosseini et al. [5] designed the PVT/ORC cycle to produce hydrogen with the aim of energy storage. They concluded that the integrated system could generate 2.378 kW of electrical power. The objective of this study is to explore the performance of an integrated solar-based hydrogen production system to decrease environmental damage using carbon dioxide, a highly natural liquid. When the studies in the literature are examined, no low-temperature operating systems integrated with PVT using CO2 as the working fluid have been found. It is thought that this study will contribute to the literature.

MATERIALS AND METHODS

Fig.1 shows the schematic representation of solar-assisted hydrogen production system by PV/T assisted transcritical power cycle with direct steam generation. The PV/T system converts solar energy into electricity and heat energy. The output thermal energy of the PV/T system drives the transcritical sCO2 cycle to generate more electricity. Thus, the total electricity generation from solar input is increased by combining the PV/T system with the

transcritical sCO_2 cycle. Lastly, the generated electrical energy is transmitted to a PEM-EC to produce hydrogen, which is the main objective of this work.

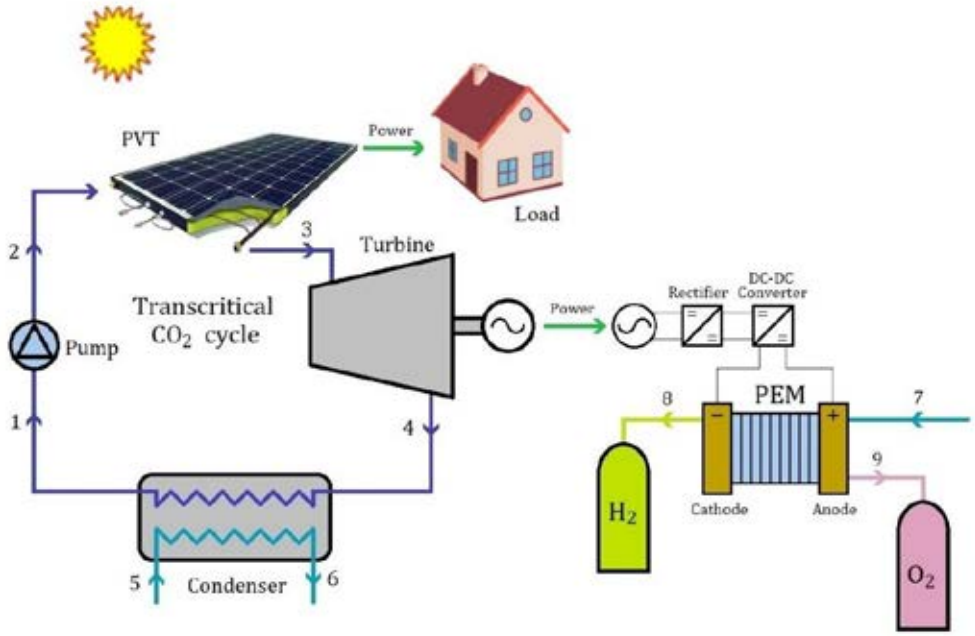

Fig. 1. Schematic representation of the PV/T based hydrogen generation system with transcritical sCO_2 cycle

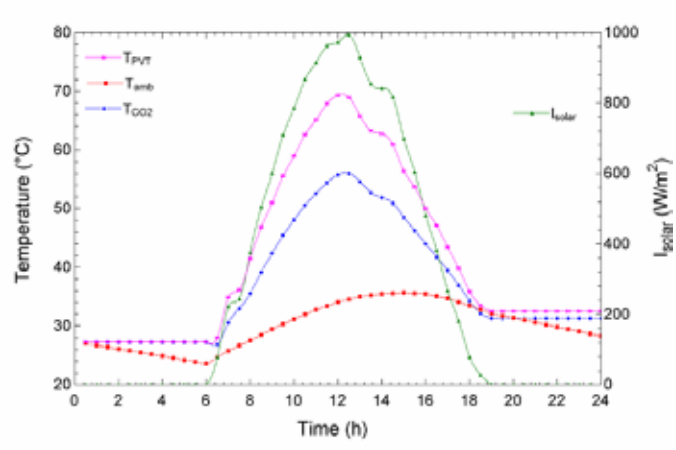

The design parameters of the integrated system used in this study are given in Table 1.

Table 1. Design parameters for the proposed multi-generation system

Design Parameters	**Values**	***Design Parameters***	**Values**
PVT		***PEM Electrolyzer***	
Length, [m]	1.649	Freshwater temperature, [℃]	25
Width [m]	0.992	PEM electrolyzer temperature, [℃]	79

RESULTS AND DISCUSSION

This part gives the results of the analysis. As indicated before, mathematical modeling of the integrated system consisting of PV/T solar panels, turbine, condenser, pump, PEM electrolyzer, and hydrogen and oxygen storage tank was made in MATLAB and EES software. For the modeling of the PV/T solar panel, Ref. [6] is used, while the PEM electrolyzer modeling is adapted from Ref. [7]. In Fig. 2, the variation of solar radiation, PV/T temperature, ambient temperature, and CO_2 temperature with the time is given. As can be seen from the figure, changes in solar radiation and temperature changes are compatible with each other. Fig. 3 shows the change in PV/T power generation and electrical efficiency with time. As can be seen from the figure, the electrical efficiency decreases with the rise in the power supplied from the PV/T panels. Fig. 4 shows that the net power generated from the transcritical cycle increases with time since solar radiation increases. After noontime, it starts to decrease. Besides, the right-hand side of the figure indicates that the cycle efficiency reaches a maximum value of nearly 5 %. Finally, the hydrogen production amount by the time is given in Fig.5. As seen from the figure, the produced H_2 amount reaches 0.514 g/h. It seems very low; however, it must be noted that the energy requirement for the PEM electrolyzer was only supplied from power generated by the transcritical cycle. Also, to increase the generated amount, additional power could be used from PV/T, yet, in this study, this condition has not been taken into account since all electricity produced from PV/T was considered to be used for the residential house.

ABSTRACT

3D concrete printing technology provides an ideal solution for resilient infrastructure development in critical and emergency situations; however, access and energy are critical challenges in such conditions. This study presented the design of an integrated renewable energy system with hydrogen storage for a unique mobile and autonomous 3D printing system for construction printing. The system has been designed to fulfil the off-grid energy requirement, such as material synthesis, printing, computation, communication, and surveillance/monitoring. The designed energy system has been analysed to produce a 3D printed structure with two different local materials; Construction and Demolishing Waste (CDW) based geopolymer concrete and direct printing of local materials. Due to the energy-intensive process and higher energy requirement for the pre-processing of waste to produce geopolymers, the designed system is more favourable for the direct printing of local materials. With the designed steady-state standard operating conditions the designed integrated system of 5.36kW can print 2.86m^3 of the final structure from direct printing of local material and 0.22m^3 of geopolymer based concrete structure in 24 hours. The analyse feasibility and production capacity of the designed system, and the overall performance of the system are also analysed for varying solar irradiance (I) conditions.

Keywords: 3D construction, Integrated renewable energy system, Hydrogen storage, Mobile 3D printing.

INTRODUCTION

The Provision of fast, inexpensive, durable and resilient solutions is a tremendous and urgent need during climate change emergencies, disasters, etc. However, such solutions are slow, expensive, and insufficient and leads to further problems and technical barriers, causing the lack of decent and humanitarian solutions for oppressed people in need. 3D Printing (3DP) technology could provide a stronger and more resilient solution to several basic human needs of the built environment in these conditions. 3D construction printing technology provides an ideal solution for resilient infrastructure development in critical and emergency situations such as wars, floods etc. However, due to damaged infrastructure in such situations, the access, printing materials and energy solutions for the printing technology are major challenges. An integrated renewable energy system provides more sustainable, off-grid and clean energy solutions in such conditions even in remote locations. In literature, researchers have designed integrated renewable energy-based integrated systems for energy electrical and thermal energy requirements [1–3]. However, the varying availability of renewable energy systems at different locations is one of the challenges which can be overcome with the design of suitable integrated renewable energy systems and energy storage [4]. In the previous publication of the research group various studies have been performed on the development of recycled demolishing and construction waste-based geopolymers [5]. This study proposed the development of an integrated multigeneration system for mobile and autonomous 3D concrete printing systems that can be used for the development of critical infrastructures such as bridges, shelters, water and health facilities etc. development in disaster and emergency conditions. The specific objectives of the design system are off-grid energy system, renewable, portable for easy mobility and cable of energy storage. The study also focused to know the building capacity of such a mobile 3D printing system installed on the truck.

SYSTEM DESIGN AND DESCRIPTION

The system is designed to fulfil the off-grid energy requirement of material synthesis, computational, communication and surveillance energy and printing energy requirements of the mobile concrete 3D printing system. The proposed integrated renewable energy system for mobile 3D printing systems is illustrated in Figure 1. In the designed system solar PV and wind turbines have been considered for the electrical energy requirement of the system. The generated electrical energy is designed to be used for direct printing and material synthesis, computational and communication and surveillance system energy. Electrical energy from the generated system is designed to be stored in the form of hydrogen and oxygen in conditions when the system is in pause mode during travelling or nighttime. The generated hydrogen and oxygen will be used for the electrical energy requirement in conditions when not enough renewable energy is available such as low wind conditions, nighttime, and bad weather for solar energy. The generated hydrogen

will also be used for the communication balloon system. The related cost of the components, subsystem or overall system is not considered.

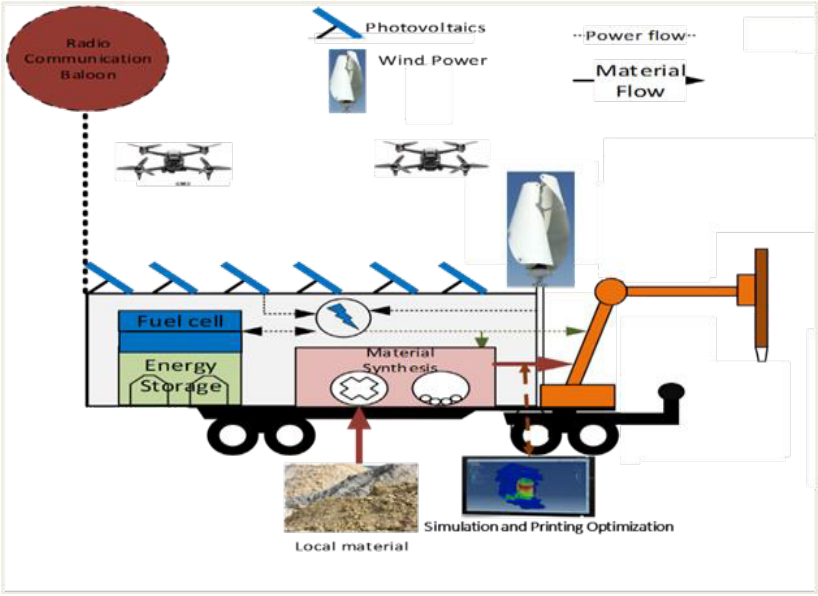

Figure 1. Designed mobile 3D printing system with integrated renewable energy, storage, material synthesis and 3D printing system.

RESULTS AND DISCUSSION

Comprehensive energy analysis has been performed for the design and performance analysis of the system at steady conditions. The initial design is considered at standard steady states of solar and wind turbines, the total Electrical energy produced has been considered as a combination of solar and wind energy during the daytime. EES software has been used for analytical modelling and calculation of the designed system. The design conditions of the installed system at a steady state are summarised in Table 1.

Table 1. Energy input requirement and the production capacity of different sub-systems at standard operating conditions.

System	Description
Solar PV	I=850 kW/m^2 at Standard operating conditions, installed at 80% of the total considered truck area. The capacity of 1.36 kW with an efficiency of 20%. Considered working hours of eight per day.
Wind Turbine	The standard wind turbine of 2 kW. Two wind turbines are installed within the available space of the considered truck of [4x 2.5]m^2 of surface area.
Energy storage	Proton Exchange Membrane Fuel Cell (PEMFC) with hydrogen and oxygen storage. The system is considered to at least store 60% of the total energy capacity of the system at standard conditions.
Printing Energy for m^3 final printed material.	The total energy required to produce material synthesis is 484.18 kWh for 1 m^3 of production of the final material. For geopolymer based concrete material the overall energy required is from the previous paper. This includes grinding, crushing, mixing and curing energy, for detail [5]
Communication, surveillance, and computation energy	The overall energy is 5% of the total required energy from material synthesis and printing.
Building Units	Considered a 3D building unit of [7x7x4] m with a double-wall structure of 10 cm thickness.

For the installed capacity and standard working conditions, the designed system can produce 106 kWh of energy per day which can print 2.86m^3 of final 3D printed volume of local material and 0.22 m^3 of the considered geopolymer concrete structure, including all the material synthesis, printing, computational and communication and surveillance energy.

The system has been analysed for the varying installed capacity and the corresponding number of possible 3D building units of [7x7x4] m^2 of the wall structure, shown in Figure 2. An installation capacity of higher than 200kWh may not be feasible to be installed on the moving system due to limitations of the installed area on the moving vehicle.

For higher such cases the system can be moved by moving vehicle and can be installed in the desired location conditioned to the feasibility of working.

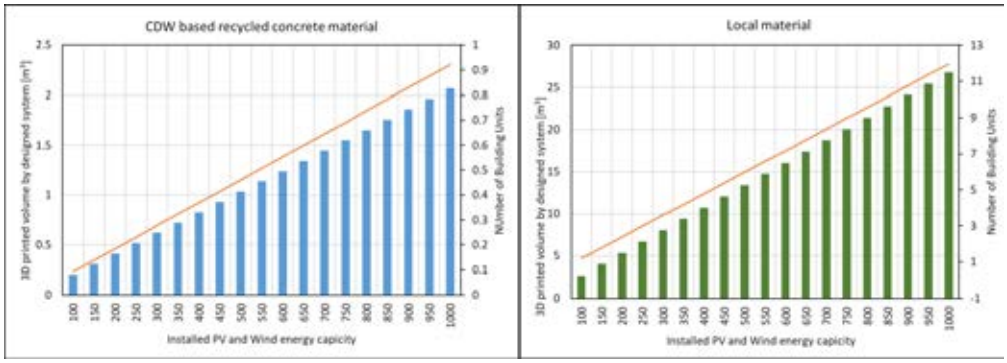

Figure 2. The capacity of the designed system for the produced 3D printed structure volume and number of building units as a function of installed integrated renewable energy system.

The output of renewable energy systems varies due to the varying availability of energy at different locations. The proposed system is intended to work at different locations depending upon the needs. Hence the final production capacity of the overall system is analysed for varying I value. For the varying value of I from 850 kW/m^2 to 1200 kW/m^2 the overall portion of solar energy varied from 10.88 to 15.36 kWh, considering 8 hours of production time. This leads to an increase in the production volume of the final 3D printed material from 2.86 m^3 to 2.98 m^3, Figure 3.

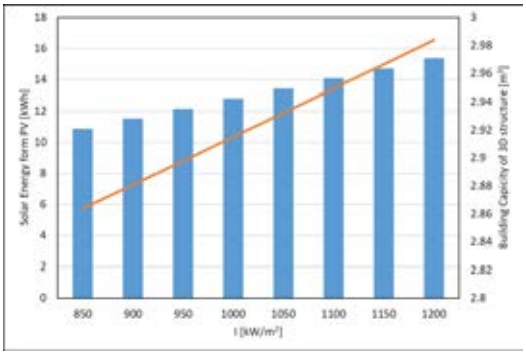

Figure 3. Solar energy production and the overall building capacity as a function of I.

CONCLUSION AND FUTURE DIRECTION

An integrated renewable energy system has been designed for an autonomous, mobile 3D printing system that can be used for the 3D construction of critical infrastructure in disaster and emergency conditions. The performed analysis verified the feasibility of the designed system for the energy requirement of the targeted system. The designed PV and wind energy integrated system of 5.36 kW with the energy production of 106.8 kWh per day has been proven up to produce 2.86 m^3 of final 3D printed material. In future studies, the detailed effect of the metrological conditions including humidity and temperature on the installed PV, wind, and storage system will be analysed using exergy and energy analysis of the designed system. A parametric study to different locations efficiency of different components cost and LCA analysis could be considered.

ABSTRACT

In this paper, a technological assessment of a small modular nuclear reactor system for hydrogen and electricity is presented. Energy and exergy analyses are being used to make the technological assessment by evaluating the efficiencies namely, energy and exergy efficiencies. A three-step thermochemical cycle based on aluminum is being used for hydrogen production. Heat and electricity from the nuclear reactor are being used to run the thermochemical cycle. Simulation results show that one can produce 2.2 tonnes of hydrogen daily with an electric input of 190 MW.

INTRODUCTION

Global energy data show that the conventional energy sources like oil and coal is leading the list of energy consumption. The fossil fuel usage is related to deleterious effects on the environment like increase in the greenhouse gases/increase in carbon footprint. With the growing energy demand researchers are investigating reliable non-conventional energy sources with minimum environmental impact. Efforts are being put in place to develop non-conventional energy-based systems. Renewable energy power generation increased by a percentage of 12.5 from 2789.2 TWh to 3147.0 TWh in the years 2019 to 2020 [1]. This finding suggests that renewable energy will play a considerable role in the future energy scenario, implying that a symbolic increase in renewable energy sources could significantly contribute to meeting future energy demand in a viable manner. To stimulate and support the use of renewable energy various countries have implemented effective programs and other critical policies. In Germany, policies have been implemented which forecast the growth of renewable energy by 40% between 2021 and 2026 [2]. It is also expected that by 2040, the consumption of renewable energy will nearly double. In spite of all these crucial characteristics and advantages, there are a number of shortcomings linked with renewable energy sources. For instance, they are recurrent in nature and are not obtainable through the year consistently [3,4]. However, integration of renewable energy with nuclear energy may act as one of the sustainable solutions for this intermittency. Hydrogen can act as an excellent connection among renewable and nuclear energies. Many techniques are being investigated to produce hydrogen in a sustainable way and thermochemical cycles are considered one of them [5].

SYSTEM DESCRIPTION

A small modular reactor based integrated energy system for hydrogen and electricity is being presented schematically in Figure 1. The system comprises of a nuclear reactor and an aluminum based thermochemical cycle. The presented thermochemical cycle comprised of three chemical reactions namely Reactions 1, 2 and 3. Reaction 2 is the electrolysis process run by the electricity (provided by nuclear reactor) while reaction 1 is the endothermic reaction (absorbing the heat from the helium at state 1 coming out of the nuclear reactor core) and reaction 3 is the exothermic reaction. In the considered thermochemical cycle all the reagents are recycled except water. After giving the heat to the reaction 1 of the thermochemical cycle, the helium stream (state 2) enters the turbine and produce the required electricity. The helium stream coming out of gas turbine at state 3 is being cooled down using a recuperator. The cooled helium gets pressurized in the compressor and its temperature gets further increase (state 6) with the help of recuperator before entering the reactor core.

ANALYSIS

Thermodynamic assessment of the presented system is done via the exergy and energy analyses. Several reasonable assumptions have been invoked to facilitate the analyses. Technical feasibility of the proposed three step aluminum-based cycle for hydrogen production is made via thermodynamic analysis and following assumptions are made:

- Pressure for all the chemical reactions assumed to be ambient i.e., 101.3 kPa.
- Chemical reactions are assumed to be as stoichiometric.

- Steady state is assumed for all chemical reactions.

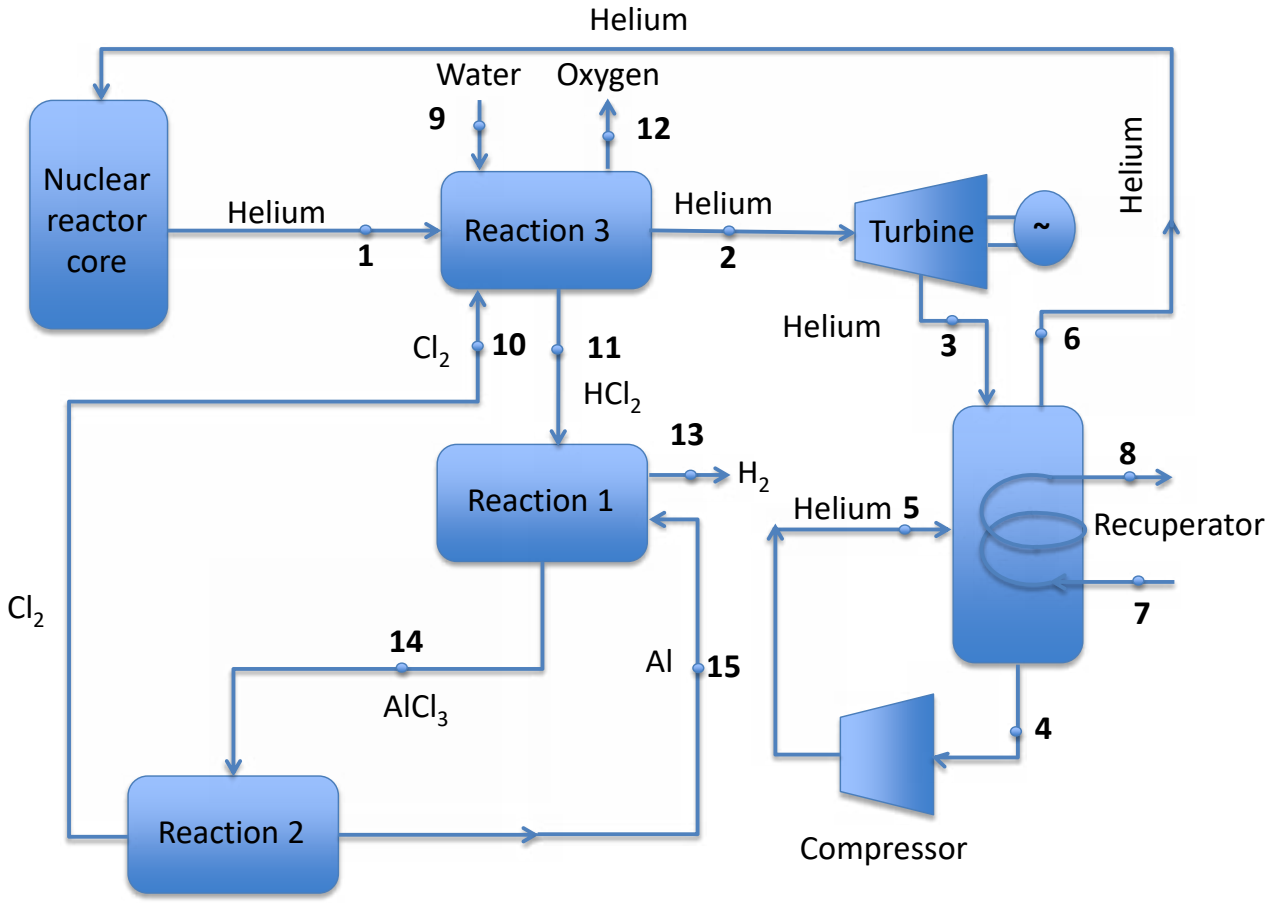

Figure 1 Schematic diagram of a small modular reactor for hydrogen and electricity

The energetic input to the electrolyser has been evaluated as follows:

$$\dot{W}_{\text{in,elec}} = \dot{m}_{H_2} \Delta g_{rxn} \quad (1)$$

RESULTS AND DISCUSSION

The presented system in the figure 1 has been analyzed via the principle of thermodynamics and results are tabulated in Table 1. To produce 0.26 kg/s of hydrogen, 190 MW of electric work has been utilized in the given thermochemical cycle.

Table 1. Parameters obtained from the study

Parameter	Value
Mass flow rate of helium (kg/s)	439
Mass flow rate of hydrogen produced (kg/s)	0.26
Work input of the electrolyser (MW)	190
Coolant Inlet Temperature (℃)	850
Maximum Operating Temperature of the Cycle (℃)	630

CONCLUSIONS

A new nuclear energy based integrated energy system for co-production of hydrogen and electricity is developed and presented. In the presented system, hydrogen is produced via a thermochemical cycle utilizing heat and electricity. Simulation is being carried out in the software called Engineering Equation Solver and results show that 0.26 kg/s of hydrogen can be produced in a sustainable manner using the heat and electricity from the small modular reactor.

ABSTRACT
In this study, the design of a new fixed-bed reactor is proposed and examined through computational fluid dynamics. The design follows a unique helical design to maximize the amount of surface area that is exposed and to reduce the need for gas recycling. The heat distribution through the reactor is measured using the surface temperature before and after cooling takes place. Additionally, the mole ratio of all of the species used in the reaction is measured along the length of the reactor. The numerical simulations reveal that less than 1 kW of cooling is sufficient to significantly reduce the temperature of the reactor and that an H_2 conversion of approximately 84% can be achieved.

Keywords: Hydrogen, Natural Gas, Methane, CFD, Reactor analysis.

INTRODUCTION
As issues revolving around climate change and the growing global energy demand continues to rise, scientists and engineers look for sustainable solutions such as using hydrogen as an energy carrier. Hydrogen as an energy carrier has tremendous potential given its high energy density [1], and non-polluting effects [2]. However, the use of hydrogen is not limited to being an energy carrier; it can also be used to synthesize many other essential gases such as CH_4 or natural gas. CH_4 can be produced through the Sabatier reaction as follows [3]:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O(g) \quad -164\ kJ\ mol^{-1} \tag{1}$$
$$CO + 3H_2 \rightarrow CH_4 + H_2O(g) \quad -206\ kJ\ mol^{-1} \tag{2}$$

The CH_4 used in the reaction has the potential to be produced renewably if the hydrogen is produced through processes such as wind/ solar electrolysis and if the CO_2 or CO are produced through biomass gasification. The CH_4 produced from these chemical reactions can be used for a multitude of applications such as fuel for transportation, as well as in residential applications (water heaters, and stoves), and industrial applications (boilers and burners). Furthermore, the methane produced can also be used to synthesize acetic acid, which is used to produce plastic, textiles, rubber, and paint. Also, natural gas has the benefit of being a cleaner hydrocarbon, considering it produces 45%, 15%, and 30% less CO_2 compared to coal, wood, and crude oil, respectively [4]. Additionally, 6 -11% less greenhouse gases are emitted by natural gas compared to gasoline during their respective fuel life cycles [5].

In order to synthesize natural gas, fixed bed reactors are most commonly used, where the typical fixed bed reactor shape comprises a cylindrical catalyst bed. A major barrier in the production of methane is attributed to the chemical reactions being highly exothermic. The reaction is most effective at 200°C, however, due to the heat being released from the chemical reaction, it elevates the temperature of the reactor and the feed gas [6]. Therefore, it is important to incorporate effective reactor cooling.

This study presents the design of a novel fixed bed reactor, which uses a helical design rather than a conventional straight cylindrical path. The helical design will increase the amount of surface area exposed within the reactor to facilitate cooling and mitigate the need for recycling a portion of the gases.

MODEL DESCRIPTION
The proposed chemical reactor geometry and boundary conditions are presented in Figures 1a and 1b respectively.

ANALYSIS
The reactor's measured H_2 mole ratio at the entrance and exit of the reactor was used to determine the amount of H_2 that was successfully converted into CH_4. Furthermore, the H_2 conversion value was calculated using concentrations along the reactor. Additionally, the CH_4 yield was used to provide a measure of the CH_4 successfully produced. The general form of the mole fraction of each respective specie is defined as follows:

$$x_i = \frac{n_i}{n_{total}} \tag{1}$$

where n_i represents the mole of a specific specie at a specific stage within the reactor, and n_{total} represents the total amount of all the species within the gas mixture.

The H_2 conversion in the reaction can be defined as follows:

$$X_{H_2} = \frac{n_{H_2 in} - n_{H_2 Out}}{n_{H_2 in}} \quad (2)$$

where $n_{H_2 in}$ represents the moles of H_2 which enters the reactor and $n_{H_2 out}$ represents the moles of H_2 leaving the reactor. Additionally, the CH_4 yield can be defined as follows:

$$Y_{CH_4} = \frac{n_{CH_4 out(actual)}}{n_{CH_4 out(theoretical)}} \quad (3)$$

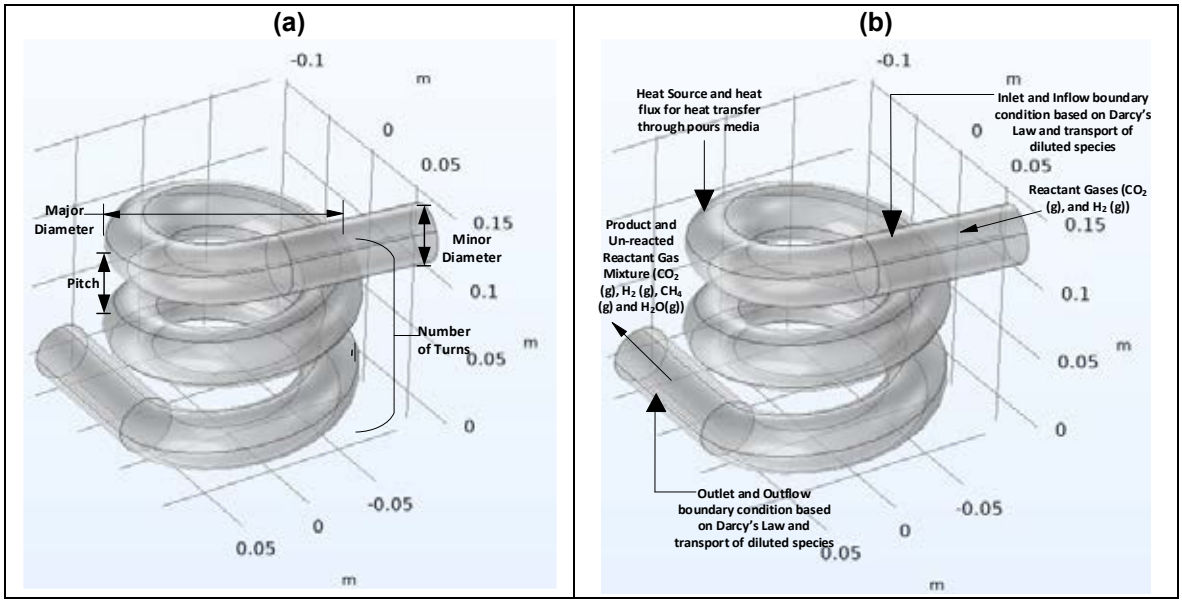

Fig.1. (a) Reactor Geometry, with the (b) Reactor Boundary Conditions

Table 1. Reactor Dimensions and Operating Conditions

Reactor Dimensions	
Parameter	**Value**
Reactor Length (m)	1.2
Reactor Major Diameter (m)	0.125
Reactor Minor Diameter (m)	0.0381 (1.5 inches)
Pitch (m)	.06
Number of Turns	2.23
Catalyst Bed Volume (m3)	.001
Operating Conditions	
Conditions	**Value**
Reactant Gas Inlet Velocity (m s^{-1})	0.45
Reactant Gas Flow Rate ($m3s^{-1}$)	5.7005E-4
Reactant Gas Inlet Pressure (bar)	10
Reactant Gas Inlet Temperature (°C)	200

4. RESULTS AND DISCUSSION

Given the exothermic nature of the reaction, effective reactor cooling is essential. Figure 2a presents a model of the reactor without the presence of external cooling. Whereas Figure 2b depicts a significantly improved version of the reactor's temperature distribution after providing 800 W of cooling along the external surface of the reactor after the inlet section.

Additionally, the mole fraction of the various species from the inlet of the reactor to the exit is presented in Figure 3. The results show that a substantial portion of the reactants used in the reactor model was successfully converted into the targeted products. At the start of the process, the observed mole fraction of H_2 was 0.8, however, it sharply decreased to 0.13. Whereas the mole fraction for H_2 started at 0 and was elevated to 0.28. The values obtained in

Fig. 3 correspond to an H_2 conversion and CH_4 yield of 84% and 93%, respectively. Additionally, the trends presented were consistent with various other research works [7].

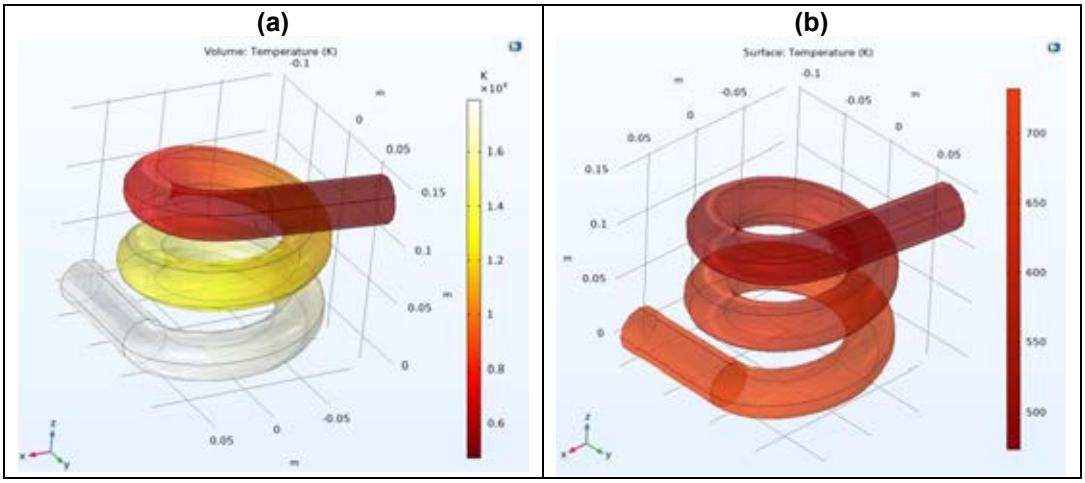

Fig.2. (a) Reactor Temperature Distribution without Cooling, (b) Reactor Temperature Distribution with 800W of Cooling

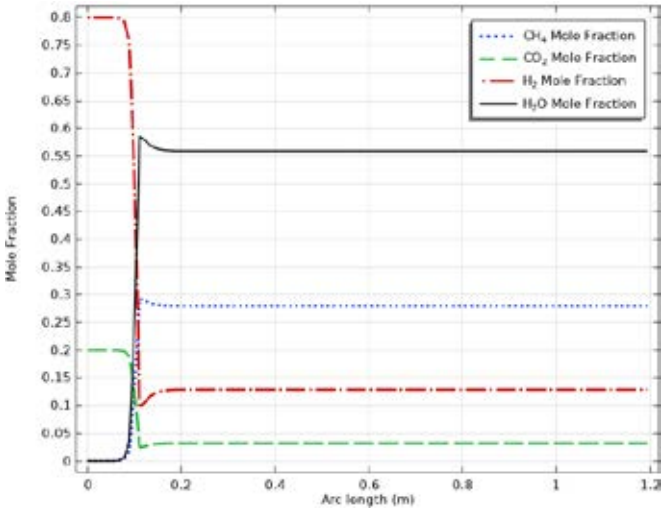

Fig.3. Species Mole Fraction Along the Length of the Reactor

CONCLUSIONS

This study has reported a new configuration for a fixed bed methane reactor which used CO_2 and H_2 as reactants. As shown earlier the proposed reactor was able to provide effective reactor cooling with less than 1kw of energy supplied to the system. Additionally, the reactor was able to achieve high H_2 conversion and CH_4 yield of 84 and 93%, respectively. The helical design presented in the system also has the potential to remove the need for reactor gas recycling and multiple passes as used in the HICOM and TREMP.

ABSTRACT

A Power-to-gas system based on high-temperature electrolysis is a feasible and environmental approach to convert low-carbon electrical energy into chemical energy stored in the form of synthetic gas (H_2 & CO). The most desirable application is to convert the syngas into synthetic fuel. The overall process is currently being studied using two different electrolyzers: Solid Oxide Electrolyzer and Molten Carbonate Electrolyzer. This work focuses on the Power to Methane technology using high-temperature Molten Carbonates electrolysis cells (MCEC). It aims to investigate the economic feasibility of the overall process in the methane production. For this purpose, a rigorous parametric study is conducting by developing a VBA excel code to acquire a better knowledge of the cost drivers of the methane production cost. This overall study revealed that if more effort is put into reducing cell and operating costs, this technology might become competitive with conventional methane production technologies. A perspective towards the future revealed that the operating cost, mainly represented by the renewable electricity cost, could attain the required target. However, estimating the time required to have an economically competitive power-to-gas plant is challenging due to the lack of data on the MCEC cell cost and its roadmap.

Keywords: Power-to-gas, Molten carbonate electrolysis cell, Economic assessment

INTRODUCTION

Power to Gas is a promising technology that is capable of resolving two main issues. This approach addresses the need for energy storage associated with renewable energy integration in the power grid. Besides, it has the potential to be a viable technique for the sequestration and the re-use of the captured CO_2 as synthetic fuels.

This technology is now encountering some economic implementation challenges that necessitate in-depth research. A series of studies were performed to investigate the economic aspect of the Power-to-Gas. They are mainly based on alkaline, proton membrane (PEM), and Solid Oxide electrolyzers. For instance, Gotz et al., 2015 [1] examined the existing electrolysis and methanation technologies in terms of the technical and economic requirements of the power-to-gas chain. Peters et al., 2019 [2] analyzed the techno-economic features of the power-to-gas system using the three existing technologies and evaluated the ecological aspects of using methane as a transport fuel. Lately, Szima & Cormos, 2021[3] assessed the techno-economic aspects of synthetic methane production from renewable hydrogen obtained from different renewable resources and captured CO_2. All studies revealed that synthetic natural gas produced from renewables is still non-competitive with conventional natural gas at the current stage.

On the other hand, Power-to-gas systems that use Molten Carbonate electrolyzers are not currently in the field of economic research. This technology is in the research and development stage, so all research focuses on the technical rather than the economic aspects. An economic study of the power-to-gas system using Molten carbonate Electrolyzer was firstly addressed in our earlier research [4]. However, this work aims to assess the economic feasibility of such technology based on the previous study outcomes and provide a future perspective on being competitive with conventional natural gas.

METHODOLOGY

The economic assessment was performed based on a developed process simulation consisting of the electrolyzer and all the balance of plant equipment, presented in [4]. This assessment evaluated the capital and operating expenses of the process at the current conditions, as well as investigated the impact of both CAPEX and OPEX on the final methane production cost by a limited sensitivity analysis. The sensitivity analysis involved the variation of different parameters, such as cell cost, lifetime, CO_2 and electricity cost within a finite margin. In this work, a profound parametric study is performed by developing a VBA excel code. It includes all the previously stated parameters and the operating hours of the plant.

RESULTS AND DISCUSSION

As inspired by the parametric study in [4], it was declared that the best conditions for having an approximate competitive methane selling price with the current market price are to have a 45000 h cell lifespan, 30€/MWh electricity cost, 20€/tonne CO_2 cost, and 1000 €/kW cell cost. The future perspectives for having these conditions depend on several criteria. The cell lifetime of MCFC has reached over 40000h lifespan in the fuel cell mode [5]. Besides, Hu et al., 2014[6] proved that the cell exhibited better electrochemical performance in MCEC mode than in MCFC mode, which leads to a higher lifetime of the MCEC. According to this information, it can be deduced that the lifetime of MCEC can easily attain 45000 hours of operation.

Based on the fact that the cell has reached 40000h lifetime, the impact of both CAPEX (cell cost) and OPEX (CO_2 and electricity cost) together on the methane selling price is simultaneously examined assuming that the plant operates for 8000 h per year. The outcomes are illustrated in Figure 1. The diagram displays an alternating repetitive pattern, where the trend changes with the variation in cell lifetime and cost, CO_2 cost, and electricity cost. It can be classified into three categories. The first category is the cell cost zone that is identified by two consecutive repetitive patterns. The second category is the cell's lifetime zone that is represented by a single pattern within the cell cost zone. The last category corresponds to the CO_2 and electricity cost zone that is expressed within each pattern. In this zone, there are two complementary trends. The first trend is the methane price with an increase in Electricity cost (green arrow), and the second one is the methane price with an increase in CO_2 cost (orange arrow).

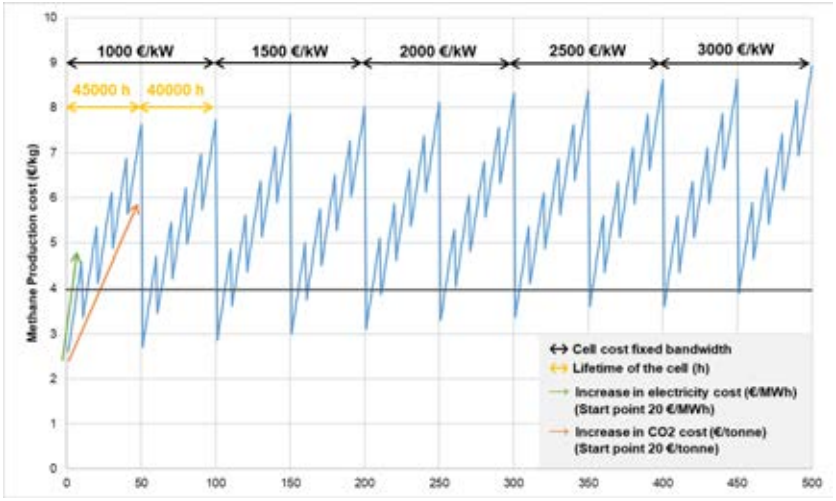

Figure 1. Impact of both CAPEX and OPEX on the methane production cost

The assessment results highly coincide with the expected ones. It can be observed that methane production cost decreases with the decrease in cell cost. However, the additional improvement in lifetime of the cell after reaching 40000 h has no significant impact on the methane selling price. Although the methane cost is highly affected by the cell capital cost, it can't reach a competitive price with the conventional ones without reducing the operating cost. To have a competitive methane price, the methane production cost must drop below 4€/kg. According to the graph, the methane price is below 4€/kg when the CO_2 cost is low (20-40€/tonne CO_2), and the electricity cost is between 20-80€/MWh at a cell cost below 2000€/kW. The selection of the maximum cost values of CO_2 and electricity highly relies on the cost values of one and the other as well as the cell cost to have methane production cost below 4€/kg. For instance, a cell with a cost of 3000€/kW requires a CO_2 cost of 20€/tonne and electricity cost of 20€/MWh, whereas a cell with a cost of 1500€/kW requires either a CO_2 cost of 20€/tonne and electricity cost ranging between 20-80€/MWh or a CO_2 cost of 40€/tonne and electricity cost between 20-30€/MWh. Therefore, it can be deduced that the operating cost combined with the cell cost considerably influence the final methane selling price. A comparable study conducted at a plant operating hours of 5000 h per year revealed a similar trend with an average increase of 6% in the methane cost compared to 8000h; whereas, at a plant operating hours of 3000h, the methane price seems unlikely to reach below 4€/kg based on the studied range of variables. In conclusion, the target of methane price below 4€/kg can be attained if the operating costs are low, the cell cost is below 3000€/kW, and the operating hours of the plant are higher than 5000 hours per year.

The parametric study outcomes encourage profound research on the operating and capital costs situation. First of all, the electricity is driven by the cost of the renewable energy source since MCEC is the most electric energy consumer. The International Renewable Energy Agency (IRENA) [7] has reported the decreasing trend of the Levelized Cost of the different renewable energy sources from the year 2010 to 2019. According to their outcomes,

the cost of onshore wind turbine electricity was 50$/MWh (~42€/MWh) and that of PV electricity was 68$/MWh (~57€/MWh) in 2019. These costs are expected to reach below 50$/MWh in the coming years. On the other hand, the CO_2 cost depends on the carbon capture technology used. Each technology has a different investment and operating cost, thus the selling price of the produced CO_2 will change. The MCEC cost is determined by the technology improvements and the manufacturing capacity, which will be reflected in an increase in the cell market causing a reduction in the cell cost per installed capacity. In 2003, MTU (a former fuel cell manufacturing company in Germany, that transferred its assets to Fuel Cell Solution Gmbh in 2012, a subsidiary of the FuelCell energy USA) expected that the commercial MCFC cost will attain a value <1250 €/kW once the production volume reaches 160 to 200 systems per year [8]. However, there is still no public available information on the current status of the MCEC cost and its roadmap.

CONCLUSION

The power-to-gas system based on Molten carbonate electrolyzer is an intriguing concept of storing energy and reusing CO_2. However, significant advances in terms of cost feasibility are required. Based on our economic study, this process might be economically competitive with other technologies if the operating costs are low, the cell cost is below 3000€/kW, and the operating hours of the plant are higher than 5000 hours per year. The vision for the future on these targets appears optimistic in terms of operating cost; nevertheless, there are still some challenges due to a lack of the cell cost forecast in the upcoming years.

ABSTRACT

The cement industry, which accounts for 7-8% of worldwide CO_2 emissions, is essential to decarbonize but challenging especially due to its high process emissions, high temperature heat requirements and low maturity of decarbonization solutions. A new electrochemical path to produce calcium hydroxide, a precursor of cement, has been proposed recently. This technology is based on a new design of a water electrolyser working in tri-phase environment. It has the potential to electrify cement production while at the same time producing valuable gases, but is still at a very early stage of development (TRL-3). In this paper, lab-scale experiments in a 200mL cell were performed to have a better understanding of the electrochemical system. The development of a pH gradient between the anode and the cathode has been quantified for different electric charges applied. Due to acidification of the anode side, the dissolution of calcium carbonate is enhanced. A solubility ten times higher than at neutral pH has been observed. At the same time, the migration of Ca^{2+} and OH^- ions to respectively the cathodic and anodic side has been demonstrated as well, thereby opening the way for an electrochemically-enhanced $Ca(OH)_2$ precipitation.

Keywords: Electrolysis, Electrification, Cement, Hydrogen

INTRODUCTION

In the race to decarbonize our society, reducing emissions from the industrial sector (32% of total greenhouse gas emissions [1]) appears as one of the major challenges to take on. The industry is known as a “hard-to-abate emission” sector due to high-temperature heat requirements, process emissions, long-lived capital assets and trade considerations [2]. This paper focuses on the decarbonization of cement production - one of the three main industries along with steel and chemicals. The cement sector accounts alone for about 7-8% of total CO_2 emissions, so that cutting these emissions is essential to tackle climate change [3-5, 7]. Among these emissions, around two third are due to the calcination reaction of limestone. These process emissions make it more challenging to achieve carbon neutrality [4-7]. Several decarbonization technologies are being studied such as carbon capture, electrification, fuel and raw material substitution [2-4].

In 2019, Ellis *et al.* proposed a new electrochemical path for cement synthesis. By taking advantage of the pH gradient established during water electrolysis in an initially neutral medium, limestone ($CaCO_3$) can be decarbonated and the dissolved Ca^{2+} further precipitated as hydrated lime ($Ca(OH)_2$). This calcium hydroxide can then be used directly for its own industrial applications or to produce alite, the major phase of conventional cement. The concentrated gaseous carbon dioxide produced can be easily collected at the outlet while hydrogen and oxygen can be used to generate power for other steps or valued in their respective markets. With the emergence of low-cost renewable energy, this new technology could allow for the production of calcium hydroxide and cement with nearly zero emissions and at a competitive cost [8].

The aim of the current paper is to go further in the understanding and optimization of this new electrolyser design in a triphase environment in order to evaluate its potential on an industrial scale.

ELECTROCHEMICAL SYSTEM

The electrolyser is divided into three compartments. At the anode, the oxidation of water (reaction 1 in Fig.1A) produces oxygen and H^+ ions. Solid calcium carbonate inserted at the anode has a low solubility (14.31mg/L at 25°C [9]). Its decomposition (reaction 4) in neutral water is weak. Thanks to the generated H^+ ions in the anodic environment, the carbonate dissolution equilibrium is modified (cf Fig.1B) and CO_3^{2-} ions react to stabilize as CO_2 (reaction 5) for a pH lower than 6.4 [10]. The chemical dissolution of $CaCO_3$ is thereby further enhanced by the release of gaseous CO_2 and by the migration of Ca^{2+} ions towards the cathode. Besides CO_2, also O_2 is being collected at the anodic side. At the cathode, hydrogen gas and hydroxide ions are produced by water reduction (reaction 2). The hydroxide ions will make the medium alkaline and will naturally migrate towards the anode. In the

central compartment, the different migrated ions (H^+, Ca^{2+} and OH^-) react together (reaction 3 and 6),calcium hydroxide precipitation being favoured at pH >12.5 [8].

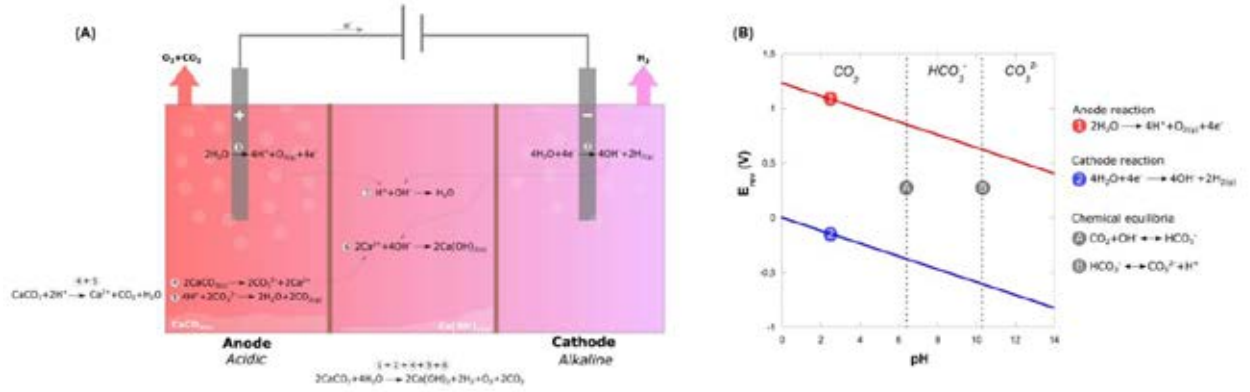

Figure 1. (A) Electrochemical system and chemical reactions (B) Pourbaix diagram for water electrolysis and carbonate equilibria

MATERIALS AND METHODS

Experiments were performed in an H-type cell (200mL, Adams & Chittenden Scientific Glass) at room temperature. The electrolyte used is a 1M $NaNO_3$ (Sigma-Aldrich BioXtra, >99%) solution in ultra-pure water (18.2MΩ/cm). The physical separations used to divide the three compartments are paper filters (VWR, 516-0818). Electrodes are platinum foils. The potentiostat used (AUTOLAB, Methrom) is equipped with a booster (allowing to go up to 10A) and two continuous pH readers. Two types of one-hour experiments have been carried out: a galvanostatic set of 6 experiments between 2.5-4.5V and a potentiostatic set of 7 experiments between 0.007-0.06A. For each experiment, 50mg of calcium carbonate (Sigma-Aldrich BioXtra, <99%) are initially inserted on the anodic side. ICP-AES analysis were performed to quantify the Ca^{2+} ions in solution.

RESULTS AND DISCUSSION

Figure 2A clearly illustrates the establishment of a pH gradient between the anodic and cathodic compartments. The higher the electric charge, the more the gradient becomes important. The theoretical pH value shown in Figure 2B is obtained as the value for which all the current applied is converted into H^+/OH^- while assuming that none of these ions will react or move from their respective compartments. As it can been seen, the difference between the theoretical and real pH is more pronounced on the anode side, essentially since H^+ are being consumed by reaction with CO_3^{2-} (reaction 5 in Fig. 1A).

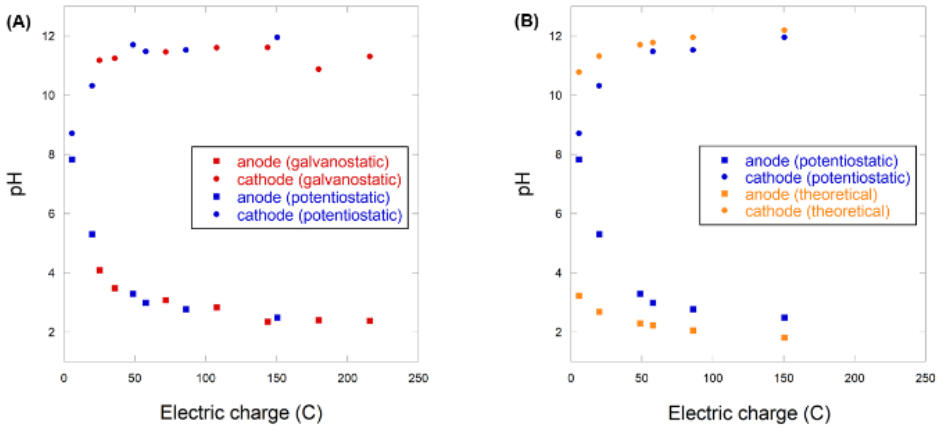

Figure 2. (A) Final pH obtained in anodic and cathodic compartments for a defined electric charge applied in one hour (B) Comparison between final pH obtained and theoretical value expected (potentiostatic experiments only)

Figure 3A shows the amount of Ca^{2+} in solution at the end of the experiments as a function of electric charge. Although all calcium is initially inserted at the anode as $CaCO_3$, a small quantity is found at the cathode as well due to its electrical field induced migration. The total amount increases as a function of the applied electric charge until it reaches a plateau. Indeed, the higher the charge, the lower the pH will be at the anode (cf Fig. 2A). A lower pH will ease the dissolution of $CaCO_3$ due to carbonate equilibrium modification as explained previously. This is illustrated on Figure 3B. The maximum amount found in solution is 13 mg out of a total of 20mg initially inserted. This amount

corresponds to a solubility of 126mg/L in the anodic side, which is almost ten times higher than the solubility at neutral pH [9]. The remaining 7mg can be either in the form of undissolved $CaCO_3$ or in the form of $Ca(OH)_2$.

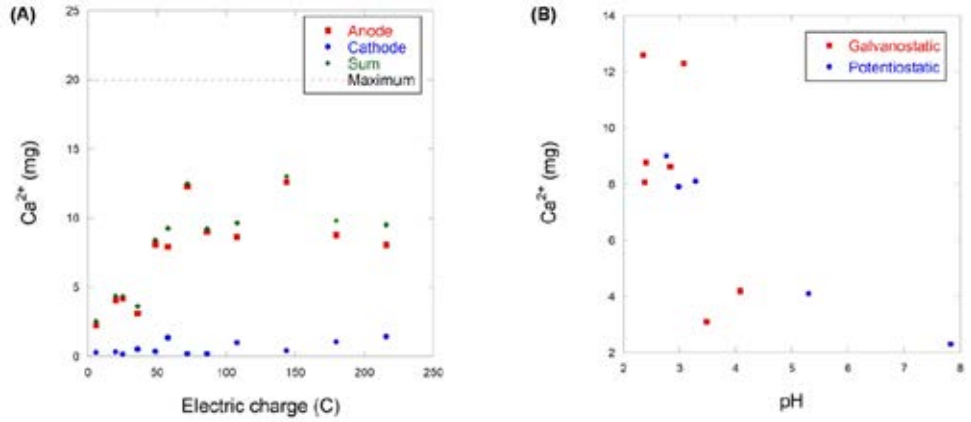

Figure 3. (A) Final mass of Ca^{2+} ions in solution in anodic and cathodic compartments for a defined electric charge applied in one hour (B) Final mass of Ca^{2+} ions in solution in anodic side vs anodic final pH

CONCLUSIONS

During neutral water electrolysis, the development of a pH gradient between anode and cathode has been demonstrated and quantified. This gradient increases with the electric charge applied. The gradient observed is lower than expected due to ion migration, reaction between H^+ and CO_3^{2-} and other potential side reactions. Due to acidification of the anodic compartment, the dissolution of calcium carbonate is favored until a maximum observed solubility of 126mg/L, ten times the value in neutral water at 25°C [9]. The migration of Ca^{2+} and OH^- ions towards the central compartment has been demonstrated as well. This migration is necessary for the production of calcium hydroxide.

ABSTRACT

The direct dehydrogenation of butane (BDH) is emerging as an attractive on-purpose technology for the direct production of 1,3-butadine. However, its product yield is hindered by the high rate of carbon deposition associated to the high temperature required for the highly endothermic reaction. In this work, we evaluated the use of membrane reactor with H_2-selective membranes, to increase the yield of the dehydrogenation process at milder operating conditions. The novel proposed membrane reactor (MR)-assisted BDH technology is compared from a techno-economic point of view with the benchmark technology. The results of this analysis reveal that the membrane reactor technology allows to maintain same production capacity as the benchmark technology, working at milder operating conditions and most importantly lowering the required shale gas-based feedstock; this will result in an overall plant efficiency almost 20% higher in the MR-assisted plant, being equal to 37.7% with respect to the one of the benchmark case, which is 50.92%. This work demonstrates that MR-assisted technology is a valuable alternative to the conventional BDH technology, reducing of almost 20% the final cost of production of 1,3-butadiene, due to the lower installation costs and the higher energy efficiency.

Keywords: Butane dehydrogenation process, Butadiene production, Membrane reactors, Hydrogen removal, Techno-economic analysis

INTRODUCTION

The direct dehydrogenation of butane (BDH) is a promising process to meet the increasing global butadiene demand by using shale gas-derived feedstock. However, this “on-purpose” technology, already commercialized and installed worldwide, is limited by rather low product yields and high energy demands, as the dehydrogenation reaction is highly endothermic and limited by the thermodynamic equilibrium [1]. In addition to that, cracking and other side reactions are thermodynamically and kinetically enhanced at the designated reaction conditions, leading to the need of periodic regenerations of the catalyst. Most of the scientific research on BDH technology is based on the development of improved catalyst formulations to increase the reactor performance [2][3].The effect of metals, the nature of supports, the nature of ligands and the polarity of active species have been investigated to better understand the structure-reactivity relationship and to develop catalysts with higher activity at lower operating temperatures. In this way, it is possible to overcome one of the main limitations for the dehydrogenation process, which is the high coking rate. Another interesting strategy to increase the yield of the dehydrogenation process at lower temperatures is the use of the membrane reactor technology with integrated H_2-selective membranes [4][5]. The selective removal of H_2 from the catalytic bed shifts the equilibrium beyond the thermodynamic restriction of the conventional process, leading to an increase of butadiene production. In this way, it would be possible to achieve same conversions of butane as in the conventional process but working at milder operating conditions. The opportunity to lower the operating temperature will reduce the rate of coke formation on the catalyst increasing the catalyst deactivation timespan. Additionally, the heat duty of the reactors is expected to be drastically reduced, making the overall process more energy efficient [6]. Therefore, the present work aims at assessing the techno-economic feasibility of the membrane reactor integrated process for the dehydrogenation of butane, and this process is compared to the benchmark technology. In this work, the potential application of the membrane reactor technology for BDH, widely used experimentally, is investigated for the first time at industrial level from a process performance point of view. The membrane reactor configuration will be compared with the conventional BDH, which uses packed bed reactors, highlighting the consequent changes in the overall process configuration and the influence of these modifications from a techno-economic point of view.

METHODOLOGY

Two different technologies for the direct dehydrogenation of n-butane into 1,3-butadiene have been simulated with Aspen Plus. The first technology, represented in Fig. 1a, is based on the benchmark CATADIENE process. In the second technology, the conventional reactor is replaced by the membrane-assisted fixed-bed reactor. The goal of this new reactor technology is to reduce the operating reaction temperature, while maintaining the same performance, in terms of conversion, as the benchmark reactors. Due to the lower operating conditions of the reaction zone, the configuration of the Membrane Reactor-Assisted BDH plant (MR-BDH) has few modifications compared to the benchmark, as shown in Fig. 1b.

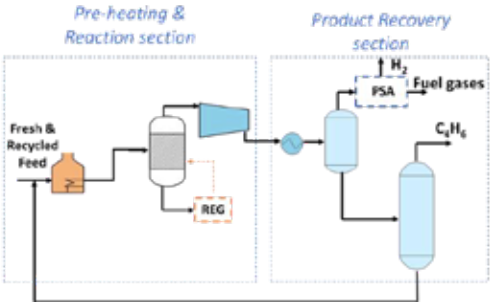

Fig. 1a: Benchmark BDH process scheme.

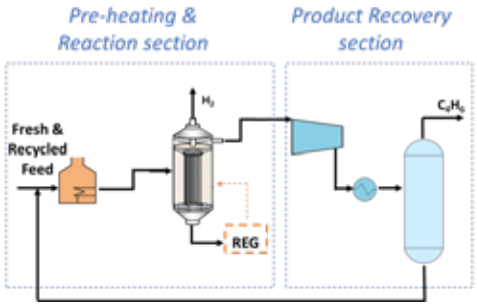

Fig. 2b: Membrane Reactor-Assisted BDH process scheme.

To allow for a fair comparison, both the technologies have been designed with a fixed plant size, equal to a target production of 11,2 kg_{C4H6}/s, which is equivalent to 320 kiloton per year (KTA) of 1,3-butadiene. The analysis of both configurations is performed under the assumptions that the overall reactions are kinetically controlled, and the heat released by the regeneration is used to keep the reactor under isothermal conditions.
Several performance indicators are used to enable a fair comparison of the technical and environmental performance of the processes. The plant performance is calculated using two main types of indexes: one, known as Feedstock-to-Chemical efficiency, accounts for the production of valuable products (i.e. 1,3-butadiene and hydrogen), and the other, known as Overall Energy Efficiency, evaluates the production/consumption of energy.
The economic analysis is performed applying the NETL (National Energy Technology Laboratory) method which differentiates the expenditures of an industrial plant into capital (CAPEX) and operational (OPEX) costs, used to determine the final cost of production of butadiene (COP), according to the following Eq. (1):

$$COP\left[\frac{€}{ton_{C_4H_6}}\right] = \frac{OPEX_{variable} + OPEX_{fixed} + CAPEX}{\dot{m}_{C_4H_6,year}} \quad (1)$$

RESULTS AND DISCUSSION

The results obtained comparing the benchmark and the MR-assisted BDH technologies, reveal that the implementation of membranes for the selective removal of H_2 from the reaction ambient allows to maintain same production capacity as in the benchmark case by lowering the required feedstock of almost 25%. This is mostly due to the more efficient reaction zone, characterized by a lower selectivity to the undesirable cracking products (CH_4, C_2H_6 and C_2H_4), going from 14.4wt% to 13.6wt%, and a higher achievable selectivity to 1,3-butadiene, going from 64.7wt% to 73.3wt%, which allows to have a more efficient downstream separation section. As a result, the overall η_{FTC} can be increased from 57.4% in the benchmark to 74.5% in the novel MR-assisted process. The energy balances of both the technologies, obtained after a detailed heat integration strategy, show that the electricity consumption is three times higher in the benchmark process, which presents a net electricity consumption equal to 1.09 MW_{el}/ton_{C4H6}, compared to 0,31 MW_{el}/ton_{C4H6} in the novel technology. In addition, the total thermal duty per unit of product results to be 62% lower in the MR-assisted plant than in the benchmark, mostly due to the more energy efficient downstream separation section. These three advantages make the MR-assisted technology to have a higher overall plant efficiency, being equal to 66.82%, with respect to the benchmark case, which can reach a total efficiency as low as 50.92%. The reduced energy consumptions in the MR-assisted BDH process allows to improve the carbon footprint of the plant, with a reduction of the total CO_2 emission per unit of product of 20% with respect to the benchmark case, as shown in Fig. 2.

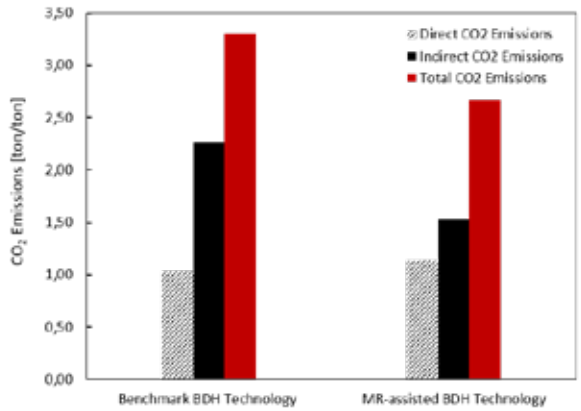

Fig. 2: CO_2 Emissions of the BDH plants.

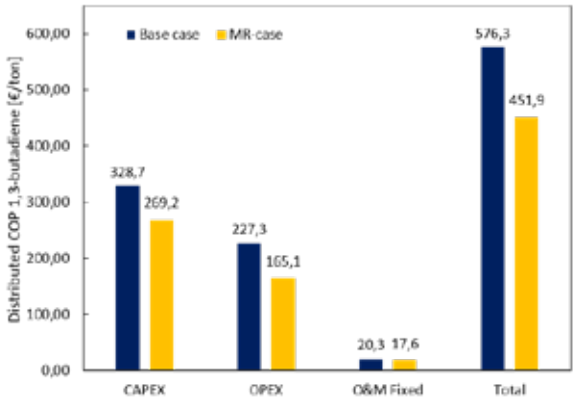

Fig. 3: Distributed COP of the BDH plants.

The MR-assisted technology allows to reduce the specific OPEX per unit of product by 26.5%. This is mostly due to the main savings associated with the feedstock, which has the major impact on the variable costs, and with the utilities. The cost for utilities is higher in the benchmark technology, both due to the larger electricity demand for the turbomachines and due to the higher amounts of cooling water and refrigerant for the condensers and steam for the reboilers of the distillation columns. These costs account for the 21.3% of the total OPEX in the benchmark technology, while for only the 9.6% in the MR-assisted case. At the same time, the better environmental performance of the MR-assisted technology results in a reduced CO_2 emission tax (4.30€/ton), compensating the additional costs associated to the membrane modules. Moreover, the implementation of the membrane reactor technology made the whole plant less intensive, and this can lead to the abolition of a few process equipment and to the reduction in size of some process components. As a result, the CAPEX reduces from 2598.5 M€ in the benchmark to 2130.2 M€ in the novel process. As a main result, the final COP of 1,3-butadiene can be reduced of almost 22%, from 576.3 €/ton$_{C4H6}$ in the benchmark process to 451,9 €/ton$_{C4H6}$ in the MR-assisted process.

CONCLUSIONS
