The techno-economic analysis conducted in this work reveals that the implementation of the membrane reactor technology to produce 1,3-butadiene makes the BDH process more cost efficient and environmentally friendly than the benchmark technology. The use of a membrane reactor technology allows to reduce the final COP by 21.6% with respect to the commercial technology, maintaining the same plant production capacity. Thus, the MR-assisted BDH technology shows great potential to be implemented in the petrochemical industry.

ABSTRACT

A gas-to-power (GtoP) system for power outages is digitally modeled and experimentally developed in this work. The design includes a solid-state hydrogen storage system based on TiFeMn as a hydride forming alloy (5 tanks, total capacity: 110 g H_2) and an air-cooled fuel cell (maximum power: 1.6 kW). In an emergency use case of the system, hydrogen is supplied to the fuel cell, and the waste heat coming from the exhaust air of the fuel cell is used for the endothermic dehydrogenation reaction of the metal hydride. This GtoP system shows fast, stable, and reliable responses from 149 W to 596 W under constant and dynamic conditions. The developed model is based on a network approach, and it is validated under static and dynamic power load scenarios, showing excellent agreement with the experimental results.

Keywords: Gas to power, Hydrides, Hydrogen storage, Fuel cell, Modeling, Hydrogen

INTRODUCTION

In today's society, fossil fuels are becoming an increasing problem, due to the high environmental impact, so the call for alternative energy sources is becoming louder [1-3]. In the last 20 years, much effort has been put into developing systems to integrate renewable sources into the current energy system [4]. The developed experimental integrated systems (renewable energy source + electrolyzer + storage system + fuel cell) present relatively low efficiency and high costs [4]. Therefore, improving the overall efficiency of these integrated systems is demanding.

This work investigates the application of low-temperature metal hydride (TiFeMn) for GtoP systems for stationary emergency power supply. The herein-developed GtoP system (“MH2-Powerbank”) consists of 5 TiFeMn powder-filled MH-tanks with a total weight of 6.7 kg, to supply hydrogen to an air-cooled 1.6 kW fuel cell. This GtoP system is experimentally tested and simulated by applying a novel network simulation approach. The simulation model was implemented in the MATLAB/Simscape environment based on conservation equations. The overall GtoP system efficiency is optimized by utilizing the waste heat of the air-cooled fuel cell as the heat supply for the desorption process of the hydride tanks. Based on the system simulation, the efficiency can be optimized in future work.

MATERIALS AND METHODS

Description of the experimental set-up

Figure 1 shows the basic design of the MH2-Powerbank test stand: a detailed sketch of the system (Figure 1 a) and a photograph of the experimental set-up (Figure 1 b). An amount of 6.7 kg of TiFeMn powder with a theoretical maximum capacity of 1.73 wt.% [5], produced by GKN Powder Metallurgy GmbH and developed within the HyCare project (Hydrogen Carrier for Renewable Energy Storage) was used [6]. The TiFeMn powder was distributed in 5 tanks (each tank of 500 cm^3 made of 316L Stainless Steel, from the company Swagelok), as seen in Figure 1 a. This low-temperature hydride was able to operate at pressures below 50 bar and loaded hydrogen at room temperatures. The 1.6 kW PEM (proton exchange membrane) Fuel Cell was from the type "DBX2000 power backup module" produced by Dantherm Power and needed a hydrogen supply of Grade 3.0 (99.9 %) or higher (Figure 1 a). The fuel cell was cooled with forced convection using a fan that provided airflow at room temperature (Figure 1 a). The heated air entered an air duct and reached the hydride storage tanks (”red arrows”). In this way, the hydride storage tanks were heated with air to carry out the endothermic hydrogen desorption. In order to reduce the thermal losses, the whole system was placed in a closed and isolated cabinet. Several sensors were integrated into the shown experimental set-up to gather data to evaluate the system performance. The temperatures of the MH-tanks (T1-5), the inlet temperature (T6) of the cooling air stream, and the air stream outlet temperature after warming up (AN) were measured. The hydrogen pressure and hydrogen flow from the MH-tanks to the fuel cell were measured by a pressure transducer (P2) and a flowmeter (between the valves V11 and V12), respectively. The air speed from the fuel cell stack to the MH-tank was measured by an anemometer (AN).

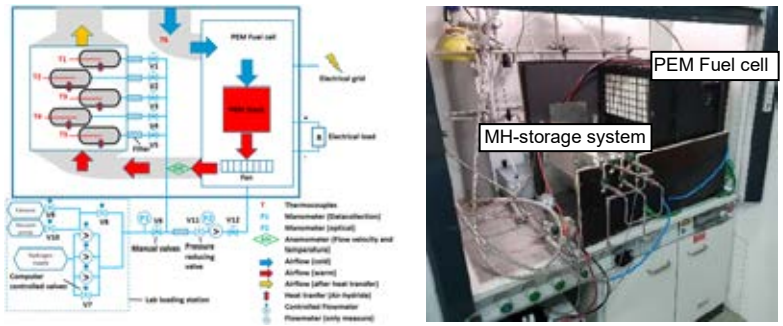

Fig. 1. a) Detailed sketch and b) photo of the MH2-Powerbank [7].

Mathematical model

The system simulation model was developed in the environment MATLAB/Simulink. Utilizing the MATLAB/Simulink included the additional component library Simscape, which contained several mathematical component models. This approach allowed the coupled simulation to form a network. The MH-tanks are modeled in 0D geometry by using the following mass and energy conservation equations (1) and (2), respectively:

$$\epsilon \frac{d\rho_s}{dt} = \dot{m}_{R.rate} \qquad (1)$$

and

$$\frac{d\left(\left(\rho_m c_p\right)_e T_m\right)}{dt} = \dot{Q}_{HE} + \frac{\dot{m}_{R.rate}}{M_{H_2}} \cdot \Delta H \qquad (2)$$

with

$$\left(\rho_m c_p\right)_e = \left(\epsilon \rho_g c_{p,g} + (1-\epsilon)\rho_s c_{p,s}\right)$$

where $\rho_s \left[\frac{kg}{m^3}\right]$ is the density of the solid, $\epsilon\,[-]$ is the porosity of the powder bed and $\dot{m}_{R.rate} \left[\frac{kg}{m^3\,s}\right]$ is the reaction rate per unit volume. In the conservation of energy $\rho_g \left[\frac{kg}{m^3}\right]$ is the density of the gas, $T_m[K]$ is the equilibrium temperature of the gas and solid phases, $c_{p,g} \left[\frac{J}{kgK}\right]$ or $c_{p,s} \left[\frac{J}{kgK}\right]$ is the specific heat capacity of gas or solid, $\dot{Q}_{HE} \left[\frac{J}{m^3\,s}\right]$ is the volume-based heat flow between the heat exchanger (HE) and the hydride, $\Delta H \left[\frac{J}{mol}\right]$ is the molar-based reaction enthalpy, and $M_{H_2} \left[\frac{kg}{mol}\right]$ is the molar mass of hydrogen. These equations provide the basis for the system simulation of MH2-Powerbank in Simscape.

Figure 2 describes the conceptual implementation of the 0D model in the platform MATLAB/Simscape. According to mass and energy conservation, the grey cylinders represent the MH-tanks modeled in Simulink. The yellow boxes represent the heat exchange between the tanks and the airstream coming from the fuel cell. The MH-tanks are assembled via a gas reservoir interphase of Simscape (blue box). As seen, the pipes (Figure 2: blue cylinders) are also represented and interconnected. The air velocities around each tank and coming from the exhaust of the fuel cell are represented by $v_{T1-T5}(t)$. $T_A\,(t)$ and $v_A(t)$ represents the temperature and velocity measured in the anemometer (Figure 1 a). These values were used as the boundary conditions.

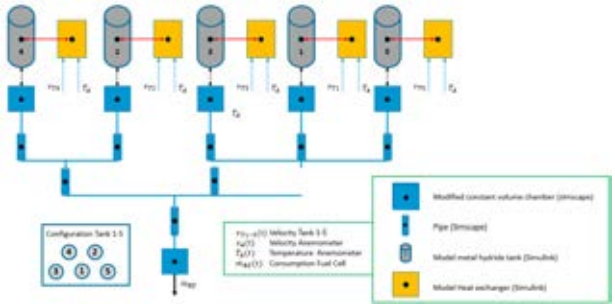

Fig. 2. Implementation of MH2-Powerbank in MATLAB Simulink/Simscape [7]

RESULTS AND DISCUSSION

As one of the main results of this investigation, the integrated MH-storage and fuel cell system was tested in a daily dynamic load. This scenario is essential to test the system for emergency power supply purposes. Thus, a representative household scenario on Saturday afternoon in winter from 5:00 p.m. with an annual power consumption of 1000 kWh/year was chosen. Figure 3 shows the results of the temperature profiles from tanks 1 and 3 (Figure 3 c), the system pressure drop (Figure 3 a) and fuel cell power (Figure 3 b). As seen, the power requirements vary in small steps, from 149 W to a maximum of 215 W every 15 min (Figure 3 b).

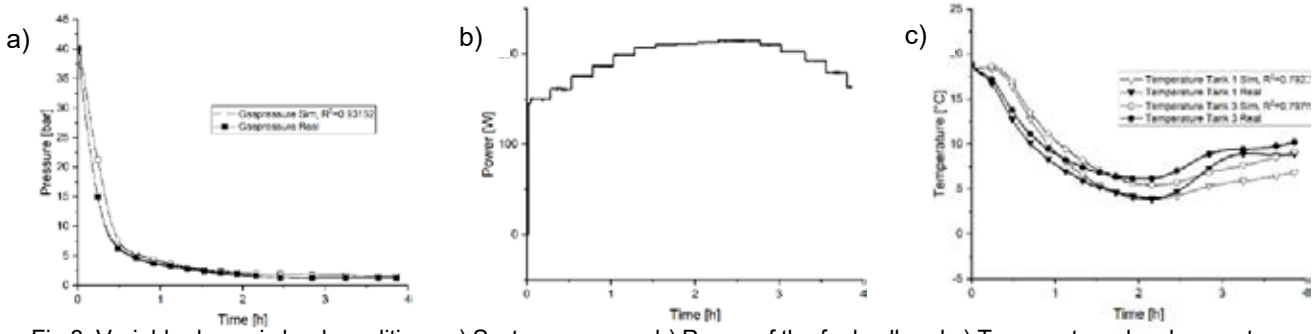

Fig 3. Variable dynamic load conditions a) System pressure b) Power of the fuel cell and c) Temperature development.

The observed substantial pressure drop (Figure 3 a) is mainly due to the hydrogen removal from the gas phase of the tanks. As soon as the pressure drops below the dehydrogenation equilibrium pressure of the hydride material, the pressure driving force increases further. Hence, a more significant hydrogen amount is desorbed from the hydride, strongly reducing the pressure curve slope. Minimum temperature values of 3.57 °C after 1.9 h and 5.68 °C after 1.8 h are reached in tanks 1 and 3, respectively (Figure 3 c). The temperature drop to the minimum value is due to the endothermic desorption reaction. In tank 1, the reached minimum temperature level is lower because the heat exchange with the waste heat airflow of the fuel cell is not as effective as in tank 3. In this regard, the temperature profiles in the last measurement stage (Figure 3 c) do not present the same behavior. For both tanks, the temperature rises after 3 h: 8.9 °C for tank 1 and 9.0 °C for tank 3. The observed temperature increase is caused by the reduced consumption of the fuel cell. The system model shows a good agreement with the experimental results, particularly for the pressure profile, and the small differences between the experimental and simulated temperature profiles (Figures 3 a and c).

CONCLUSIONS

The digital and experimental development of a gas-to-power system (GtoP) for power outages has been successfully demonstrated. Such GtoP system, called MH2-Powerbank, is composed of a 1.6 kW air-cooled PEM fuel cell and a TiFeMn based MH-system. The MH2-Powerbank can provide energy under different scenarios in a power range between 149-596 W. The waste heat from the air-cooled fuel cell is effectively utilized as a heat source for the dehydrogenation process of the MH-system. The dynamic consumption scenario, shown here, demonstrates that the concept of the MH2-Powerbank system is suitable for the emergency power supply of households, due to its fast and reliable response to the power load changes. The novel developed 0D model, using the MATLAB/Simscape library, shows the advantages of low computational cost and full coupling between the fuel cell and the MH-system. This work presents an experimental and digital strategy for integrating MH-systems in any hydrogen network for GtoP system applications and potential dimensioning.

ACKNOWLEDGEMENT

The authors thank Mr. Jürgen Stolzenberger for the great support with the programming in Labview. Thanks to the colleagues from the workshop at the HZ-hereon, who helped with the construction of MH2-Powerbank.

PROCESS IMPLICATIONS OF ELECTRIFYING AMMONIA PRODUCTION

ABSTRACT

The current ammonia production plants - Steam Methane Reforming (SMR) and Haber-Bosch (HB) - are responsible for 1.2% of global CO_2 emissions. As more sectors are shifting to electrification, so does the NH_3 industry as shown by the amount of studies focusing on electrolysers and Pressure Swing Adsorbers (PSA) to replace SMR. Haber-Bosch itself is being questioned as a new alternative technology is emerging: Chemical Looping (CL). Such transformations imply changes to the current process. This work assesses such implications by comparing 2 alternative scenarios with the conventional case. In terms of emissions, the electrification is clearly benefic with a cut of 74-95% when using wind energy. The replacement of SMR by electrolysers and PSA also improves the energy efficiency, as >60% of the energy consumption in conventional plants originates from the compressors and heat integration. Finally, the combination of Alkaline Electrolysers (AE) and CL is determined as the most suitable for small-scall flexible and economical installations.

Keywords: Ammonia synthesis, Hydrogen production, Electrolysis, Electrification, Green hydrogen

INTRODUCTION

There is no doubt that the climate crisis is the number one issue the world has to tackle. As a consequence, paradigm shifts are happening globally to reduce greenhouse gas emissions, be it on small scales such as in individuals' routines, or on larger scales such as in the transport, building, power and industrial sector. Looking closer at the chemical sector, it was responsible for 1.4 $GtCO_2$ in 2019, which is equivalent to 4.2% of global CO_2 emissions [1][2]. Within those 4.2%, 1.2% are attributable to ammonia production and its methane-based Haber-Bosch (HB) process, making it one of the largest greenhouse gas emitters within the chemical sector [3][4]. Solutions to reduce its carbon footprint could therefore have quite a significant impact on global emissions. Lately, electrification has been one of the main focuses when assessing decarbonizing solutions for different sectors [5], and the chemical industry is one of them. Several studies have assessed the electrification of NH_3 production by replacing the standard Steam Methane Reforming (SMR) by water electrolysis [3][4][6]. Implementing such a change in technology implies changes in the process. The main objective of this work is to review these implications by comparing three scenarios. Scenario 0 is the current situation of NH_3 production: the combination of SMR and HB. Scenario 1 replaces SMR by a Solid Oxide Electrolyser (SOE). Finally, Scenario 2 replaces SMR by an Alkaline Electrolyser (AE) and HB by Chemical Looping (CL).

SCENARIOS DESCRIPTION

Scenario 0: SMR + HB

Scenario 0 is the reference scenario as it describes the current situation. Ammonia is produced through a Haber-Bosch process which is fed with a H_2/N_2 mix produced by Steam Methane Reforming (Fig. 1a). The combination of SMR and HB currently represents the Best Available Technique (BAT) for NH_3 production as it yields the highest efficiency and lowest carbon emissions while being the most economical route for large scale NH_3 production [3][4].

The SMR is composed of several units. It is first supplied with methane (CH_4) and air which enter a primary and secondary reforming reactor. The reforming is endothermal. Its primary reactor is thus heated by a methane-fed furnace while the secondary reactor is autothermal. The latter generates a gas mixture which comprises N_2, H_2, CO and unreacted steam and CH_4. It enters a water-gas shift reactor (WGS) where the CO reacts with steam to produce H_2. This reaction is exothermal, and heat should be removed to decrease the CO equilibrium concentration. The mixture at the output, stripped from most of the CO, successively goes through an acid gas removal unit and a methanator to respectively strip the remaining CO_2 and CO. The product mixture is sent to the HB loop. It is first compressed and pre-heated before entering the HB catalytic reactor. The resulting feed is then condensed to separate the NH_3 from the remaining reactants and inerts. The latter are partially purged and recycled to the reactants feed. Overall, this system works at high temperatures and pressures (550°C and 250 bar). [4][6]

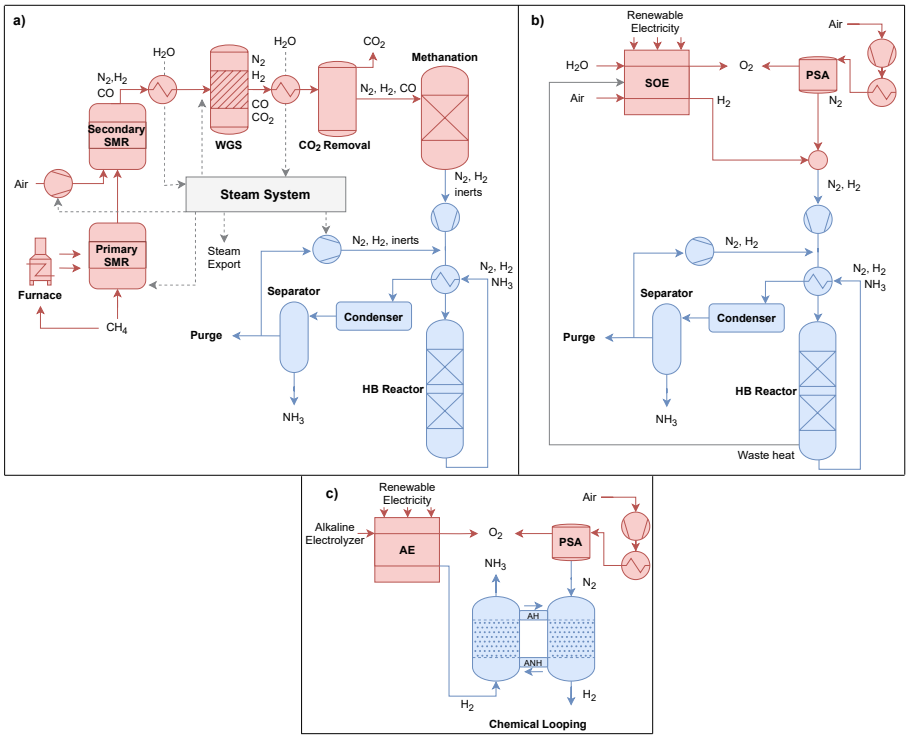

Fig. 1. Process diagrams of Scenario 0 (a), 1 (b) and 2 (c). Each has a H2/N2 production unit (red) and a NH_3 production unit (blue)

Scenario 1: SOE + HB

The first alternative scenario involves a change of technology by implementing a Solid Oxide Electrolyser (SOE) to replace the SMR process while keeping the HB loop (Fig. 1b). As the SOE only produces H_2, the N_2 feed is produced via Pressure Swing Adsorption (PSA). Both technologies are powered electrically. Assuming that the electricity comes from renewable sources, the hydrogen produced here can be qualified as Green H_2 [7]. The SOE unit can be represented as a single block, as opposed to the SMR process which is a succession of numerous units. It is fed with air and water and generates H_2. At the output, the H_2 is separated from the unreacted water and mixed with the N_2, which is produced through the PSA unit fed with air. The resulting mixture is then compressed and heated before being sent to the conventional HB loop. In terms of operating conditions, the SOE must operate at high temperature and pressure to match the HB conditions (650°C and 550 bar) and the HB reactor waste heat can therefore be recycled to the SOE. [6]

Scenario 2: AE + CL

The second alternative scenario implies a change in both hydrogen and ammonia production units. The SMR is replaced by an Alkaline Electrolyser (AE) for the H_2 production and a PSA for the N_2. The HB loop is replaced by a Chemical Looping (CL) unit (Fig. 1c). Just as in the first alternative scenario, the electrolyser is represented by a single block. This time, it is only fed with an alkaline electrolyte. In this scenario, however, the H_2 output is not mixed with the N_2 output. In fact, both are sent to two distinct entries in the CL reactor. The latter technology relies on a decoupling of the conventional catalytic reaction that normally takes place in a single HB reactor. The CL reactor is here composed of 2 separate reactors connected in a cycle and in which two sub-reactions are conducted. The CL process of interest in this case is the one proposed by Gao et al. which uses alkaline earth metal hydrides (AH) and imides (ANH). During the first step, N_2 is fed into the first reactor and reduced by the H in the AH catalysts, producing ANH intermediates. The latter are sent to the second reactor and undergo a hydrogenation by the H_2 feed. This last step produces the NH_3 but also regenerates the metal hydride which is recycled back to the first step. In terms of operating conditions, both AE and CL run at a relatively low temperature (~100°C) and pressure (1 bar) compared to the previous scenarios. [9]

COMPARISON AND DISCUSSION

To compare the three scenarios, four characteristics are examined: emissions, energy losses, scalability and flexibility. In terms of emission, it appears that the conventional process described in Scenario 0 is the most polluting. Specifically, it emits in average 2.0-2.5 ton $CO_{2,eq}$ per ton NH_3, and these numbers would be higher for smaller plants.

In comparison, only 0.12-0.53 ton $CO_{2,eq}$ are emitted for a wind powered plant in Scenario 1 and 2, which is 74 to 95% smaller [4][10].

This trend is comparable regarding energy intensity. In fact, the steam compressors alone account for 60% of the energy consumption in Scenario 0. In addition, the heat integration system and the HB purge also take part in decreasing the energy efficiency [4]. Considering the steam system would not be present anymore in both Scenario 1 and 2, this is a sensible optimisation in energy efficiency. The losses due to the purge in those scenarios are also negligible as almost no inerts are present in the feeds [6]. Furthermore, Chemical Looping in Scenario 2 allows an in-situ separation of the NH_3, which allows more energy savings as the separation system in HB is very energy-intensive [11].

The scalability aspect is directly linked to the latter observations. First, due to the absence of any steam management units (compressors and steam turbines) when using electrolysers, and due to the latter's compactness, both electrified scenarios are suitable for small-scale installations. Then, regarding pressure, the NH_3 production cost being affected by the operating pressure, Scenario 1 and its high-pressure conditions make it less favorable to be scaled down [12]. This makes Scenario 2 the best to build small and agile production plants at low capital costs and flexible operation to cope with the intermittent nature of renewable energy.

CONCLUSIONS

- The carbon intensity in the current NH_3 production can be cut by 70-95% by electrifying the process.
- Replacing the SMR by electrolysers and PSA allows energy savings of at least 60% and avoid the need of a purge.
- It also allows more compact and straightforward installations.
- Replacing HB by CL avoid the use of an energy intensive separation unit.
- Combining AE and CL allows ambient operating pressure, making it favorable for small-scale agile plants.

ABSTRACT:

The utilization of hydrogen fuel in internal combustion engine is one step towards the implementation of zero-carbon foot print. The main drawback is higher PPM of NOx emission. Numerous techniques are applied by different researchers to bring NOx emission under EURO-VI emission standards. The experiments have been performed at different spark timings (0 to 60°CA bTDC), hydrogen percentages (0 to 40%) in CNG fuel, EGR rates (0 to 35.8%), MAP (65 to 178 kPa), speed (700 to 2000 rpm) at ***lambda*** = 1.0. The simulation of NO_x emission has been conducted by support vector machine. The sensitivity analysis has been carried out for the selection of best combination of input variables for the formation of NOx emissions that are: controllable parameters (MAP, hydrogen fractions in CNG, EGR rate, spark timing & RPM) and combustion parameters (maximum pressure, IMEP, adiabatic flame temperature, HRR & COV). The minimum mean absolute percentage error is 7.6996% & MRE is 57.05 corresponding to the best combination (RPM-MAP-ST-EGR-P_{max}/T_{ad}).

Keywords: Hydrogen enriched compressed natural gas, NOx emission, Support Vector Machine.

INTRODUCTION

The global warming, depleting in hydrocarbons and emission hazards are the main factors that encourage the policy makers and scientists to look forward the other possible alternative resources. The hydrogen fuel is an alternative fuel to achieve the zero-carbon foot prints for transportation sector. Huang et al.[1] & Ma et al.[2] have performed an extensive work on hydrogen enriched compressed natural gas at different lean burn operations and EGR ratios in heavy duty spark ignition engine. Rao et al.[3–5] have simulated the quasi-dimensional combustion model of HCNG engine under a wide range of operating conditions. They have coupled the thermal NOx mechanism with quasi-dimensional combustion model of SI engine. They have also conducted the mathematical modelling of NO_x emission in HCNG engine under a wide range of operating conditions. Mehra et al. [6] have applied the artificial neural network for training of hydrogen enriched compressed natural gas at lean burn operations. Huang et al. [7] compared the quadratic polynomial, neural network, and support vector machine for tuning of engine torque, BSFC and NO_x emission of HCNG engine. They have concluded that support vector machine has better prediction accuracy as compare to the other two algorithms. Duan et al.[8–10] analyzed the particle swarm optimization (PSO), GRID and genetic algorithm of SVM in terms of engine torque, BSFC and NO_x emission at different operating conditions in HCNG engine. They have concluded that PSO optimization is the best one with respect to regression correlation = 0.97. They have also iterated the different factors such as: penalty factor, width and loss function for training of NOx emissions in HCNG engine. They have also studied the laminar burning speed and maximum in-cylinder pressures of HCNG engine at different hydrogen fractions in CNG fuel, equivalence ratios and electric fields in constant volume combustion chamber and support vector machine. The thermal NOx emission has a large prediction error. The main parameters in Zeldovich' mechanism are combustion pressure and temperature. The motivation of this research is to train the NOx emission of HCNG engine under EURO-VI emission standard by support vector machine. The other objective is to analyze the combination of different parameters such: hydrogen percentage in CNG fuel, spark timing, speed, MAP, EGR ratios, maximum pressure, indicated mean effective pressure, adiabatic flame temperature, heat released rate and coefficient of variance. The best combination is RPM-MAP-ST-EGR-P_{max}/T_{ad} with the combination of four controllable variables and one combustion parameter.

METHODOLOGY

The experiments have been conducted under a wide range of operating conditions to obtain PPM of NOx emission in HCNG engine at different spark timings (0 to 60°CA bTDC), hydrogen percentages (0 to 40%) in CNG fuel, EGR rates (0 to 35.8%), MAPs (65 to 178 kPa) and speed (700 to 2000 rpm) at lambda= 1. The maximum pressures, indicated pressures, heat released rates and coefficient of variances have been attained with aid of Kistler KIBOX combustion software. The adiabatic flame temperatures are calculated by balanced chemical equation. The total 666 sample points have been utilized for the training purpose and 59 operating conditions for the testing purpose. The PSO algorithm and radial based function have been applied for the optimization of support vector machine with tuning

of penalty kernel (c) and intensive loss function (g) at kernel width (p=0.01). The sensitivity analysis has been carried out with different combinations of independent variables.

RESULTS & DISCUSSION:

The support vector machine has been applied as a tool for sensitivity analysis of different independent variables related to the controllable parameters (MAP, hydrogen fractions in CNG, EGR rate, spark timing & RPM) and combustion parameters (maximum pressure, IMEP, adiabatic flame temperature, HRR & COV) as shown in figure 1. The best combination for the prediction of NO_x emission with respect to independent variables has been chosen on the basis of mean absolute percentage errors (MAPE), maximum regression errors (MRE) and squared regression (R^2). The PSO algorithm has been applied for tuning the penalty factor (c) & loss width (g) at function width (p=0.01). The first combination (IMEP-P_{max}-Tad-MAP-EGR) consists of three combustion variables (maximum pressure, indicated mean effective pressure & adiabatic flame temperature) and two controllable parameters (manifold absolute pressure & EGR rate). The MAPE=8.5215%, MRE=76.9089% and R^2=0.9859 with tuning factors c= 207.0429, g=6.5566 & p=0.01. The second combination (H_2-EGR-IMEP-P_{max}-T_{ad}) consists of three combustion parameters (indicated mean effective pressure, maximum pressure & adiabatic flame temperature) and two controllable factors (hydrogen fractions in CNG & EGR rate). The MAPE=10.3135%, MRE=94.1157% and R^2=0.9716 with optimized factors c= 814.909, g=9.0673 & p=0.01. The third combination (MAP-ST-EGR-H_2-P_{max}/T_{ad}) consists of one combustion factor. (Maximum pressure over adiabatic flame temperature) and four controllable factors (hydrogen fractions in CNG, EGR rate, manifold absolute pressure & spark timing). The MAPE=8.4497%, MRE=79.3387% and R^2=0.9906 with optimized factors c= 207.0429, g=6.5566 & p=0.01. The fourth combination (RPM-MAP-ST-EGR-P_{max}/T_{ad}) consists of one combustion variable (maximum pressure over adiabatic flame temperature) and four controllable parameters (speed, EGR rate, manifold absolute pressure & spark timing). The MAPE=7.6996%, MRE=57.04852% and R^2=0.9826 with tuning factors c= 276.0174, g=3.9427 & p=0.01. The fifth combination (RPM-ST-MAP-H_2-P_{max}/T_{ad}) consists of one combustion parameter (maximum pressure over adiabatic flame temperature) and four controllable variables (speed, manifold absolute pressure, hydrogen fractions & ignition timing). The MAPE=7.9125%, MRE=116.2818% and R^2=0.9753 with iterated constants c= 814.909, g=9.0673 & p=0.01. The sixth combination (RPM-ST-EGR-H_2-P_{max}/T_{ad}) consists of one combustion parameter (maximum pressure over adiabatic flame temperature) and four controllable variables (speed, EGR rate, hydrogen fractions & spark timing). The MAPE=14.8866%, MRE=116.2818% and R^2=0.9753 with tuning of variables c= 207.0429, g=6.5566 & p=0.01. The seventh combination (RPM-MAP-ST-EGR- P_{max}/(IMEP $_x$ T_{ad})) consists of one combustion parameter (maximum pressure over the product of adiabatic flame temperature and indicated mean effective pressure) and four controllable variables (speed, EGR rate, ignition timing and manifold absolute pressure). The MAPE=8.9920%, MRE=113.1708% and R^2=0.9900 with tuning of variables c= 276.0174, g=3.9427 & p=0.01. The eight combination (P_{max}-IMEP-COV-HRR-T_{ad}) consists of five combustion parameters that included (maximum pressure, indicated mean effective pressure, coefficient of variance, heat released rate & adiabatic flame temperature). The MAPE=15.1538%, MRE=172.0425% and R^2=0.9651 with tuning factors c= 737.4321, g=5.7792 & p=0.01

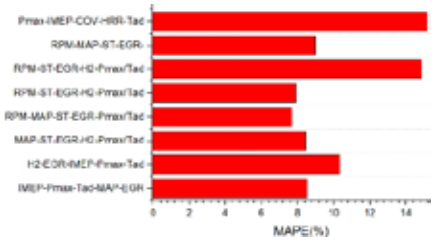

Fig 1(a) MAPE

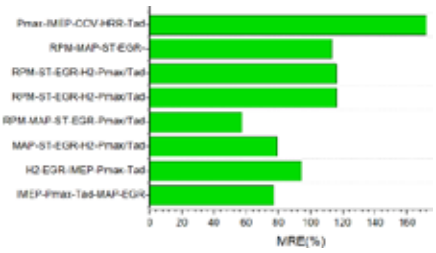

Fig 1(b) MRE

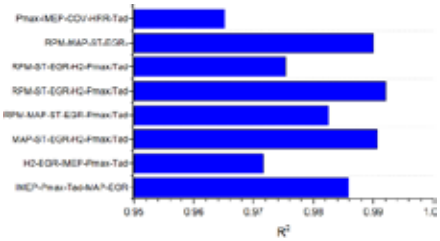

Fig 1(c) R^2

CONCLUSIONS

1) The best combination of input variables is RPM-MAP-ST-EGR-P_{max}/T_{ad} with respect to MAPE=7.6996 & MRE=57.04852 as shown in fig (2).

2) The best combination of independent parameters is RPM-ST-EGR-H_2-P_{max}/T_{ad} with respect to R^2=0.9920.

3) The order of combination in terms of NOx emission is as follows: (RPM-MAP-ST-EGR-P_{max}/T_{ad} > RPM-ST-EGR-H_2-P_{max}/T_{ad} > MAP-ST-EGR-H_2-P_{max}/T_{ad} > IMEP-P_{max}-Tad-MAP-EGR > RPM-MAP-ST-EGR-$P_{max}/(IMEP_x T_{ad})$ > H_2-EGR-IMEP-P_{max}-T_{ad} > RPM-ST-EGR-H_2-P_{max}/T_{ad} > P_{max}-IMEP-COV-HRR-T_{ad}.

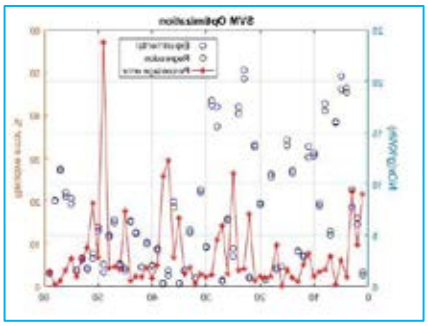

Figure 2. Best combination

ABSTRACT

The CO_2 methanation reaction was investigated over bimetallic Ni-NM catalysts supported on Pr-doped CeO_2, where NM represents a noble metal (NM = Ru, Pt, Rh, Pd and Ir). 10% Ni and 1% NM were loaded over a mesoporous Pr-CeO_2 support via co-impregnation and directly reduced at 400°C, without prior calcination. The prepared catalysts were characterized via XRD, N_2-physisorption and HAADF-STEM along with EDS mapping. The addition of 1% Ru and Rh was shown to improve the dispersion of the metallic Ni phase and reduce pore blockage upon impregnation. Catalytic activity evaluation revealed that the addition of 1% Ru led to a remarkable increase in the catalytic activity, especially at lower temperatures. Pt and Ir addition led to minor changes in activity, whereas Rh and Pd incorporation surprisingly reduced CO_2 conversion. The most active 1% Ru, 10% Ni/ Pr-CeO_2 catalyst was shown to be particularly stable over a 50h time-on-stream experiment at 325°C, with CO_2 conversion and CH_4 selectivity values at 80% and 99.5% respectively.

Keywords: Power-to-Gas, Synthetic natural gas, CO_2 methanation, Bimetallic catalysts, Noble metals

INTRODUCTION

Global warming induced by anthropogenic CO_2 emissions is increasingly becoming a major concern. On the other hand, the intermittency in renewable energy production and problems associated with the handling, storage and transportation of hydrogen undermine the efforts made to decarbonize the energy sector. The CO_2 methanation reaction attempts to tackle both problems by utilizing captured CO_2, as well as green hydrogen produced via water electrolysis, for the production of high energy density synthetic natural gas, in an overall carbon neutral process [1-3]. Ni-based catalysts are often favoured for the CO_2 methanation reaction due to their high activity and the low cost of Ni [1,3]. On the other hand, noble metal catalysts can offer a much higher activity at lower temperatures, as well as improved stability, but they are being held back from industrial implementation due to their prohibiting cost [3]. Thus, a lot of research has been focussed on the creation of bimetallic Ni-NM (NM=Noble Metal) catalysts with a very low noble metal content, aiming to exploit the Ni-NM synergy and achieve a high catalytic activity at low temperatures, without greatly increasing the material cost [1]. In this work, we prepared 1% NM, 10% Ni catalysts loaded over a mesoporous sol-gel prepared Pr-doped CeO_2 support with a tailored pore structure, to achieve improved metal dispersion. The active metals were introduced via co-impregnation and reduced directly in-situ without prior calcination. The prepared catalysts were characterized via XRD, N_2-physisorption and HAADF-STEM with EDS mapping, whereas their catalytic activity was evaluated for the CO_2 methanation reaction.

MATERIALS AND METHODS

The Pr-doped CeO_2 support ($Ce_{0.9}Pr_{0.1}O_{2-\delta}$) was prepared via a modified Pechini method. At first, citric acid and the corresponding metal nitrates ($Ce(NO_3)_3{\cdot}6H_2O$ and $Pr(NO_3)_3{\cdot}6H_2O$) were dissolved in ethylene glycol at 30 min intervals at 60 °C, under stirring. The molar ratio of ethylene glycol: citric acid: total metal cations was set at 15:1.5:1. The temperature was then increased under stirring to 130 °C for 2 h to promote polycondensation between citric acid and ethylene glycol. The polymer gel was then further dried at 130 °C and calcined at 400 °C for 1 h and 500 °C for 4 h. Ni and the noble metals (NM = Ru, Pt, Rh, Pd, Ir) were subsequently introduced to the supports via a single wet impregnation step (co-impregnation) using calculated amounts of $Ni(NO_3)_2{\cdot}6H_2O$ and a noble metal precursor salt ($Ru(NO)(NO_3)_x(OH)_y$, $[Pt(NH_3)_4](NO_3)_2$, $RhCl_3{\cdot}xH_2O$, $PdCl_2$, $IrCl_3{\cdot}xH_2O$) to obtain a final Ni loading of 10 wt% and final noble metal loading of 1%. The metal salts were first dissolved in 100 ml of d-H_2O, followed by the addition of the support powder and after water evaporation, the resulting slurry was dried at 90 °C overnight. The dried powders were

reduced under H_2 flow at 400 °C for 1 h and named as 1NM10Ni (NM = Ru, Pt, Rh, Pd, Ir). Following the synthesis, the catalysts were characterized via XRD, N_2 physisorption, TEM, HAADF STEM and EDS mapping.

Catalytic tests were carried out at atmospheric pressure in a continuous flow fixed-bed quartz reactor (I.D. = 0.9 cm). Evaluation of the catalytic activity as a function of reaction temperature was performed under Experimental Protocol #1. 0.24 g of the catalyst, diluted with quartz sand till 0.5 g, were initially loaded into the quartz reactor. The total gas flow rate was set at 100 ml min^{-1} (10% CO_2, 40% H_2 and 50% Ar), while the reactor temperature was varied between 200 °C and 400 °C, remaining for 30 min at each temperature step to achieve steady-state. In Experimental Protocol #2, the catalytic stability of the catalysts was evaluated during 50h time-on-stream at a constant temperature of 325 °C. The gas composition in the reactor outlet was analyzed online by gas chromatography.

RESULTS AND DISCUSSION

XRD patterns of the reduced catalysts (Fig. 1a) reveal the presence of diffraction peaks attributed to the fluorite lattice of CeO_2. The small diffraction peak at $2\theta \approx 44.5°$ is indicative of the presence of the crystalline metallic Ni phase, whereas diffraction peaks attributed to the noble metals could not be distinguished, either due to their low loading and high dispersion, or due to alloying with the Ni metal phase. The incorporation of Ru, and especially Rh, led to a broadening of the Ni^0 (111) peak (Fig. 1b), thereby leading to a reduced Ni crystallite size (17 nm and 12 nm for 1Ru10Ni and 1Rh10Ni respectively, compared to 19 nm for 10Ni), while the introduction of the other noble metals did not greatly affect the Ni dispersion. N_2 physisorption reveals a mesoporous structure for all catalysts (Fig. 1c, type IV isotherm with a hysteresis loop). 1Ru10Ni and 1Rh10Ni exhibit a higher surface area (47 m^2/g and 45 m^2/g, compared to 40 m^2/g for 10Ni), which could be attributed to reduced pore blockage via the higher active metal dispersion. Furthermore, HAADF-STEM coupled with EDS mapping for the 1Ru10Ni catalyst (Fig. 1d) shows the presence of medium-sized Ni nanoparticles, while Ru appears to be homogeneously dispersed over the catalyst.

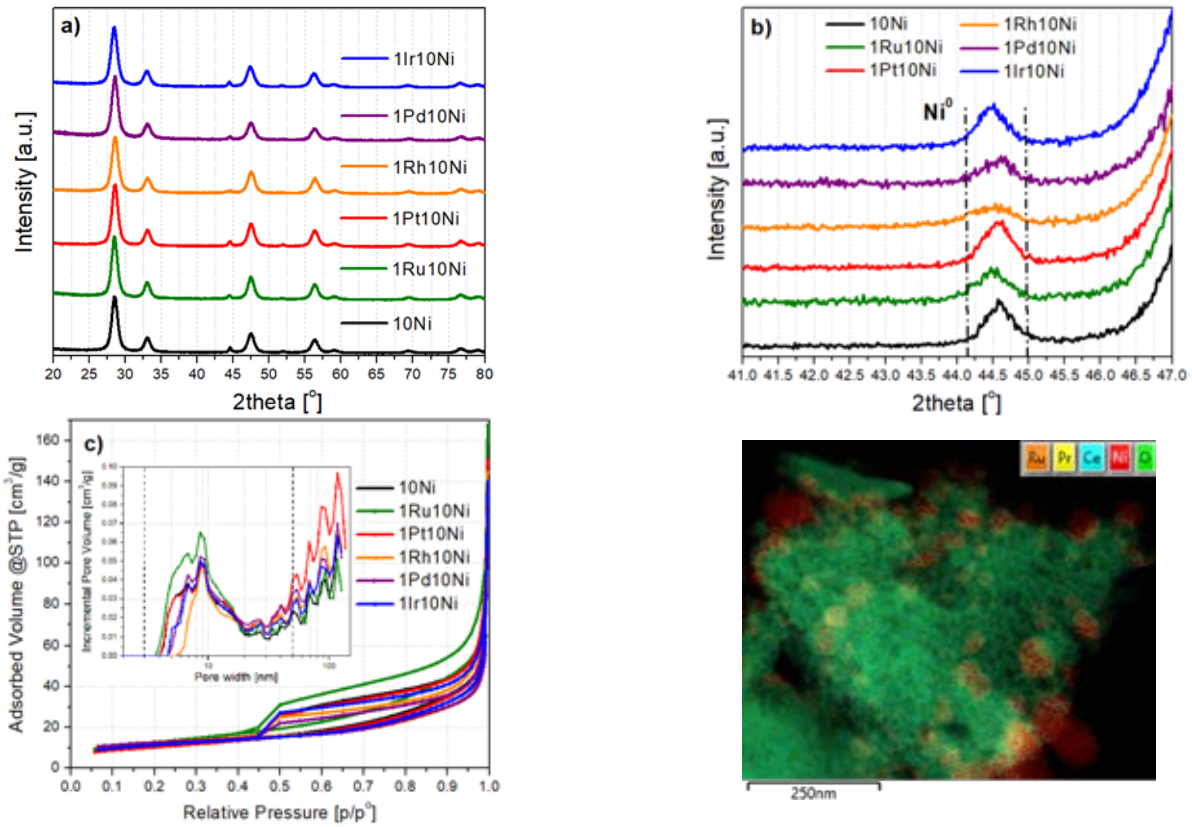

Fig. 1. (a,b) X-ray diffractograms with (b) focussing on the Ni^0 (111) reflection region. (c) N_2 physisorption isotherms and pore size distribution (inset) of the reduced catalysts. (d) HAADF-STEM and EDS elemental mapping image of the 1Ru10Ni reduced catalyst.

Fig. 2a shows the evolution of the catalytic performance as a function of reaction temperature. Among all the noble metal promoters, the addition of 1% Ru led to by far the best improvement in the catalytic activity, which was especially apparent at lower temperatures. As a result, the bimetallic 1Ru10Ni catalyst led to a drop in the

temperature for 50% conversion (T_{50}) by around 50 °C compared to the monometallic 10Ni catalyst, while also improving the low-temperature CH_4 selectivity (Fig. 2b). This can be attributed to a favourable Ni-Ru synergy, where Ru can greatly promote the reducibility, dispersion and CH_4 producing capability of the Ni phase, while also providing additional CO_2 methanation active sites [1,4]. The addition of Pt led to negligible differences in activity but favored the reverse water-gas shift reaction at low temperatures [4]. Interestingly, Ir promoted the low-temperature activity and CH_4 selectivity but hampered the catalytic activity at higher temperatures, indicating a major change in the reaction pathway. On the other hand, the introduction of Rh and Pd greatly decreased the catalytic activity but maintained a high CH_4 selectivity. In the case of Rh, this has also been reported by other works [1,4]. The 1Ru10Ni catalyst underwent a further 50h time-on-stream experiment at 325 °C (Fig. 2c), which showed a negligible drop in catalytic activity, with CO_2 conversion and CH_4 selectivity values stabilizing at around 80% and 99.5% respectively.

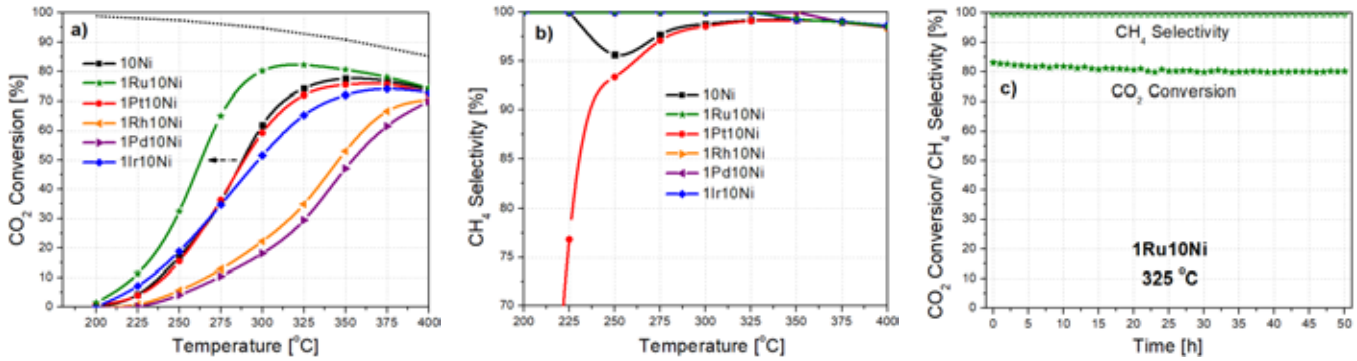

Fig. 2. (a) CO_2 Conversion and (b) CH_4 selectivity of the catalysts as a function of reaction temperature; Reaction conditions: Experimental Protocol #1. (c) CO_2 Conversion and CH_4 selectivity for the 1Ru10Ni catalyst at 325 °C as a function of reaction time; Reaction conditions: Experimental Protocol #2.

CONCLUSIONS

This study reported on the synthesis of bimetallic 1% NM, 10% Ni catalysts (NM = Ru, Pt, Rh, Pd and Ir) supported on Pr-doped CeO_2 for the CO_2 methanation reaction. The introduction of Ru and Rh could promote the dispersion of Ni and reduce pore blockage. Catalytic activity evaluation evidenced that Ru was the sole noble metal able to dramatically enhance the catalytic performance, by providing a 50 °C decrease in the T_{50} due to a favorable Ni-Ru synergy. The 1% Ru, 10% Ni/ Pr-CeO_2 catalyst could provide a stable catalytic performance with around 80% CH_4 yield at just 325 °C.

ABSTRACT

According to many studies, economic growth is closely correlated with energy consumption. Specifically, electricity is required in the regional development to support all residential, government, or private agencies and industrial sectors. Unfortunately, because of unexpected low demand due to a complex economic system, the increase in power generation is predicted to result in an oversupply. Power-to-Gas is a vital part of a future renewable energy system to convert water into hydrogen. Surplus electricity can be utilized by adopting this technology via the electrolysis of water to produce hydrogen; therefore, it can be stored or converted into other energy carriers. The pre-feasibility of investing in hydrogen production is investigated in the Java-Bali grid of the Indonesian power system, considering volatilities and future uncertainties in the region as background. Some scenarios are evaluated for different parameters such as electricity demand projection, electrolyzer cost and efficiency, including plant capacity factor. With a very large electrolyzer, operating with an efficiency of about 70% for about 8000 hours per year, the annual hydrogen production potential would be 600-900 Mt of hydrogen, assuming 50-80 kWh could produce 1 Kg of H_2. A proper approach to the cost reduction in raw material procurement, power generation, and related H_2 facilities should be taken and established. Therefore, the overall H_2 production cost can be minimized. Further investigation will be conducted for storage scenarios, including distribution strategies.

Keywords: Hydrogen, Power-to-Gas, Surplus electricity, Electrolyzer

INTRODUCTION

Rapid economic growth necessitates energy use, particularly electricity, for regional developments. Energy is required in all sectors, including residences, government agencies, offices, and industry, implying that the availability of electricity is critical for a better life and a rising economy. Unfortunately, because the available electricity continues to expand in significant quantities despite low demand, the increase in power generation is expected to result in an oversupply. Due to the mismatch between power supply and demand, a period of excess energy (or excess generation) arises as this increase in generation growth increases [1]. Keeping the power system dynamic is essential to export, absorb, or reduce surplus electricity as soon as possible.

Suppose it cannot be addressed with the correct approach. In that case, increasing the amount of excess energy from installed capacity undermines the reason for obtaining high penetration of renewable energy sources. In this context, it is necessary to widen the scope of decarbonization goals to include the absorption of excess energy from the grid for use in transportation and gas systems. PtG and PtL (Power-to-Gas and Liquids) are frequently mentioned as vital parts of a future renewable energy system [2]. Most PtG systems use electrolysis to convert water into hydrogen. Several excellent reviews have been conducted on general electrolysis technologies, including developments in alkaline electrolysis [3], PEM electrolysis [4], and solid oxide electrolysis [5]. The H_2 obtained can be used directly as a fuel or stored or converted into other carriers such as syngas, methane, or LPG. The generated gas can further be distributed, stored, and used without political or geographical constraints [6]. It can also act as power storage by converting the gas back into electricity.

The main objective of this study is to identify the operating profile of the electrolyzer required if an oversupply of electricity in the Java-Bali system is utilized and to estimate the contribution that this energy can make to the generation of hydrogen as storage or secondary form of energy. Indonesia has a very high penetration of coal power plants due to the 35 GW government program, some of which ignore the electricity demand. This excess electricity could be utilized via water electrolysis to satisfy the future carbon society.

MATERIALS AND METHODS

Java-Bali Grid Current System and Scenario

Indonesia's system planning is mainly island-based, such as Java-Bali, Sumatera, Kalimantan, Sulawesi, Nusa Tenggara, Maluku, Papua, and other minor systems, as it is the largest archipelago country. Economic growth, which is expected to be 6–7% per year, is one of the key aspects of demand forecasting; therefore, the load projection is relatively high. In 2020, the state electricity company (PLN) had a total installed capacity of 63.3 GW. For the next 10 years, the total new plan will be 40,6 GW, with renewable energy accounting for 20.9 GW or 51.6 %. The coal power plant will be retired at a capacity of 1.1 GW. With an installed capacity of roughly 41 GW in 2020, the Java-Bali system dominates the number of power plants (almost 65% of the national capacity). In this region, the additional generating capacity will be 13 GW in the next 10 years, dominated by coal power plants. The addition of new power plants with very large capacity combined with low demand growth may result in an oversupply in the near future.

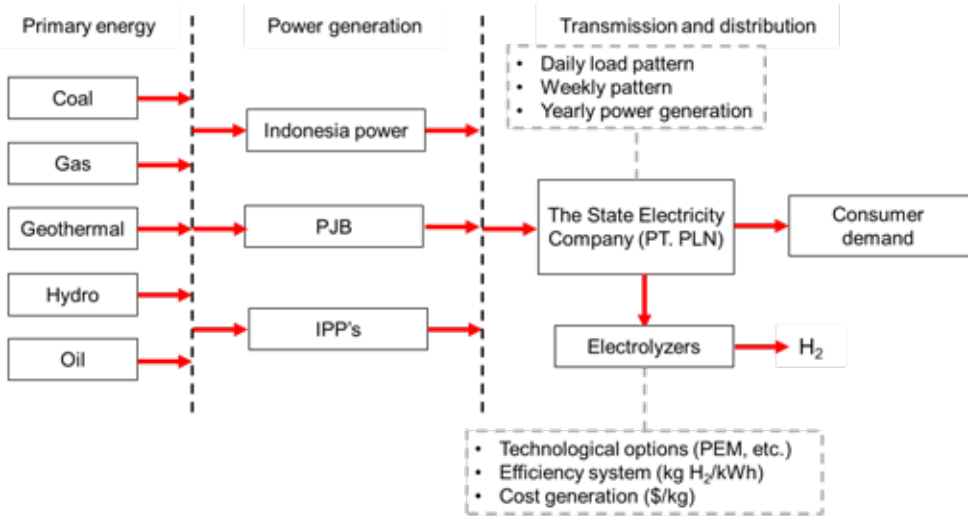

Fig. 1. Current Java-Bali power system

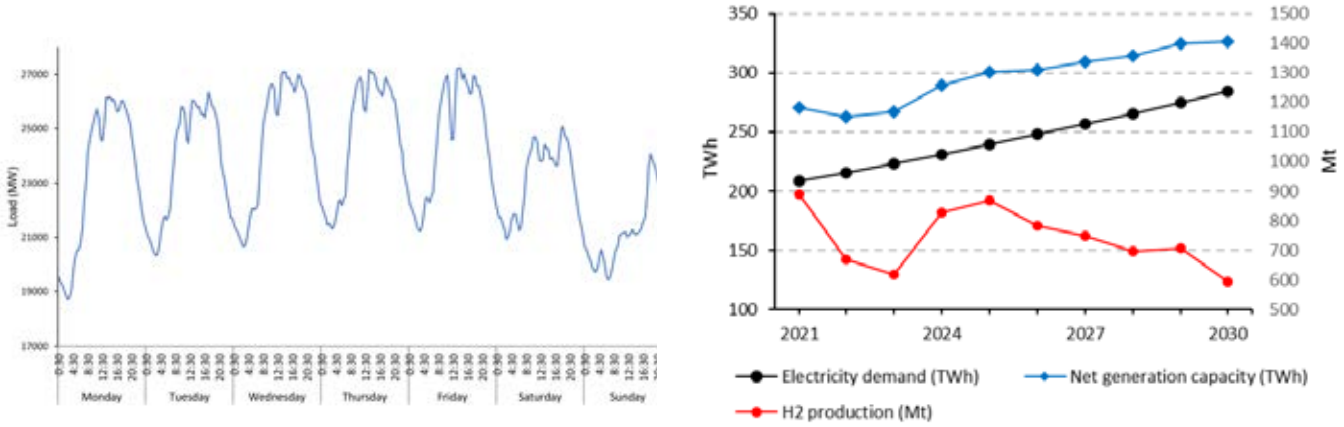
The electricity market model in Indonesia is a single buyer multi-seller in Indonesia, where PLN is the only buyer requiring a take-or-pay (TOP) contract to guarantee the IPP developer's return of investment (ROI) (see Fig. 1). However, in the current situation, the TOP contract is quite burdensome for PLN. The growth in electricity consumption has decreased, but PLN electricity from IPPs should not be reduced. Consequently, PLN is forced to reduce its electricity purchases from its power plants to reduce costs and avoid penalties (deemed dispatch) due to the TOP contract [7]

Modeling approach



In order to estimate the effects of using P2G alternatives and capacities to absorb surplus electricity, the modeling and calculation are developed based on existing/future power plants, government plan until 2030, daily/weekly/annual power generation profiles, and some parameters of electrolyzer technology. Also, several assumptions are made, which are presented in Table 1.

Table 1. Modeling assumptions [8]

	Description
Scenario planning	2021-2030
Type of electrolyzer	PEM and Alkaline
Efficiency (system)	50-80 kWh/KgH_2
Lifetime	7-10 years
Capital costs estimate for large system	500-1000 USD/kW_{el} for Alkaline 700-1400 USD/kW_{el} for PEM

PRELIMINARY RESULTS AND DISCUSSION

The typical hourly electricity load profile for the Java-Bali power system is shown in figure 2a. The load data were recorded in December 2021 for one week to compare weekdays and weekends (Saturday-Sunday). The electricity consumption at night is higher than the day time. Due to residential activities, the peak load typically occurred at 26,000-27,000 MW from 18:00 to 19:00. Considering a very large electrolyzer, operating with an efficiency of about 70% for 8000 hours per year, the annual hydrogen production potential would be 600-900 Mt of hydrogen, as shown in Fig. 2(b).

(a) (b)

Fig. 2. (a) Weekly load profile in December 2021, (b) Hydrogen production potential

Hydrogen can be stored or converted into other energy carriers such as ammonia, methanol, methane, and liquid hydrocarbons once produced at scale and a competitive cost. Further investigation will be conducted for storage scenarios, including distribution strategies. A proper approach to the cost reduction in raw material procurement, power generation, and related H_2 facilities should be taken and established. Therefore, the overall H_2 production cost can be minimized.

CONCLUSIONS

White hydrogen production uses water as a key feedstock and surplus electricity as an energy source to separate hydrogen and oxygen from water in an electrolyzer. The annual hydrogen production potential for the Java-Bali system would be 600-900 Mt of hydrogen, assuming 50-80 kWh could produce 1 Kg of H_2. Further investigation will be conducted for storage scenarios, including utilization and distribution strategies.

ABSTRACT

A microgrid is a power network section including distributed generators, storage systems, and loads. A "*Power to Gas*" (PtG) system is a rising technology that produces synthetic methane (or similar gas) by using electricity and carbon dioxide extracted from the flue gases. Recently, Turkey has been preparing to make strict sanctions on energy producers to decrease the greenhouse gas emissions due to the Paris Agreement. Additionally, it is struggling with the outage of imported natural gas. Accordingly, PtG systems may handle both the problems of natural gas shortages and carbon dioxide emissions. This study aims to propose methods to optimally design and schedule a PtG system integrated microgrid by Mixed-Integer Nonlinear Programming (MINLP). PtG system is assumed to be installed, whereas other equipment, consisting of renewable and non-renewable sourced generators and a battery, is nominated as selection candidates. Two different integrated gasification combined cycle generators and one combined heat and power generator are selected to be installed. The model does not prefer to choose renewable sourced generators, such as wind turbines and solar panels, for the investigated location due to fixed and maintenance costs, weather conditions, and demand levels.

Keywords: Power to Gas, Microgrid, Carbon dioxide emission, MINLP, Optimal design and scheduling

INTRODUCTION

Today, Turkey is dependent on imported gas reserves. Although it has just found natural gas reserves in the Black Sea, the usage will have been possible in the upcoming seven to ten years, at the same time not securing the whole demand of the country [1]. Turkey's energy sector uses a high amount of natural gas. Hence, electricity outage linked to the natural gas shortage is a significant threat to Turkey's economy. In addition, the Paris Agreement dictates Turkey to reduce its carbon dioxide emission as soon as possible.

A PtG system is a technology that includes an electrolyzer, carbon capture and storage (CCS) unit, and a methanation reactor. Excess electricity produced by the microgrid is used to convert water into hydrogen. Obtained hydrogen and carbon dioxide are consumed to produce methane, and later synthetic natural gas. Therefore, PtG systems may be a nice solution for both the problems of natural gas shortages and the carbon dioxide emissions in Turkey.

Optimization of integrated microgrids with economically and environmentally promising technologies, such as Power to Gas (PtG) systems and Green Hydrogen, has frequently been studied in recent years [2,3]. Most studies include Mixed Integer Linear Programming (MILP) formulations to avoid computational complexity, but they underestimate the nonlinear nature of model equations [4,5]. On the other hand, MINLP-based studies mostly focus on optimal sizing of installed equipment in the grid or optimal scheduling of the grid without addressing optimal equipment selection and design [6,7]. In addition, some of those studies include only renewable sourced generators coupled with PtG systems [8]. There are also some studies that comprise wider equipment variety in addition to renewable strategies while not considering the optimal design level [6,7]. Yet, studies of equipment selection from candidates, rich in diversity, for optimal design and scheduling by MINLP are scarce in the literature, especially for coupled green hydrogen and synthetic methanation.

This study offers both optimal design and scheduling at the same level, in contrast to the aforementioned studies, of a PtG system integrated by deterministic MINLP based on carbon dioxide emission sanctions. Moreover, a candidate equipment pool is formed by considering the newest technologies and higher diversity compared to similar studies. Furthermore, the actual data belonging to Samandağ, Antakya, is used to obtain the results. Thus, this study can be claimed to provide more reliable decision-making structures compared to many other studies using MILPs including more detailed analysis.

MATERIALS AND METHODS

Description of the Optimization Problem

The deterministic MINLP is used to meet the electricity demand of Samandağ, Antakya. Each day is set to have the same data of hourly electricity demand, wind speed, solar irradiance, and air temperature through a year. Each day is divided into 24-hour intervals and each interval is assumed to be in the quasi-steady-state condition.

The candidate equipment pool consists of two wind turbine farms, two solar panel arrays, two bio-gasifier generators, one biomass generator, two coal-fired conventional generators, two natural gas-fired combined heat and power (CHP) generators, two coal-fired integrated gasification combined cycle generators (IGCC), one synthetic natural gas production system, and one battery.

Mathematical Formulation of the Optimization Model

The objective function of the problem is to minimize the total annualized cost (*TAC*) of the microgrid:

$$\min \quad TAC = (CRF)\, f^{Capital} + f^{O\&M} + f^{EC} - f^{SNG} \tag{1}$$

$f^{Capital}$ is the installation cost of the microgrid, and $f^{O\&M}$ presents the total operational and maintenance costs through a year. f^{EC} is the emission cost for carbon dioxide, and f^{SNG} is the income from the sale of synthetic natural gas (SNG) to the national grid. *K* is the life span of candidate equipment of the microgrid, and $|\mathcal{K}|$ is twenty for all of them. *CRF* is the capital recovery factor.

MINLP problem is solved by SCIP (Solving Constraint Integer Programs) in GAMS (General Algebraic Modeling System). SCIP is a global solver for nonconvex MINLP problems. OptCA (Absolute optimality criterion of solver) and OptCR (Relative optimality criterion of solver) are set to 0.001.

RESULTS AND DISCUSSION

Excess electricity production and the purchase of electricity from the national grid are not allowed in the optimization model. PtG system's working duration is limited to 8 hours a day. Spinning reserve is included in the model to compensate for possible shortages in each interval.

The optimization model selects two different integrated gasification combined cycle generators, whose rated powers are 50 MW, and one combined heat and power, whose rated power is 105 MW. IGCC generators consume coal but generate much lower carbon dioxide than conventional coal-fired generators. CHP units can produce only electricity within their tetragonal feasible regions. They emit more carbon dioxide than IGCC generators while releasing much lower carbon dioxide than conventional coal-fired generators. Even though bio-gasifiers and bio-generators emit much less carbon dioxide than IGCC and CHP generators, the MILNP model does not prefer to bio-gasifiers and bio-generators, because installation costs of bio-gasifiers and bio-generator are higher than them. In addition, they consume much more amount of wood fuel and biomass even though biomass and wood fuels are cheaper than coal and natural gas. Moreover, the model does not choose wind turbines and solar panels. The reason may be their intermittent production due to weather conditions. The PtG system uses 10 MW of electricity, which is produced inside the grid for all operating intervals.

The optimal TAC value is found as 2.06 billion ₺. The capital cost is 4.21 billion ₺, the maintenance cost is 163 million ₺, and the operational cost is 799 million ₺. The emission cost is calculated as 444 million ₺. The revenue coming from the sale of SNG is 14 million ₺. The PtG system consumes 1.414 tons of CO_2 in each interval. If the PtG system were not used, the emission cost of this amount of CO_2 would be 9.9 million ₺. In other words, installation of the PtG system to the microgrid decreases the total emission cost of the microgrid by using carbon dioxide. In addition, it reduces the total annualized cost by producing synthetic natural gas, at the same time satisfying the emission limits of the microgrid with respect to the Paris Agreement. Finally, the optimal energy production schedule is shown in Figure 1.

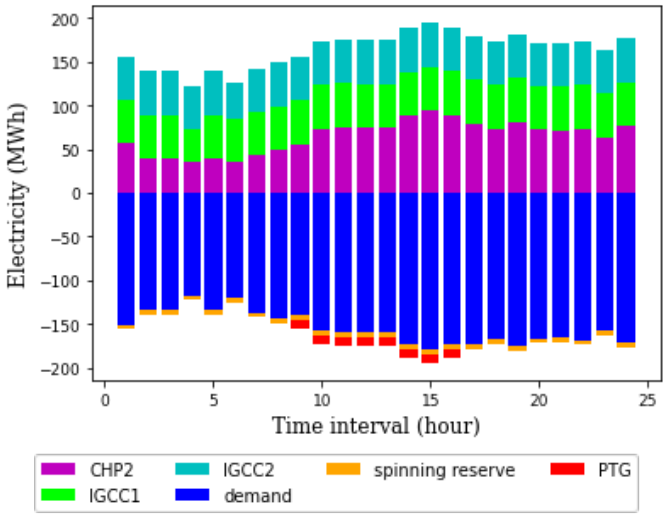

Figure 1. Energy balance of the microgrid over a day.

CONCLUSIONS

The aim of this study is to design a PtG system integrated microgrid and to schedule the energy production over a year. Candidate equipment pool includes renewable and non-renewable sourced generators. Results show that it is vital to design a microgrid, both from an economic and environmental perspective, to overcome greenhouse emissions and shortages of energy sources. PtG systems are state-of-the-art and preferable technologies producing a financially valuable energy source, SNG, while reducing the cost coming from environmental sanctions. Thus, integration of PtG systems into the microgrids by selecting the optimal interconnected equipment is critical for the energy producers.

Results also show that IGCC and CHP generators are selected by the decision-making model. They all produce a lower amount of carbon dioxide than conventional generators. Wind turbines and solar panels are not preferred due to their intermittent and insufficient production profile, although they generate the lowest amount of carbon dioxide. Therefore, installation of them is simply not economically feasible under current conditions. The PtG system provides a considerable amount of revenue, 14 million ₺, decreasing the emission cost by 9.9 million ₺ annually. When a multi-period design for the microgrid is considered and natural gas decreases year by year worldwide, PtG system integrated microgrids will be much more profitable in the upcoming future.

ABSTRACT

Recently, CO_2 methanation has gained attention for mitigating global warming. In our previous study, it has been demonstrated that the methanation of CO_2 takes place by mechanochemical reaction under H_2+CO_2 atmospheric conditions if a small amount of hydrogen storage alloys like $LaNi_5$ are present. It has also been found that the $LaNi_5$ partially decomposed into La-oxides, hydroxides, carbonate, and metallic Ni formed metal/oxide nanostructure complex during the reaction. However, the impact of this decomposed structure on the CO_2 methanation itself has not been revealed yet. In this study, we attempted *in-situ* measurements of gas composition during the mechanochemical CO_2 methanation using ball mill connected with quadrupole mass spectrometer (QMS).

Keywords: Methanation, CO_2, $LaNi_5$, Hydrogen storage alloys

INTRODUCTION

Recently, CO_2 concentration in the atmosphere has been increasing, which may enhance on-going global warming issue[1]. Thus, reduction of CO_2 emission and effective utilization of CO_2 have been considered inevitable measures for global sustainability. Methanation of CO_2 with green hydrogen is one of such approaches to utilize CO_2 with reducing atmospheric CO_2. This reaction (Sabatier reaction) is exothermic, but, requires high temperatures varied at 300 ~ 400 ^oC in the presence of catalysts like Ru, Rh, Ni etc. [2]. Indeed, Castellani et al. reported CO_2 methanation using hydrogen from renewable energy sources, e.g., solar energy[3]. They reported CO_2 conversion rate higher than 95 % at 2.0 MPa at reaction temperatures of about 400 ^oC using Ni supported catalysts, while the spent energy/stored energy marked around 0.4 in the process. Therefore, in view of energy saving and thermodynamic point of view, low temperature processes with high methane yield are preferred to further gain the energy profit. Previously, we demonstrated mechanochemical CO_2 methanation over La-Ni based hydrogen storage alloys using ball-milling method and reported CH_4 generation at room temperature without heat source [4]. It has also been found that the $LaNi_5$ alloy partially decomposes into Ni, La-oxides, hydroxides, and carbonates. However, its microstructural impact on the CO_2 methanation reaction is still unclear. Namely, following issues can be posed here: if such decomposed structure could be the origin of CO_2 methanation during the mechanochemical treatment and also, if hydrogen once absorbed in the hydrogen storage alloy ($LaNi_5$) could have activated the observed methanation reaction. In order to elucidate above mentioned aspects, we conducted *in-situ* measurements of gas composition during the mechanochemical CO_2 methanation by using ball-milling apparatus connected with high pressure Sieverts' type apparatus and mass spectrometer.

In the said process, H_2 dissociation reaction is necessary in the first place at the surface of the reaction site, i.e. the surface of alloy. If atomic H supply is sufficient due to hydrogen absorption reaction in the alloy powder, it is anticipated that the conversion of CO_2 to CH_4 would be enhanced. We, therefore, have chosen several Ni-based hydrogen storage alloys with different maximum hydrogen content to investigate the impact of atomic H supply on the mechanochemical CO_2 methanation. In addition, we studied possible influences of La compounds formed by the phase decomposition.

MATERIALS AND METHODS

A schematic picture of the experimental setup is shown in Figure 1. A vibratory ball-milling apparatus (Nissin-Giken, NEV-MA-8) is connected to homemade type Sieverts' apparatus and quadrupole mass spectrometer (QMS), allowing for control of H_2 gas and CO_2 gas introduction separately and *in-situ* gas composition analysis. $LaNi_5$ or Mg_2Ni powder together with ten balls (SUS304, diameter: 10 mm) were filled into the milling vial (SUS304, φ 54 mm x 43 mm). The vial interior was evacuated below 8.0×10^{-5} Pa by a turbo molecular pump, followed by the introduction of H2 and CO_2 from Sieverts' type apparatus. The ratio of H_2 and CO_2 was 4: 1 and initial total pressure was set at 2.0×10^{-2} Pa. The ball-milling was carried out at 11.7 Hz of vibration frequency, and the vial temperature was controlled at 20 °C by running water during the milling. The gas composition was continuously monitored by QMS.

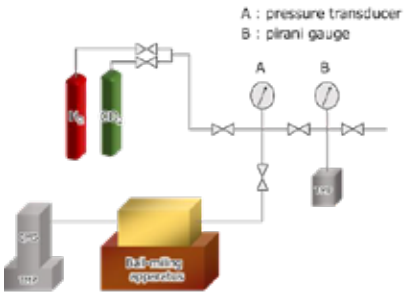

Figure 1 Experimental setup

RESULTS AND DISCUSSION

Figure 2 shows the time-course gas composition during $LaNi_5$ milling under continuous CO_2+H_2 flow. At the beginning, the ion current m/z = 2 (H_2^+) decreases rapidly and increases gradually. The rapid decrease is considered as a result of H-uptake into $LaNi_5$ alloy powder. The gradual increase indicates H desorption of once absorbed H, but this does not immediately mean that the amount of gaseous H_2 is increased compared to the initial state. Only after 4800s, the ion current of H_2^+ exceeds the initial level. This means that the desorbed H contributes to form H_2, with exceeding the initial amount of H_2 in the system. Notably, after 4800 s, continuous increase of CH_4 (ion current m/z = 15 (CH_3^+), fragment ion of CH_4) with gradual decrease of CO_2 (ion current m/z = 44 (CO_2^+),) was observed. This hints that the H supplied from $LaNi_5$ contributes to the methane generation. Results of XRD measurements of the powder sample milled for less than 4800 s showed H disordered structure. In case of the powder sample milled longer than 4800 s showed the decomposed structure of Ni and La oxides. This indicates that the desorption of H due to the phase decomposition might be responsible for the CH_4 generation. In the early stages of methanation, it was previously shown that the atomic hydrogen from sub-surface accelerates the methanation reaction, as reported by Kato et.al. [5,6].

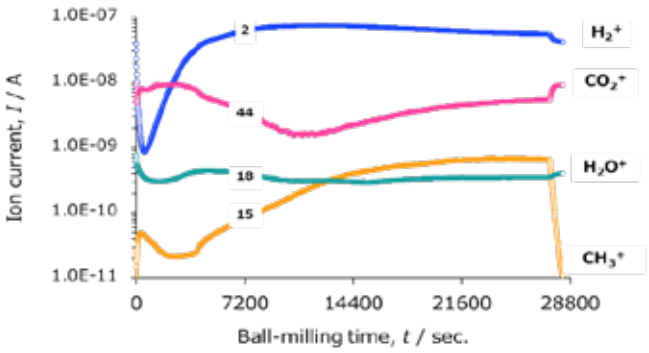

Figure 2. Result of gas composition analysis of $LaNi_5$ milling under CO_2 +H_2 atmosphere

After milling for 14400 s, we confirmed $LaNi_5$ phase completely disappeared and was changed to La-oxide, hydroxide, carbonate, and metallic Ni phases by XRD analysis. Also, it has been suggested that the formed La-compounds is effective for mechanochemical methanation [4]. We observed the methane generation continues even after 14400 s, as long as the ball-milling is carried out. It is suggested also here that a composite structure of Ni and La-compound formed as a result of the phase decomposition could be responsible as a catalyst for the mechanochemical methanation.

CONCLUSIONS

In this study, we reported *in-situ* monitoring results of CO_2 methanation over Ni based hydrogen storage alloy, $LaNi_5$, by mechanochemical methods with the mixture of CO_2 and H_2. The *In-situ* gas composition measurements revealed a rapid decrease of hydrogen until 4800 s by the absorption into $LaNi_5$. After then, once absorbed hydrogen was gradually desorbed, and methane was generated in this period. This indicates that the mechanochemical CO_2 methanation was caused by atomic hydrogen supply from sub-surface. We suggest that the observed methane generation occurred in two stages. The first stage was dominated by atomic hydrogen desorption from sub-surface, and the second stage of methanation involves Ni/Lanthanum compound formed by phase decomposition, which catalytically drives the methane generation.

ABSTRACT

The planning of new offshore wind farms (OWP) is characterized by increasing complexity. In addition to technical factors like water depth, ground conditions, wind development, and others, there is also an increasing range of design options in the wind farm concept. This concerns in particular the integration of hydrogen into the value chain for offshore wind power. For the wind farm planner, the decision, whether a decentralized electrolysis is directly implemented at the wind farm or a centralized electrolysis is built at the harbor edge, is crucial. Again, the influencing factors are manifold. The cable length for shore connection, the potential storage and offtake of hydrogen close to the harbor edge, the hydrogen transport via pipelines or ships have to be considered.

To address this complexity, a planning tool is being developed that enables an evaluation of offshore wind farm options. The core of the tool is a holistic cost model for the installation of offshore wind farms for hydrogen production. Based on this, an interactive 3D planning tool is developed, which enables the flexible structural planning of new wind farms based on GIS data to be displayed in a VR environment. The interactive adjustment of the wind farm changes the cost drivers of the cost model. In addition, the land connection and associated transport routes are selected in the 3D model and transferred to the cost model. The wind farm planner directly sees the impact of changes on the total costs. Thus, the system helps in the design and structural planning of new offshore wind farms as well as the conversion planning of existing offshore wind farms for hydrogen generation. Here we present the first results of this ongoing project.

Keywords: Planning tool, Offshore wind farm, Hydrogen

INTRODUCTION

The use of hydrogen (H2) as an energy carrier is increasingly becoming the focus of public attention. The main focus has to be on the so-called green hydrogen, which is produced from wind energy [1]. The combination of offshore wind farms and integrated H2 generation has so far only been considered theoretically but is discussed as a promising future topic [2]. One reason for the low realization rate is the complexity of a holistic planning of offshore wind farms with an associated H2 generation. Up to now, no tools exist to support this highly complex process to advance towards the realization of environmentally friendly H2 generation on an industrial scale [3]. Therefore, this project aims to develop a planning tool that enables flexible cost and 3D structural planning of new OWPs with H2 generation from offshore electricity based on geographic information system (GIS) data. To simplify the complex and interdisciplinary planning process and the associated coordination, the implementation will be done in a VR-environment. Cost models will be integrated into the planning tool to calculate the prime costs for offshore hydrogen production depending on the location and the distance to the mainland as well as the associated logistics costs. The results of the project should thus drive the implementation of corresponding projects. The project is currently in the implementation phase and is expected to be completed by the end of this year. In this abstract, only an excerpt of the work done so far is presented.

METHODOLOGY

In the first step, the technical data of current electrolysis technologies were collected with a literature review as well as expert surveys with partners from the industry. The data was evaluated by means of a utility value analysis. This is followed by data collection of hydrogen storage technologies and a subsequent evaluation.

RESULTS AND DISCUSSION

The various data of the electrolysis technologies were collected, and the technical parameters were compared with each other. To evaluate the market maturity of the various water electrolysis processes for offshore use, a utility value analysis of existing technologies was carried out. Based on a point system from 1 (bad) to 10 (very good). A weighting of important parameters for the question of offshore suitability was made. The total score represents the comparative value of the technology. Proton Exchange Membrane (PEM) electrolysis is best suited for offshore use with a total score of 914, followed by by AEL with only 767 points.

Table 1: Utility value analysis of electrolysis technologies

	PEM	AEL	AEM	HTL	utility [%]
Power-to-weight ratio	10	5	10	6	4,76
Footprint	10	8	8	4	9,52
Efficiency LHV	7	8	7	10	9,52
Working pressure	9	8	8	9	4,76
Load dynamics	10	5	3	1	14,29
Lifetime (Stack)	8	10	3	4	14,29
Suitability (Offshore)	10	6	7	1	14,29
Market readiness in the MW range	9	10	7	6	14,29
Maintenance & Operating Costs	10	7	8	5	9,52
Cost per MW	8	9	8	7	4,76
Sum	**914**	**767**	**629**	**457**	**2.767**

The reason for the margin needs to be discussed. PEM electrolysis is already available on the market in the MW range and, if scaled accordingly, can even have similar or even lower acquisition costs than the other comparable technologies [4]. Although high-temperature electrolysis (HTL) offers the advantage of being able to use water in the form of hot steam for the manufacturing process and thus achieve significantly better efficiencies, this technology can hardly be operated dynamically so far [5]. This eliminates the possibility of adjusting performance to the volatile energy flows of a wind farm. Furthermore, the technology is still in the development phase and currently has a technology readiness level (TRL) between 6-7 [3,6] and has so far only been tested in pilot plants. Figure 1 compares the four electrolysis processes available on the market. The percentage represents the results of the sum (2767 points) in the utility value analysis for the applications in OWP. PEM water electrolysis has proven to be the reference technology for offshore use. This technology was able to clearly assert itself in important comparative values such as: power-to-weight ratio, footprint, load dynamics, service life, TRL and OPEX [7].

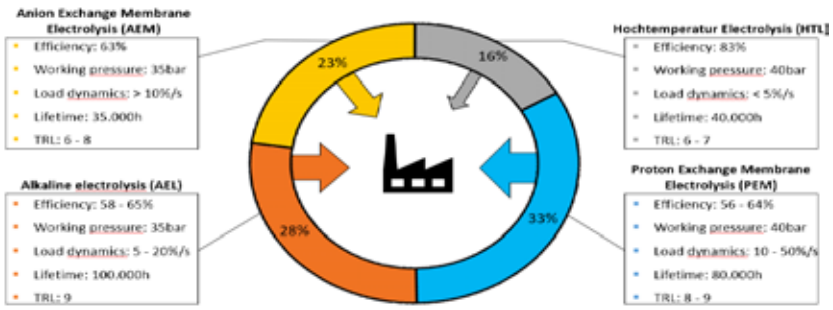

Figure 1. Comparison of ELY technologies

In the second phase of the project a comparative evaluation of different hydrogen storage technologies, their advantages and disadvantages were carried out showing the state of the art and suitability for different logistics systems in offshore applications. The focus was here on Tank & Bunker Systems such as (LH2 / CGH2 / MH / LOHC / CH4 / CH3OH / NH3), see Table 2.

Table 2: Utility value analysis of H2-storage technologies

	CGH2 (350bar)	LH2	MH	CH4 (liquid)	CH3OH	HCOOH	LOHC	NH3 (liquid)	Utility [%]
Energy per litre	1	4	9	10	7	3	3	7	9,52
Efficiency (provisioning)	9	5	8	8	5	3	6	6	9,52
Lifetime (storage)	9	8	9	8	10	10	10	9	4,76
Cycles (carrier medium)	10	10	5	10	10	10	2	10	4,76

Cost (Storage)	9	6	4	7	10	10	7	8	4,76
Transport (in the MW range)	10	4	2	10	10	7	10	7	14,29
Sum	**871**	**633**	**633**	**829**	**762**	**552**	**581**	**733**	**5.595**

Here a summary of the second phase of the project will be presented. Surprisingly it turns out that gaseous hydrogen clearly prevails as the reference technology. A particularly high energy transfer potential was found for transmission via pipelines. Furthermore, in the utility analysis, compressed hydrogen had decisive advantages over liquid / chemical storage technologies in the following parameters: efficiency (supply), dynamics (storage & generation), market maturity (in the MW range), suitability (offshore), environmental compatibility (carrier medium), storage costs, and transportation (in the MW range). The total score for each storage technology is presented in figure 2, showing the significant margin of CGH2 to the alternatives.

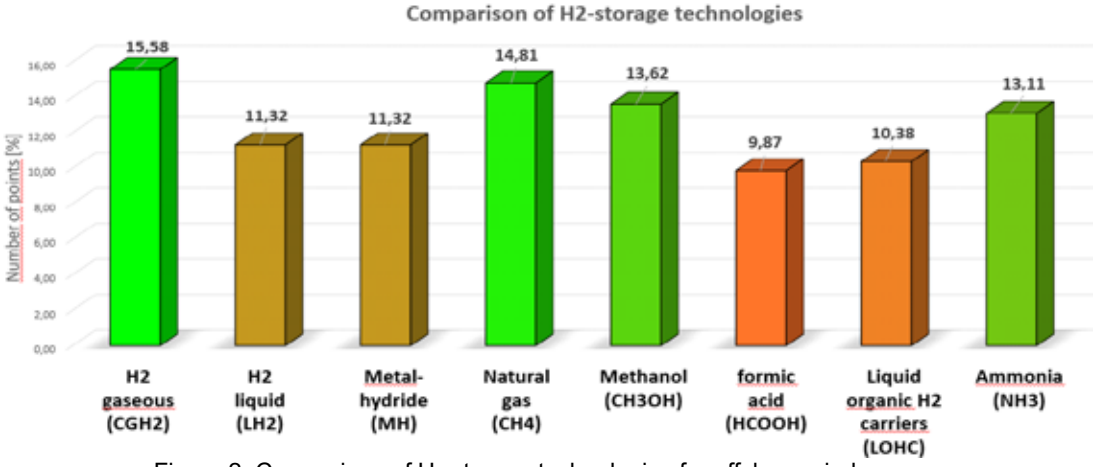

Figure 2: Comparison of H_2 storage technologies for offshore wind energy

Energy transfer in the form of gaseous hydrogen can enable a supply efficiency >90% depending on the transfer distance, which is currently not possible to the same extent with any other hydrogen carrier. As a storage option in this magnitude only salt caverns offer an economical option. For example, a cavern with a diameter of 60m, a height of 300m and a usable pressure range of 120bar can store about 100MNm³ of hydrogen. This corresponds to an energy quantity of 300GWh in relation to the LHV of H2. At the same time, loading and unloading can be performed at over 10t per hour, which corresponds to an output of more than 333MW per cavern. This enables direct operation with volatile renewable energy sources such as wind power [8]. The technology is already available and could make an important contribution to hydrogen storage. For Europe a total storage capacity in salt caverns is estimated to be of 84,8PWh (H2, LHV) [9]. Since hydrogen is a non-toxic gas, the impact on the environment and nature is significantly lower compared to the other storage technologies. In the event of a leak there is no poisoning of aquatic organisms (MeOH) or increased emissions of greenhouse gases (CH4). The storage costs per $MWh_{_H2}$ in a salt cavern are significantly below a standard hydrogen pressure storage up to 350bar [10]. The energy transport from the offshore wind farm can be easily implemented in a pipeline using gaseous hydrogen. Thus, a transmission capacity of more than $10GW_{_H2}$ can be realized in only one pipeline with a diameter of one meter.

CONCLUSIONS

PEM water electrolysis has emerged as the reference technology for offshore use. This technology was able to clearly prevail in important comparison values. Though the other technologies are not far off, and a future development might change the result. Especially AEM and HTL are still at a low TRL and will see further developments in the future.

Gaseous hydrogen has established itself as a reference technology for hydrogen storage. The utility value analysis of the various hydrogen storage technologies showed significant advantages in critical parameters for the connection to offshore wind farms. Storage on a TWh-scale could be implemented economically and safely by means of cavern storage.

In the next phase of the project, an economic evaluation of the location of an electrolysis plant will be carried out. The influencing parameters such as the distance of the OWP to the mainland and the power to be transmitted are compared with the transmission technologies available on the market and compared in a break-even analysis. The aim of this section is to find the most economical location for the hydrogen production plant. Subsequently, all data from the previous work packages will be incorporated into a cost tool and thus the production costs for the hydrogen supply will be determined. In the final step the model will be merged with the VR planning tool.

ABSTRACT

In this study, the effect of underlying V film on the CO_2 methanation on $LaNi_5$ surface was investigated using a quadrupole mass spectrometer, using a stacked film of LaNi-based thin film as a catalyst layer on top of a V layer as a hydrogen supply layer. It was confirmed that CO_2 methanation over thin film samples can be experimentally observed. Also, the underlying V layer was found to absorb hydrogen, thereby possibly prevented severe oxidation of La and concomitant phase decomposition of the $LaNi_5$ upper layer in to La oxide and Ni.

Keywords: CO_2 methanation, Hydrogen, Hydrogen storage alloys

INTRODUCTION

In recent years, global warming has been progressing due to rapid increase in the concentration of carbon dioxide (CO_2) in the atmosphere triggered by massive consumption of fossil fuels. To mitigate this impact, the conversion of CO_2 into methane by the Sabatier reaction (Eq.1) has been proposed. For example, the generation of methane from renewable hydrogen and CO_2 has been considered [1].

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad (1)$$

Even though this Sabatier reaction is exothermic ($\Delta H_{298\,K}$ = -165 kJ/mol), high temperatures of 300~400°C or higher and catalysts like Ni are necessary due to its high activation barrier. Thus, reducing the reaction temperature is desirable if coking on the catalyst surface can be avoided. In search of effective catalysts, various combinations of metal catalyst/support have been investigated [2].

According to our previous research, with using planetary ball-mill, it was found that mechanochemical process of La-Ni based alloys under the presence of CO_2 and H_2 generates CH_4 without any external heating [3]. But post-experimental sample analysis confirmed that the alloy decomposed into Ni and La compounds including carbonates. Even in this phase-separated state, Ni was dispersed on nanometer scale, suggesting that Ni acts as a catalyst and is involved in the Sabatier reaction. In addition, recent results of our research [4] and other reports [5,6] suggest possible impacts of atomic hydrogen supply on the methanation. It is suggested that hydrogen once stored in a hydrogen storage alloy, is discharged due to phase separation, atomic hydrogen is supplied to the reaction surface, which may directly/indirectly enhance the methanation [5].

In this study, the possibility of improving the methane generation rate by supplying atomic hydrogen was investigated by applying thin film technique. A catalytic layer was formed as a thin film on top of the hydrogen supply layer. Specifically, the effect of underlying V film on the methane generation reaction on $LaNi_x$ surface was investigated using a quadrupole mass spectrometer. The findings obtained in this study may be applied to the design of more efficient methanation catalysts.

EXPERIMENTAL

Film preparation

Thin film samples were prepared by a D.C. magnetron sputtering process. A glass substrate (18 mm × 18 mm × 0.2 mm) was used. As target materials, a disk-shaped La-Ni mosaic target and a disk-shaped V target were prepared. The sputtering conditions are shown in Table 1. The films with a total thickness of about 1.4 μm (LaNi: 400 nm, V: 1000 nm) were prepared in this study.

Sample analysis

Phase identification of the prepared films was carried out by X-ray Diffraction: XRD (MiniFlex600, Rigaku). Cross-sectional observation and elemental analysis of the samples were conducted by scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) (JSM-7100F, JEOL), respectively.

Table1: Deposition conditions

Base pressure (Pa)		Sputtering power (W)		Ar gas flow rate (ccm)
8.0×10^{-5}		50		30
Ar gas pressure (Pa)		Time (min)		Substrate holder temperature (K)
$LaNi_5$	V	$LaNi_5$	V	623
3.6	1.2	10	50	

CO_2 methanation

Eleven film samples were placed in an homemade methanation equipment. The reaction chamber was evacuated below 5.33×10^{-5} Pa by rotary pump and turbo molecular pump. The reaction tube of the methanation equipment was heated up to 773 K by external heating using an electric furnace. Surface activation was carried out for 1 hour by flowing 10 ccm of H_2. After that, CO_2 was fed into the reaction tube at a flow rate of 2.5 ccm. Gas analysis inside the tube was carried out using quadrupole mass spectrometer (QMS: Prisma 200, Pfeiffer). A blank test without the film samples was also conducted under the same conditions.

RESULTS AND DISCUSSION

Results of EDX analysis showed that the composition of prepared films was 17.9 at% La and 82.1 at% Ni, which closely agreed with $LaNi_5$. Figure 1 shows the secondary electron image of the cross section of $LaNi_5$/V film. V and $LaNi_5$ were found to be stacked on the glass substrate. The thickness of the film was found to be about 1000 nm for the V layer and about 400 nm for the $LaNi_5$ layer. Figure 2 shows change in ion current of CH_2^+ ($LaNi_5$/V film vs. blank test). Figure 3 shows change in ion current of CH_3^+ ($LaNi_5$/V film vs. blank test). In this study, we focused on the behavior of CH_2^+ and CH_3^+, which are fragment ions of methane, because CH_4^+ overlaps with the peak of O^+. After initiating CO_2 gas flow, the ion current of methane fragment ions (CH_2^+, CH_3^+) increased. When the film samples were present, the ion current of CH_2^+ after CO_2 gas flow increased by 11 % compared to the ion current of blank test. Similarly, the ion current of CH_3^+ after CO_2 gas flow increased by 42 % compared to that of blank test.

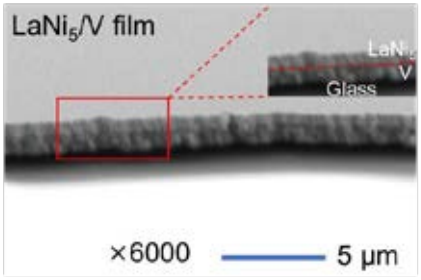

Figure1: Secondary electron image of the cross section of $LaNi_5$/V film.

Figure 4 shows the results of XRD measurements. Bragg peaks of $LaNi_5$ and V were found in as-received state, verifying the EDX results. The peak around 80° was close to the Ni reference pattern, suggesting the presence of Ni precipitates. After the methanation, peaks of La oxide, which has been reported to be formed after phase decomposition during the methanation [4], were not observed. This suggests that the $LaNi_5$ layer did not decompose in this case. Interestingly, the peaks of V shifted to the lower angle side after the methanation experiment, suggesting the V lattice being expanded. This could be due to hydrogen absorption in the V layer. Atomic hydrogen supplied from the V layer might have kept the $LaNi_5$ surface free from severe oxidation, as confirmed in our XRD results.

CONCLUSIONS

We found that the CO_2 methanation reaction over thin film samples can be monitored by using QMS. In the methanation of CO_2 using $LaNi_5$/V layered film, an increase in the ion current of methane was observed when compared to the results of blank tests. In addition, it was suggested that hydrogen was kept stored in the V layer even after the methanation, which might have avoided previously reported phase decomposition of $LaNi_5$ phase into Ni and La oxides.

ABSTRACT

Recent increase in the concentration of carbon dioxide (CO_2) in the atmosphere has led to global warming. For mitigating the increase in atmospheric CO_2, CO_2 methanation using hydrogen (H_2) has been proposed. In this study, we attempted to convert CO_2 into methane using $LaNi_5$ alloy thin films prepared by DC magnetron sputtering. The surface was decollated with palladium (Pd) islands, which is known as a hydrogen dissociation catalyst. Monitoring of gas species in the reaction chamber by quadrupole mass spectroscopy revealed successful methane generation over the film sample. The findings from such thin film samples with artificially formed interfaces as attempted in this study can be translated to the design of catalysts in powder form, in search of more efficient methanation catalysts.

Keywords: Thin Film, $LaNi_5$, Methanation, Palladium

INTRODUCTION

Recently, the increase in the atmospheric concentration of carbon dioxide (CO_2) has caused serious global warming, and climate changes. Therefore, reducing the CO_2 emission is necessary, and hydrogen energy system has been attracting great attention. Hydrogen-based energy storage systems have proven to be one of the of the most promising energy storage techniques. [1] However, research on hydrogen technologies has been facing many challenges, including production, storage, and transportation infrastructure.[2] To mitigate the impact of CO_2 emission on climate change as soon as possible, it has been proposed to convert atmospheric CO_2 into methane (CH_4) using hydrogen (H_2), under the concept of carbon recycling. Methane is the main component of city gas and can be used with only simple modifications to existing infrastructure facilities. The Sabatier reaction is known as a reaction to produce methane, as shown in Eq. (1).

$$CO_2 + 4H_2 = CH_4 + 2H_2O \quad \Delta H_{298\,K} = -165\ \mathrm{kJ/mol} \tag{1}$$

The reaction generally proceeds at 300-400°C under the presence of catalysts like Ni or other precious metals supported by oxides. In our previous study [3,4], we confirmed the formation of methane by ball-milling without heating, using $LaNi_5$ powder as a catalyst precursor. It was also confirmed after the experiment that the phase decomposition of the powder into Ni and La compounds occurs at nanometer scale as confirmed by atom probe tomography (APT) analysis [5]. Our recent on-going investigation suggested that this phase-decomposed structure might also contribute to methane generation, strongly indicating a need for nano-structural investigation of the hetero interfaces in these powder samples. Meanwhile, thin film techniques enable fabrication of artificial interfaces and flat film samples are more advantageous than powder samples for the observation of such microstructures by surface analysis. In this study, we employed thin film deposition technique to investigate CO_2 methanation reaction over LaNi-thin films. In addition, we attempted to investigate the impact of surface modification of LaNi-film by Pd islands on the methane generation since Pd surface is known to dissociate H_2 easily [6]. The findings obtained from the thin film samples with artificially formed interfaces in this study might be applicable to the design of catalysts that are generally used in powder form.

MATERIALS AND METHODS

Film preparation

Film samples were prepared by DC magnetron sputtering system. Films were deposited on glass substrates. The substrates were first cleaned by ultrasonication in acetone and in ethanol for 5 minutes, respectively. For LaNi-based thin films, mosaic targets were prepared aiming for obtaining $LaNi_5$ films. The film thickness was about 400 nm. Pd was deposited in the form of islands through a mesh mask (#40) placed over the $LaNi_5$ films. Table 1 shows the deposition conditions. Films obtained were evaluated by XRD (Miniflex 600, Rigaku) and AFM (SPM-9700, SHIMADZU).

Table 1. Film forming conditions

Sample	$LaNi_5$	Pd
Base pressure (Pa)	7.51×10^{-5}	3.22×10^{-5}
Argon (Ar) gas flow rate (ccm)	30	
Ar gas pressure (ccm)	3.6	4.5
Substrate holder temperature (℃)	350	29
Power (W)	50	10
Sputtering time (min)	10	0.5~1

Methanation experiment

The prepared film samples were introduced into the self-made methanation system for thin film samples [7] as shown in the schematic diagram in Figure 1. The base pressure of the reaction chamber was 1.39×10^{-5}. Prior to the methanation experiment, the reaction tube was heated up to 500°C in an electric furnace attached to the outside of the tube, and H_2 was introduced up to 10 ccm with a flow meter to reduce the sample surface for 1 hour. Subsequently, the temperature was lowered to 400°C and 2.5 ccm of CO_2 was introduced with the flow ratio of H_2 : CO_2 = 4:1 to initiate the methanation. The gas composition in the reaction chamber was analyzed with a mass spectrometer (QMS: Prisma™, PFEIFFER VACCUM) to verify the methane generation. The amount of methane generated was confirmed by monitoring changes in the ion current values of CH_3^+ and CH_2^+ (fragment ions of CH_4). In order to investigate the impact of sample holder on methane generation, gas composition analysis was also conducted with only the sample holder in place (Blank test).

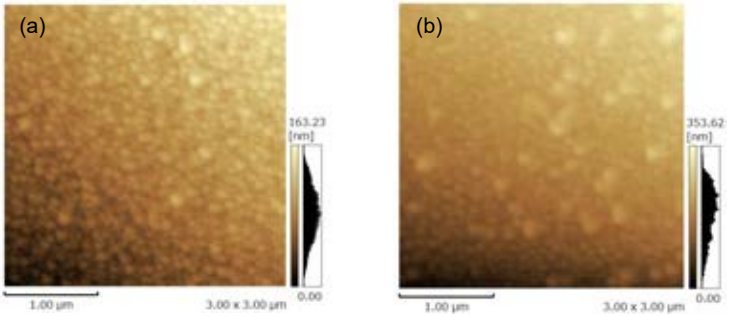
RESULTS AND DISCUSSION

Figs. 2(a) and 2(b) show surface topography of Pd/$LaNi_5$ stacked films obtained by AFM. The Pd deposition time of (a) is 30 seconds, (b) is 60 seconds. It can be seen that Pd is distributed as islands on the area where the height is partially increasing. When the deposition time was 30 s, the average surface roughness (Ra) was 5.5 nm, whereas the average surface roughness marks 10.7 nm at 60 s. The histogram of the height distribution for 60 s shows that the maximum value of the scale is about twice as large as for 30 s. Likewise, the median value of the distribution is also about twice as large at 60 s compared to 30 s, suggesting that the desired island-like growth of Pd could be achieved on the surface.



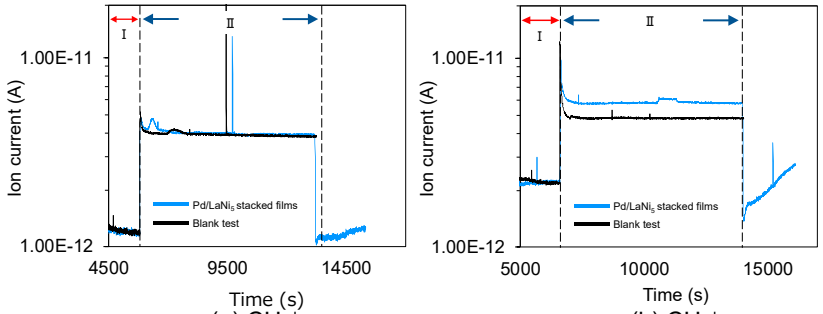


Figure.2 Sample surface scanning image in AFM

Figure 3 shows the results of CO_2 methanation experiments using Pd/$LaNi_5$ films (CH_3^+, CH_2^+). Region I depicts the reduction process using hydrogen and Region II means the period where CO_2 was introduced. The deposition time of Pd in this case was 60 s. The results are compared with the blank test. Compared to the blank test results, the Pd/$LaNi_5$ stacked film sample showed detectable increase in the ion current value of CH_3^+. The increase in the ion current value of CH_2^+ was negligible. It was also confirmed that the ion current value of CH_3^+ slowly increased after the CO_2 inflow was stopped. This is considered to be due to the gradual methanation process as the CO_2 adsorbed on the sample surface was released.

(a) CH_2^+ (b) CH_3^+

Figure.3 Gas composition analysis results (Pd/$LaNi_5$ stacked films vs. Blank test)

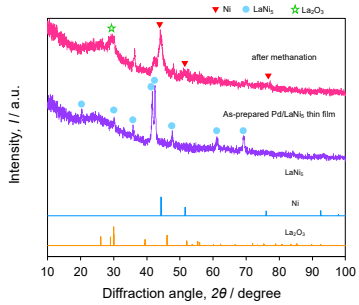

Figure.4 XRD measurement results

Figure 4 shows the results of XRD measurements. The results show that the underlying LaNi-based film has a structure similar to $LaNi_5$. Pd peaks were not clearly detected due to peak overlap and also probably because the thickness of Pd was too small. In the sample after the methanation experiment, Ni and La oxide were detected, suggesting previously reported phase separation [3,4] during the CO_2 methanation.

CONCLUSIONS

In this study, we have investigated CO_2 methanation behavior over Pd/$LaNi_5$ films using a thin film-oriented experimental setup. The use of a mesh mask allowed AFM to confirm the island-like deposition of Pd on $LaNi_5$. Methane generation the prepared thin films was successfully detected by mass spectroscopy. We confirmed that the phase decomposition of the $LaNi_5$ film occurs upon the methanation, which is a similar behavior to our previous findings on powder samples. This suggests that the methanation experiment using thin film samples can be a useful alternative to explore candidates of effective methanation catalysts in powder form.

PRELIMINARY DESIGN AND FLOW SHEETING OF A SABATIER BASED POWER-TO-GAS SYSTEM WITH INTEGRAL HEAT RECOVERY AND DOWNSTREAM SYNGAS CLEANING

R.Capata[a], R.Melli[b], E.Sciubba[c,d]
a: roberto.capata@uniroma1.it; b: xpertsystems@mpessrl.it; c: enrico.sciubba@unicusano.it

ABSTRACT
The present global energy scenario -and the consequences of the invasion of Ukraine- forces researchers, designers and policymakers to face the technical and economic challenges of an unavoidable and urgent mitigation of global Greenhouse gas (GHG) emissions. Such emissions from anthropogenic sources have been continuously growing since the beginning of the industrial revolution. The perturbing potential of these GHG emissions on the natural atmospheric concentration cycle might trigger, or at least hasten, an amplification of the global climate change.
Besides continuous efforts to improve the efficiency of combustion processes and the recourse to "CO_2 neutral" secondary fuels, the only feasible path -at least in the so-called "transition phase" towards a less unsustainable energy scenario- is the implementation of CO_2 capture and storage solutions. Since Thermodynamics teaches us that in the energy conversion arena "there is no free lunch", technical feasibility must be combined with economical positive returns, and thus the energy community must address the problem of the high CO_2 sequestration costs.
Sabatier based power-to-gas systems are potential answers for this issue, and this paper describes the modelling, process design and simulation of a CO_2 methanation plant based on the Sabatier reaction. To cure one of the problems of this technology, namely its low overall conversion efficiency, an exergy-based optimization of the thermal recovery within the system boundary was introduced. The results of our study demonstrate the great technical and economic potential of this solution as an H_2-mediated "energy storage" and CO_2 capture facility.

INTRODUCTION
The present global energy scenario -and the consequences of the invasion of Ukraine- forces researchers, designers and policymakers to face the technical and economic challenges of an unavoidable and urgent mitigation of global Greenhouse gas (GHG) emissions. Such emissions from anthropogenic sources have been continuously growing since the beginning of the industrial revolution. The perturbing potential of these GHG emissions on the natural atmospheric concentration cycle might trigger, or at least hasten, an amplification of the global climate change.
Besides continuous efforts to improve the efficiency of combustion processes and the recourse to "CO_2 neutral" secondary fuels, the only feasible path -at least in the so-called "transition phase" towards a less unsustainable energy scenario- is the implementation of CO_2 capture and storage solutions. Since Thermodynamics teaches us that in the energy conversion arena "there is no free lunch", technical feasibility must be combined with economical positive returns, and thus the energy community must address the problem of the high CO_2 sequestration costs.
Sabatier based power-to-gas systems are potential answers for this issue, and this paper describes the modelling, process design and simulation of a CO_2 methanation plant based on the Sabatier reaction. To cure one of the problems of this technology, namely its low overall conversion efficiency, an exergy-based optimization of the thermal recovery within the system boundary was introduced. The results of our study demonstrate the great technical and economic potential of this solution as an H_2-mediated "energy storage" and CO_2 capture facility. While the insistence of public opinion, media and policymakers on the absolute necessity of reducing anthropic atmospheric emission of CO_2 into the atmosphere is obviously correct, and so is their urging to evolve into an alternative power generation with zero-emission to prevent future catastrophic effects, non-specialists are in general unprepared to understand the enormous technical problems connected with such a transition, and very often also unwilling to accept either the unavoidable economic effects on the cost of the final kWh or the efficiency measures that they perceive as attempts to "reduce their standard of life". It is therefore imperative for the scientific community to bring about substantial advances in GHG reduction that combine a satisfactory degree of technological feasibility (i.e. are reliable, efficient, safe and low-impact) with a sufficient economic return (in terms for example of payback and of low impact on the final kWh cost). Policymakers are well-aware of this in fact, and the incentivation campaigns are designed to facilitate such a transition.
All forecasts for the world global electricity consumption indicate that, in spite of the evermore stringent source-demand matching and energy recycles and recovery, the electricity demand will be on the rise. At the current state of affairs, it is impossible to cover this demand by renewable sources only, and therefore the recourse to fossil-fueled electricity generation is unavoidable. The main harmful pollutants are NO_x, SO_x, dust, CO_2, and wastewater from flue-gas treatment installations. Keeping in mind that carbon dioxide emissions are an unavoidable consequence of combustion, we shall address here a possible mitigation strategy.

There are several proposals for carbon capture, utilization and storage (CCS or CCUS). Their common goal is to capture CO_2 from industrial sources and either store it in underground structures or convert it into useful products. All this is happening while emissions from the industrial and energy sectors are reduced mostly thanks to the so-called Carbon Tax: the current fees related to CO_2 emissions in the European Union run in the range of 50 €/t_{CO2}, and there is an expected upward trend in the coming years.

MATERIALS AND METHODS – DESCRIPTION OF THE PROPOSED SYSTEM

In this study we examine a possible alternative solution to CCS, namely a chemical conversion: an attractive final product being *methane* (CH_4): through the well-known *Sabatier reaction* or *methanation*, exhaust CO_2 can be converted into a very valuable and easy-to-use fuel. In this way, CO_2 mitigation is achieved not only through carbon chemical storage, but also through a reduction of the final energy use, because the generated CH_4 is a perfect local substitute for natural gas.

Even though, contrary to geological sequestration, the captured CO_2 will be almost immediately released into the atmosphere by the combustion of CH_4, the methanation process provides a profitable CO_2 zero emission-cycle if it is fed by renewable energy sources. But since it requires the generation of H_2 -usually via an electrolytic process, it is also economically attractive if it uses a portion of the electricity generated in low-demand hours: in this sense, it is a sort of “chemical H_2 storage and reuse” system. When compared to competing capture systems, it combines a higher efficiency and an easily handled the final product (CH_4). In the process we are proposing, this methane can be burned on-site to generate the electricity required by the H_2 electrolysis and -in an economic but obviously not in a thermodynamics sense- “close” the loop.

The simplified scheme of the proposed process is shown in figure 1: electricity from renewable sources –or alternatively energy generated by fossil-fuelled power plants in low-demand hours-is used to generate H_2 in a standard electrolyser. The hydrogen is then injected into the Sabatier reactor together with combustion fumes. The final products are Steam, CH_4, NO_x (which is not affected by the catalytic conversion reaction) and, since the system is obviously not 100% efficient, a small amount of residual CO_2 (5-10%).

A first innovative feature of the proposed system is a carefully designed waste heat recovery (the Sabatier reaction is strongly exothermic) via a Heat Exchangers Network (HEN) that substantially improves the overall efficiency of the plant. The second innovative feature is a cryogenic separation of the NO_x from the CH_4 performed downstream of the process, that ensures a quality of the Syngas sufficient for it being burnt on-site in standard gas engines to generate electricity and reduce the overall primary consumption. To design the integrated system and analyze the plant performance a steady state simulation of the plant was performed with an open-source Process Simulator, COCO by AMSTERCHEM.

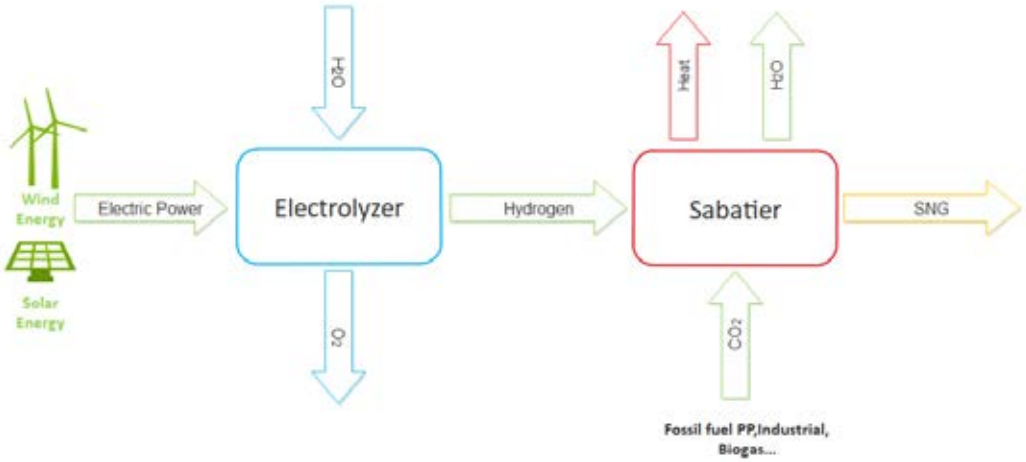

Figure 1 Sabatier Methanation scheme: the main processes

CONCLUSIONS

This paper presents and discusses the modelling and process design of a CO_2 methanation system. Heat Exchange Network (HEN) optimization techniques have been integrated in order to increase system efficiency. The Sabatier reactor treats the stack fumes, and thus no prior CO_2 separation is required: a cryogenic system is installed downstream to separate NO_x and SNG. A preliminary economic analysis demonstrates that the CH_4 costs are competitive with the current market situation.

ABSTRACT

It is expected that generation of electricity from renewable energy sources will significantly increase in the next decades. As a basic assumption for successful integration of renewable energy, any large-scale and long-term energy storage system will be needed. Power-to-Gas (P2G) technology is often mentioned as a promising solution. The surplus of electricity can be used for electrolytic hydrogen production. In the second step, the synthetic natural gas (SNG) is produced via catalytic hydrogenation of carbon dioxide. Experiments based on direct biogas methanation show, that this technology provides an effective way of production storable and transportable energy medium. Once national SNG quality requirements are met, the existing natural gas infrastructure give a massive energy storage system.

Keywords: Power-to-Gas, Methanation, Biogas, Synthetic natural gas, Biogas upgrading

INTRODUCTION

As share of renewable electricity has increased recent years, energy storage is more and more important. Balancing of power demand and supply is required at different time levels (hour, day, season) and scales. It results in different energy storage technologies suitable for various applications. It was observed [1,2] that there are many technologies suitable for short-term storage from minutes to hours. These technologies have limited capacities. When focused on large-scale or seasonal storage, the possibilities are limited to pumped hydro, compressed-air storage and P2G [3]. In the Czech Republic, the potential of pumped hydro has been already deployed and compressed-air storage is very limited by its specific geological requirements as well as significant thermal loss for long-term usage. Thus, P2G is consider as a technology capable to provide flexible large-scale storage solution from hours to months [4].

Nowadays, there are two basic approaches for methanation of carbon dioxide. The first one uses methanogenic microorganisms as biocatalysts, while the second is based on chemical catalytical synthesis [5]. Both conversions can be described by following reaction:

$$4\,H_2 + CO_2 \rightarrow CH_4 + 2\,H_2O \qquad (-165\ kj/mol) \qquad (1)$$

Nowadays carbon dioxide that is needed for the methanation reaction is usually separated with the use of several technologies based on physical or chemical absorption, adsorption, membrane or cryogenic separation. Carbon dioxide can be used from fossil fuel power plants, industrial processes or from biogas [5].

Biogas is an interesting source of carbon dioxide. Biogas consists mainly of carbon dioxide and methane, so it can be used directly as a source of carbon dioxide for the methanation reaction. However, biogas also contains many minor components (e.g. sulphane and other sulphur compounds) which must be removed before to methanation unity otherwise they could permanently deactivate the catalyst [6].

When biogas is directly used as a source of carbon dioxide, the reaction (1) can be rewritten by:

$$4\,H_2 + CO_2 + n\,CH_4 \rightarrow (n+1)\,CH_4 + 2\,H_2O \qquad (2)$$

While n can usually differ from 0.2 to 1.5 depending on biogas composition.

Catalytic methanation provides an alternative way to upgrade biogas without the need to separate carbon dioxide. The added benefit when compared to conventional methods is elimination of waste carbon dioxide and the possibility of storing electrical energy [7].

MATERIALS AND METHODS

For experimental evaluation of P2G technology in Czech Republic, chain of photovoltaic power plant, proton exchange membrane (PEM) electrolysis and chemical methanation has been selected. Main components of the system and its technical parameters are shown in Table 1.

Table 1. Technical parameters of P2G system

	Component	Technical parameters
Primary energy source	Photovoltaic power plant	13 kW(p), 60 polycrystalline panels
Hydrogen generation	PEM electrolyzer (HOGEN S40)	6.7 kW, 1.5 MPa, 1.05 $Nm^3/hr.$ H_2
P2G technology	Fixed-bed chemical reactor	0.4-1.2 MPa, Ni-based catalyst

Design of one-stage chemical reactor with fixed-bed of catalyst and external cooling is shown on Fig. 1. This configuration allows efficient heat management crucial for high conversion of methanation process. Also, a various composition of inlet gas can be introduced to study influence of biogas composition as well as influence of non-stoichiometric H_2/CO_2 ratio. Synthetic, organic oil Marlotherm LH has been used as a heat-transfer medium. Its boiling point set a limitation up to 380 °C.

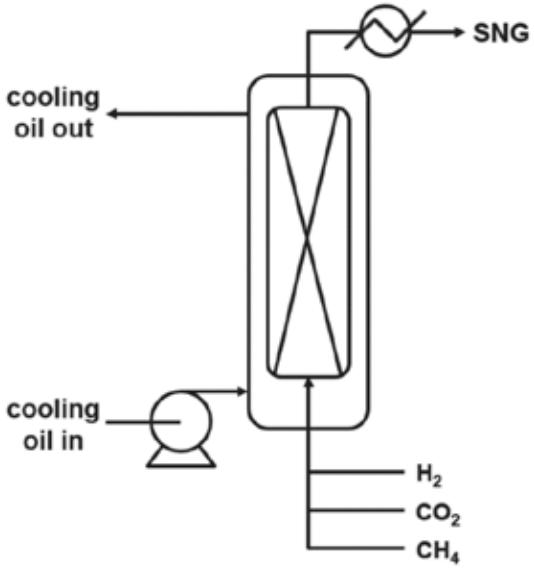

Fig. 1. Chemical reactor design

Series of experiments have been done with focus on influence of methane presence in inlet gas to carbon dioxide conversion. The applied nickel-based catalyst supported onto alumina has been developed in cooperation with University of Chemistry and Technology in Prague. This catalyst shows high selectivity for methanation and long-term stability. Constant pressure 0.5 MPa has been set for all experiments while various inlet gas composition has been introduced with methane content of 20 – 60 vol. %. The experimental unit has been coupled with on-line analysis of produced SNG to allowed evaluation of carbon dioxide conversion.

RESULTS AND DISCUSSION

At the beginning methanation of carbon dioxide with no methane has been carried out to set base for comparison. In next steps 20, 40 respectively 60 vol. % of methane have been introduced to carbon dioxide flow to simulate differ composition of biogas while H_2/CO_2 ratio has been fixed on stoichiometric value 4. When the methane concentration in produced SNG is influenced by its presents in inlet mixture, carbon dioxide conversion has been calculated for evaluation the methanation process. Carbon dioxide conversion within temperatures 250 – 370 °C for differ inlet gas composition is shown on Fig. 2.

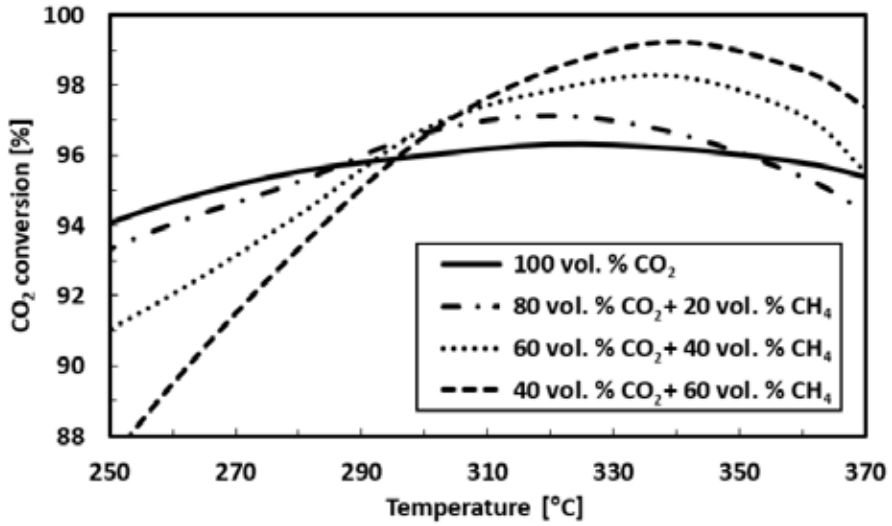

Fig. 2. Conversion of carbon dioxide within methanation process

The results show of significant increase in carbon dioxide conversion from 96 % to 99 % with increasing concentration of methane in inlet gas. Also, a slight shift in maximal conversion temperature is visible (310 – 340 °C). This phenomenon is probably caused by different thermal conductivity of carbon dioxide and methane and has not been described in previous works. More experiments will be needed for detail understanding of whole process.

CONCLUSIONS

P2G technology will play significant role as share of renewable energy sources will increase. The chemical catalytic reaction of hydrogen and carbon dioxide can provide a suitable, storable and transportable energy medium. While hydrogen can be produced via electrolysis, one of the main sources of carbon dioxide the biogas is considered.

This experimental work focuses on influence of methane presence in biogas to carbon dioxide conversion during methanation process. A phenomenon of increasing carbon dioxide conversion as well as optimal methanation temperature have been discovered. The presence of methane helps to convert carbon dioxide and reach SNG with a high heating value. Next experiments with nickel-cobalt and nickel-molybdenum catalysts will be carried out in future.

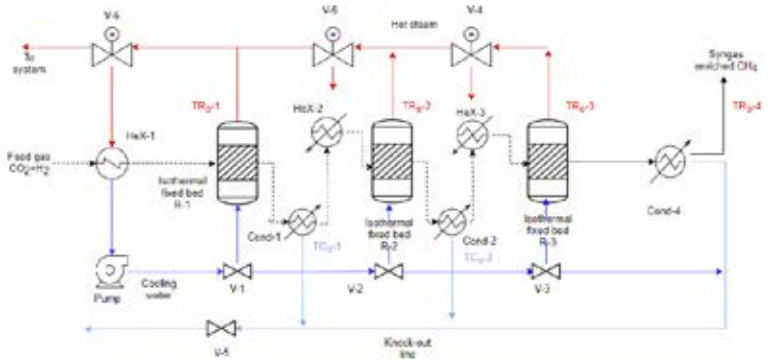
ABSTRACT

The interest in methane production from the utilization of electricity and hydrogen, also well-known as power-to-methane (PtM), has increased significantly in the last decades. A typical PtM system mainly consists of an electrolyzer (for hydrogen production) that is powered by a renewable power production technology, such as a solar PV module, a CO_2 source and a chemical reactor for methane production. In this study, the sizing of a PtM system is first performed based on the operating strategy that relies on the avoidance of hydrogen storage and selection of appropriate hydrogen content of syngas and catalyst loading in the reactor. Then, thermodynamic analysis is performed for this system. Finally, cost analysis is conducted for new reactor installation considering sizing and thermodynamic performance of the system. The combined simulation shows that the electrical efficiency is found as 50-55 % according to various operating conditions. The syngas production rate decreases even though the methane content of syngas increases when the operating pressure of the reactor decreases. Moreover, the total investment cost decreases from 4,354,200 $ to 3,470,200 $ when the reactor pressure increase from 1 bar to 7 bar.



Keywords: Power-to-methane, Syngas, Cost analysis, Economic model, Methane reactor

INTRODUCTION

Storage of methane (or syngas) is easier compared to hydrogen because methane has readily available delivery infrastructure in many countries. This makes the synthetic methane production systems more attractive. Power-to-methane (PtM) is an effective concept to produce synthetic methane utilizing electricity and hydrogen through an eco-friendly pathway compared to the traditional methane production systems [1]. A typical PtM system mainly consists of an electrolyzer (for hydrogen production) that is powered by a solar PV module, CO_2 capture unit, and reactor system for methane production, as displayed in Figs. 1a and 1b. The financial feasibility of the PtM systems has been increased in the last decade, making these systems more cost-competitive [2–4]. Techno-economic assessment is an effective method to evaluate the PtM systems as the cost of the methane production, investment cost of the plant, and payback time, which show the economic competitiveness of the process, can be found using this method. In this study, a PtM system is sized based on the operating strategy. Then, a thermodynamic assessment for this system is performed. The cost analysis for the reactor system of the PtM plant based on the sizing and thermodynamic results is eventually conducted.

a)

b)

Fig 1. a) Schematic of the PtM system and b) the isothermal fixed bed methane reactor system of the PtM

SYSTEM DESCRIPTION AND MATHEMATICAL MODEL

The schematic of the PtM system considered in this study is displayed in Figs 1a and 1b. The required power for hydrogen production from the electrolyzer is provided by a solar PV module. The CO_2 capture unit is used to capture CO_2 from flue gas. However, the modeling of the CO_2 capture unit is neglected in this study. The hydrogen and CO_2 are fed to the methanation subsystem where Sabatier reactors and balance of plant components (e.g., pumps, valves, condensers, heat exchangers) are employed. The system sizing is first performed based on the operating strategy The thermodynamic assessment of the sized system is then done. Finally, an economic analysis is performed for this system based on the revenue requirement method [5].

Thermodynamic performance is evaluated by using energy efficiency:

$$\eta = \frac{\dot{n}_{CH_4} \cdot LHV_{CH_4} + \dot{n}_{H_2} \cdot LHV_{H_2}}{P_{total}} \quad (1)$$

The economic performance is evaluated for the methanation section by estimating investment cost and methane production cost. It is assumed that the total investment cost (TCI) is mainly composed of fixed capital investment (FCI) that covers direct and indirect costs neglecting other outlays (e.g., start-up costs, costs of licensing, research and development). For the calculation of FCI for main equipment, acquisition costs in the base state $\left(C_p^0\right)$ are needed to be calculated:

$$C_p^0 = 10^{K_1 + K_2 \log_{10}(Z) + K_3 [\log_{10}(Z)]^2} \quad (2)$$

where Z is the capacity or size parameter, and K represents the coefficient.

Since some cost data used in an economic analysis refers to the year 2001, they are needed to be brought to the same reference year:

$$C_{p,\$}^0(2022) = C_{p,\$}^0(2001) \cdot \frac{cost\ index\ (2022)}{cost\ index\ (2001)} \quad (3)$$

Purchased equipment cost of the methanation section (including pumps, heat exchangers, and reactors which are made of the higher quality material) considers the material factor F_M, and the pressure factor F_P as given in Eq (4).

$$C_{p,\$} = C_{p,\$}^0(2022) \cdot (2.25 + 1.82 \cdot F_M \cdot F_P) \quad (4)$$

Some simplified relations can be then used to predict the total capital investment required for a new methanation system. The relations can be found in the literature [6].

RESULTS AND DISCUSSION

In this study, a PtM system is first sized, and its thermodynamic performance is performed based on various operating strategies basically based on the avoidance of hydrogen storage and selection of appropriate hydrogen content of syngas and catalyst loading in the reactor. Economic analysis is then conducted. Sizing analysis shows that the methanation section has three serial reactors which have catalyst weights of 6800 g, 2990 g, and 1510 g,

respectively. Moreover, the number of cells at which an active area of 200 cm^2 in the stack is calculated as 180, while the number of solar PV panels which has an area of 2 m^2 is found as 120. This system is capable of producing 0.101 mol/s syngas (roughly 50 % methane, 30 % hydrogen, 12 % water, and 8 % carbon dioxide). Thermodynamic calculations show that the LHV-based system energy efficiency is found around 50-55% under various operating conditions. Moreover, the system has a capacity to generate around 10000 W of heat in these conditions. For this purpose, the hydrogen production flow rate and CO_2 flow rate used are calculated as 0.09221 and 0.02323 mol/s, respectively.

From the economic point of view, the investment costs for reactors in the methanation section are found as given in Table 1. To produce 50 tons of syngas per year, the total investment cost of new reactors is found as 2,397 M$ for the following reactor operating conditions: Pressure, temperature, the contact time in the first reactor (R1), and stoichiometric ratio (H_2/CO_2) are 1 bar, 498 K, 83 g·h/mol, 4, respectively. When the pressure increases from 1 bar to 7 bar while other parameters are taken the same, the sizing analysis shows that two reactors can be operated for the operating strategy. In this case, the system is capable of producing 26-ton syngas per year. Total investment cost decreases to 1.860 M$.

Table 1. Estimate of total capital investment costs for new reactor(s) installation in the PtM system

Equipment	Operating pressure of the reactor	The number of reactors	Syngas production rate	Methane content	FCI	TCI
R-1 R-2 R-3	1 bar	3	50 ton/year	50 %	2,960,000 $	4,354,200 $
R-1 R-2	7 bar	2	26 ton/year	70 %	2,360,700 $	3,470,2000 $

CONCLUSIONS

In this study, a power-to-methane (PtM) system is first sized based on operating strategies. Then, a thermodynamic simulation is performed on the system. Finally, the cost analysis for new reactor(s) installation in the PtM system is done. Sizing analysis shows that when the pressure of the methane reactor increases, the number of reactors decreases to meet the operating strategy. Based on this result, the syngas production rate decreases even though the methane content of syngas increases. Moreover, the total investment cost decreases from 4,354,200 $ to 3,470,200 $ when the pressure increase from 1 bar to 7 bar.

ABSTRACT

Atmospheric, laminar, premixed flames of hydrogen and air are computationally investigated in an annular diverging channel. This used configuration closely resembles the one that was recently used in a series of experimental studies to obtain the burning velocities and quenching distances for premixed flames of different fuels, including hydrogen. Three different equivalence ratios are considered. Global and detailed reaction mechanisms are adopted to describe the combustion process. For ensuring an adequately fine resolution of the flame fronts, local adaptive grid refinement techniques are applied to track the flame front. The goal of the current analysis is the validation of the applied prediction procedures by comparing them with the experimental results. To this purpose, the predicted burning speeds and quenching distances are compared with the measured values.

Keywords: Hydrogen combustion, Premixed flame, Flame speed, Quenching distance, Computational Fluid Dynamics

INTRODUCTION

Power generation by thermal machinery largely depends on the conversion of the chemically bound energy by the combustion process. Parallel to the exploitation of new energy sources and recovery techniques [1], combustion continues to play an important role in power generation. Combustion of H_2 and H_2-blend fuels plays an important role in clean and efficient energy supply. On the one hand, H_2 represents an attractive alternative to storing excess energy in renewable power generation [2]. On the other hand, instead of combustion [3,4] gasification of biomass and coal [5] is a good possibility for clean power generation. The synthesis gas contains, in addition to CO and small amounts of CH_4, significant amounts of H_2. Additionally, there is a growing interest in hydrogen production using nuclear power plants [6].

Use of H_2 in combustion systems represents a great challenge. In power generation, the state-of-the-art technology for gas turbines is the lean premixed combustion, due to its high potential for achieving very low NO_x emissions. A principal problem here is the so-called “flashback” [7]. This makes the use of H_2 containing fuels in premixed combustion to a great challenge, since its high reactivity increases the flame speed and flashback propensity. Thus, effective measures are needed to prevent flashback when using H_2 containing fuels in premixed mode. Combustion of H_2 has relevance also for safety engineering. H_2 has a high diffusivity and its leakage is more likely to be an issue compared to other gases. H_2 plays also a special role in conjunction with the safety of nuclear power plants on conjunction with the storage of the released slightly radioactive H_2-steam mix.

A measure against flashback is the “quenching mesh”. Here, a primary cause preventing flame propagation is heat loss to walls. A temperature decrease in the flame front retards the combustion, and, thus, flame propagation. A termination of the combustion reactions as result is “quenching”. The range, in which the flame is quenched is termed as “quenching distance”. Thus, a solid mesh in the flow path, with mesh sizes smaller than the quenching distance can prevent flashback. Although experimental values for quenching distances can be found in the literature, there is a need for a better understanding of the phenomenon with respect to the influence of different conditions [8]. Until recently a number of further experimental and theoretical studies were performed on the subject. Computational investigations are, however, still rare and bound to simplifications leaving room for further exploration.

A computational analysis of the flow, heat and mass transfer processes for a laminar hydrogen flame in the presence of a quenching mesh was presented by the present authors [9,10]. In that study several modelling aspects were investigated and conclusions were drawn for the modelling and for quenching mesh design. The results were found to be in agreement with the experimental observations in general, while a direct comparison with measurements was not performed. The present work is to be understood as a continuation of the previous work, where explicit comparisons of the predictions with the experimental data are aimed. In recent years, an experimental method based on a so-called “Annular Stepwise Diverging Tube” (ASDT) was applied to measure the burning velocities and quenching distances for premixed flames of different fuels [11,12]. The measurements for a premixed hydrogen flame

are taken as the experimental basis for the present paper. Computational investigations are performed for premixed hydrogen flames in this configuration and the results are compared with the measurements [13] for validation purposes.

The preliminary results of the present work were presented in a recent publication [14]. In that publication, the geometry of the analyzed diverging tube was, however, not very similar to the one used by Jung et al. [13] in their measurements. A planar diverging tube was used in the previous work [14] without a very close resemblance of the annular tube used by Jung et al. [13]. In the present study, a geometry with a closer similarity to the one used in the experiments is considered. Furthermore, lean and rich mixture compositions are additionally investigated, whereas a stoichiometric flame was considered in the previous work [14]. The prediction of burning velocities is also put into the focus of the investigation, whereas only the prediction of the quenching distance was addressed previously [14].

MODELING

The differential transport equations of the chemically reacting mixture are numerically solved, assuming a subsonic flow and an ideal gas behavior [15,16]. Buoyancy is neglected. The radiative heat transfer is also neglected. Laminar flames are considered. Thus, modelling errors with respect to the modelling of turbulence [17,18] and turbulence-chemistry interaction [19] are avoided. Considering the multi-component diffusion, the Soret and Dufour effects are neglected, in the species transport and energy equations. For the numerical simulations, ANSYS Fluent 18.0 [20] is used. As Navier-Stokes solver, the SIMPLEC [21] scheme is used. For discretizing the convective terms, a second-order upwind scheme [20] is applied. The chemical kinetics software Cantera [21], is also used 1D calculations for verifying different reaction mechanisms. Flame propagation depends on the material properties. Thus, their accurate modeling is attempted. The specific heat capacities as function of temperature are obtained using a pair of fourth order polynomials [15], for low and high temperature ranges. Transport properties are obtained from the kinetic theory [15]. Chemical kinetics rate coefficients are modeled by Arrhenius expressions [16]. A single-step mechanism a detailed reaction mechanism are considered. The single-step mechanism is that of Marinov et al. [22]. The detailed mechanisms is the mechanism of Conaire et al. [23].

RESULTS

The predicted distributions of temperature and OH mass fractions are displayed in Figure 1 for a stoichiometric hydrogen-air premixed flame stabilized in a planar diverging duct with cooled walls. The fresh mixture flows from left to right (Figure 1). The flame cannot propagate further upstream, since the flow velocity balances the propagation speed of the flame. The “tulip” like shape of the flame front is affected by the shape of the velocity profile of the fresh mixture approaching the flame in the duct. With a reduction of the flow speed, the flame would stabilize at a further upstream position. Since the duct height is getting smaller in the upstream, the quenching effects of the cold walls will affect the flame front more strongly. At a position, the flame cannot be sustained and gets completely quenched. Through this procedure, the quenching distance can be obtained.

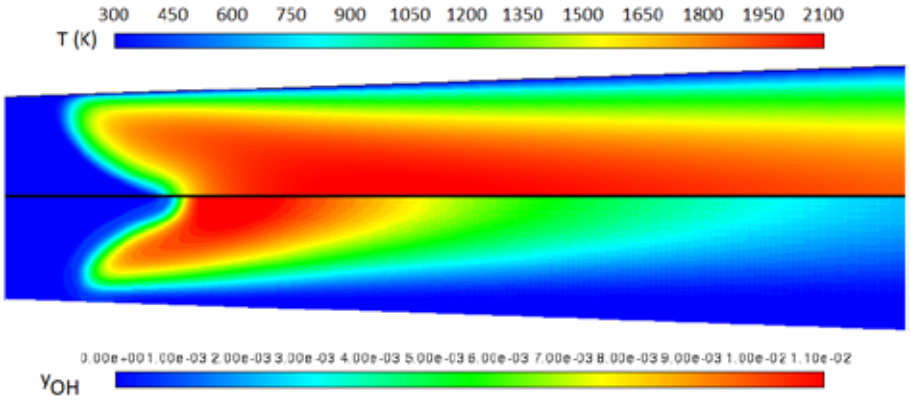

Fig. 1. Laminar stoichiometric hydrogen-air premixed flame stabilized in planar diverging duct with cooled walls, above: temperature distribution, below: distribution of OH mass fraction

CONCLUSIONS

Laminar premixed flames of hydrogen air mixtures in diverging ducts are numerically simulated for different equivalence ratios using different reaction mechanisms. For a given flow rate, the stabilization of the flame at an axial position along

the diffuser is predicted, allowing convenient means for the determination of the burning speed and quenching distance. The applied computational procedures are validated by comparing the predictions with the measurements of other authors.

ABSTRACT

The use of high-fidelity simulation methods based on large-eddy simulation (LES) are proving useful for understanding and mitigating the safety hazards associated with hydrogen release in nuclear facilities. However, accurate modeling of turbulent premixed hydrogen flames via LES can require very high resolution to capture both the large-scale turbulence and its interaction with the flame fronts. Standard meshing strategies can result in impractically high computational costs, especially for thin hydrogen flame fronts. The use of a recently formulated integral length scale approximation (ILSA) subfilter-scale model in combination with an efficient anisotropic block-based adaptive mesh refinement (AMR) technique is examined herein for performing LES of hydrogen flames in large-scale vented vessels. The proposed LES methodology has already been applied to simulations within closed vessels. The anisotropic AMR method resolves the flame fronts. The grid-independent properties of the ILSA model ensure that numerical errors associated with implicitly-filtered LES techniques in regions with varying spatial resolution, and hence filter widths as well, are avoided and therefore, formally converged LES solutions are allowed. The final paper will provide a detail description of the computational framework along with an assessment of the capabilities of the combined approach based on comparisons between predictions and experimental data.

Keywords: large-eddy simulation, adaptive mesh refinement, integral length scale approximation, large-scale vented vessels, hydrogen release in nuclear plants

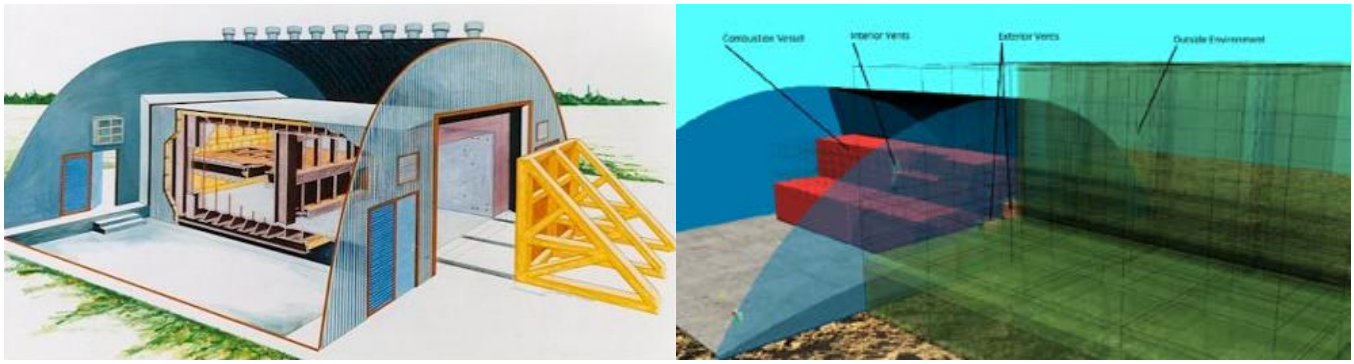
INTRODUCTION AND MOTIVATION

The accurate prediction of hydrogen flames in closed and vented vessels is beneficial in a number of safety related fields, including the assessment of the hazards of hydrogen combustion within the containment building of a nuclear reactor. The use of three-dimensional (3D) computational fluid dynamics (CFD) methods has proven useful in this regard, with many organizations and studies adopting such methods to perform high-fidelity detailed simulations of hydrogen release and combustion under postulated accident conditions [1].

The widespread application of large-eddy simulation (LES) to hydrogen combustion in nuclear containments has been limited by the high-resolution requirements for capturing the flame front and flame brush to accurately predict large-scale flame wrinkling and propagation. Unfortunately, computationally tractable, static, numerical meshes are usually not fine enough to sufficiently resolve the critical length scales associated with practical configurations. For instance, the computational cost incurred by static meshes is generally prohibitive to resolve the width of the flame brush (mili- or micro-meters) in a vessel on the order of meters. Therefore, the use of adaptive mesh refinement (AMR) [2, 3], wherein the mesh is dynamically refined and coarsened depending on the local solution content to accurately treat the required regions of the flow while reducing the overall computational cost, is an attractive alternative for LES of reactive flows. The use of AMR is especially attractive for large-scale facilities for which the mesh requirements to resolve solutions can vary significantly. However, the use of mesh-dependent LES subfilter-scale (SFS) turbulence models, such as the popular Smagorinsky model, can cause problems when used in conjunction with AMR or even with static meshes featuring varying cell sizes [4]. Specifically, mesh-dependent LES SFS models tie the SFS viscosity directly to the cell volume, which can lead to sharp changes in the unresolved fluctuating quantities with cells of largely different sizes. These undesirable sudden changes can introduce significant numerical error and even instabilities into the simulation [4], thereby negatively impacting the quality of the LES results.

In this study, a novel block-based anisotropic AMR scheme [2, 3] is applied in conjunction with a recently proposed mesh-independent integral length scale approximation (ILSA) SFS model [5] to the LES of turbulent premixed hydrogen flames in large-scale vented vessels. The application and evaluation of the proposed approach has been already considered for closed vessels [6] by performing simulations of a number of the well-studied THAI (Thermal-

hydraulics, Hydrogen, Aerosol, and Iodine) experiments [1], and it is extended here to include large-scale vented vessels.



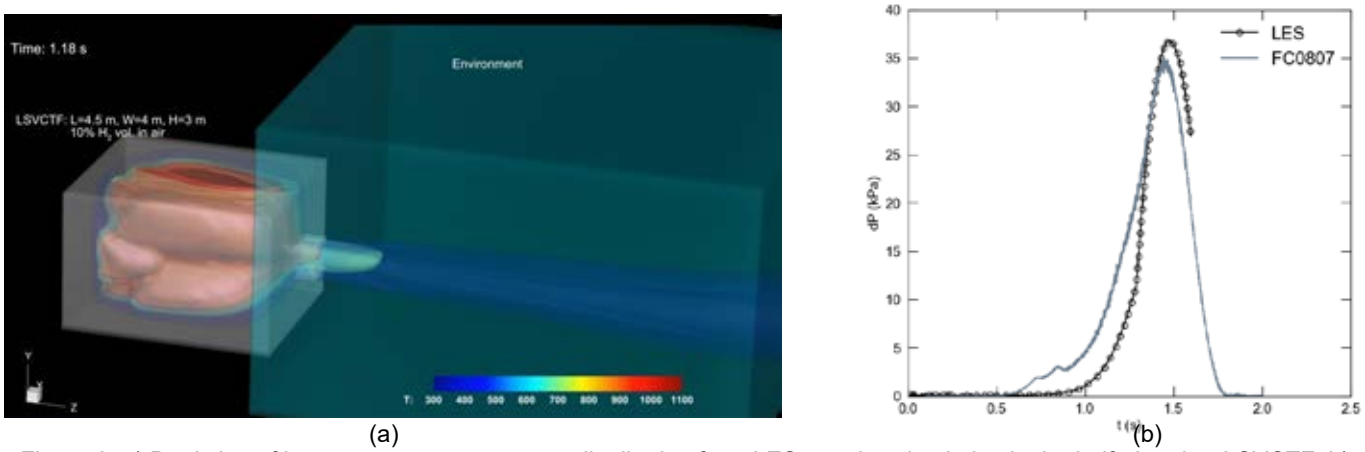
In what follows, a brief summary of the solution approach and numerical results to demonstrate the capabilities of the proposed approach are provided. The final paper will provide details of the proposed computational model for turbulent premixed hydrogen combustion flames, and the numerical discretization and solution procedure on anisotropically-refined grids. To illustrate the performance of the proposed approach, comparisons between the LES results and available experimental data are provided in this abstract. Simulation results for a range of experimental conditions for vented vessels will be provided in the final paper.

COMPUTATIONAL MODEL FOR PREMIXED LEAN HYDROGEN COMBUSTION

In this work, the Favre-filtered form of the Navier-Stokes equations governing compressible flows of a thermally perfect reactive gaseous mixture is solved to describe the turbulent premixed combustion processes. Dufour and Soret radiation effects are neglected. The partial differential equations governing the transport of the mixture mass, momentum, energy, and species concentrations are solved by applying a finite-volume discretization procedure in combination with a solution-driven anisotropic AMR procedure on 3D, multi-block, body-fitted, computational mesh consisting of hexahedral volume elements. The system of governing equations is closed by modelling the LES SFS turbulence stress tensor. The current work investigates the use of the ILSA model [5], which makes use of a similar eddy viscosity approach as the classical Smagorinsky model but differs in the evaluation of the SFS turbulent viscosity, to enable mesh-independent LES solutions to be achieved. To model the interaction between turbulence and chemistry and thermal-diffusive instabilities of the hydrogen flames, a multi-phenomena burning velocity combustion model is adopted here [6].

DESCRIPTION OF THE VENTED COMBUSTION EXPERIMENTAL FACILITY

The large-scale vented combustion test facility (LSVCTF) was operated at Canadian Nuclear Laboratories for over two decades. LSVCTF is a rectangular chamber with dimensions of 10-m long, 4-m wide, and 3-m high for an internal volume of 120 m^3. A schematic cutaway representation is shown in Fig. 1a. Two removable internal walls made of structural steel can divide the entire chamber into two or three rooms. For instance, the half chamber configuration is 4.5-m long. Both the front end and rear end walls are covered with rectangular steel plates bolted to the end wall structure. The vent area can be changed by removing an appropriate number of panels. During an experiment, the vent openings are covered with aluminum foil to prevent premature loss of pre-combustion gases; however, they can easily break open during combustion.



(a) (b)

Figure 1: a) Schematic representation of the Large-Scale Vented Combustion Test Facility (LSVCTF), b) cutaway of an initial multiblock structured mesh for the LSVCTF depicting the combustion vessel, interior and exterior vents, and the outside environment.

COMPUTATIONAL MODELLING OF THE LSVCTF

The LES modelling procedure for hydrogen deflagration described above is considered now for performing simulations of vented vessels. In particular, the conditions tested experimentally in the LSVCTF are considered. Figure 1b depicts an example of the computational mesh developed for the LSVCTF, in which the combustion vessel consists of two chambers separated by an interior vent. The two exterior vents that connect the combustion vessel with the outside environment are triggered to open dynamically if the wall pressure becomes greater than a desired vent burst pressure.

To demonstrate current capabilities of the computational framework, simulation results for the half-chamber configuration are depicted in Fig. 2. The instantaneous temperature distribution predicted by the LES framework at t=1.18 s is shown in Fig. 1a. The experimental conditions are for an initially quiescent mixture with 10% H_2 vol. in air. Figure 2b shows a comparison between the LES predicted and experimental time histories of the vessel overpressure at the location of a pressure sensor in the LSVCTF.

(a) (b)

Figure 2: a) Depiction of instantaneous temperature distribution for a LES reactive simulation in the half-chamber LSVCTF, b) comparison of predicted time history of the vessel overpressure to the LSVCTF measurements for the FC0807 experiment (9% H_2 vol. in air and an initially turbulent mixture).

Preliminary simulations with AMR indicate that the use of dynamically-adaptive grids is desirable to accurately capture the flow behaviour at vent interfaces. The final paper will present a full set of numerical results for a range of conditions studied in the LSVCTF and additional comparisons against the experimental data. Furthermore, the performance of the ILSA model for meshes with varying mesh resolution will be assessed.

ABSTRACT

Fuel cell vehicle hydrogen supply system is an important part of fuel cell vehicle driving. Ensuring the safety of hydrogen supply system is very important for fuel cell vehicles. At present, the main safety problems in hydrogen supply system of fuel cell include hydrogen leakage, overtemperature and overpressure. In this paper, the fault tree is used to analyze the explosion caused by internal faults in the hydrogen system, and the safety protection for the hydrogen supply system is carried out. As the monitoring equipment of hydrogen supply system, hydrogen controller plays an important role in ensuring the safety of on-board hydrogen supply system. The safety status of hydrogen supply system is verified by hydrogen controller test.

Keywords: Hydrogen Supply System, Hydrogen Controller, Solenoid Valve, Fault Tree, Labview

INTRODUCTION

With the emergence of new problems such as energy shortage and greenhouse gas emissions, more and more attention has pay to new energy. The emergence of new energy vehicles promotes the rapid transformation of traditional vehicles, and vigorously developing new energy vehicles has become the current industry trend. As an ideal energy source for new energy vehicles, fuel cell has become a research hotspot for its advantages of environmental protection, continuous power supply, good durability and no noise. At the same time, hydrogen plays an important role in the new energy system. As the world's largest hydrogen producer, China's annual output can reach 10 million tons, which has significant advantages in the development and utilization of hydrogen energy [1]. At present, environment and energy have become the global common concern. Therefore, as an important measure of energy structure adjustment, fuel cell vehicle is an important development direction of energy technology in the future[2]. As the power source of vehicles, on-board hydrogen supply system is an important part of fuel cell vehicles. To ensure the safety of hydrogen supply system is of great significance for fuel cell vehicles.

The hydrogen controller is mainly responsible for monitoring the temperature and pressure of the hydrogen bottle, the pressure of the hydrogen supply pipeline and the hydrogen leakage concentration in the hydrogen supply system, and then controlling the opening and closing of the electromagnetic valve. As the monitoring equipment, the controller plays an important role in ensuring the safety of on-board hydrogen supply system[3]. Therefore, it is necessary to conduct the fault test of hydrogen controller, in order to verify the safety state of hydrogen supply system.

Hydrogen Supply System

Structure And Composition of Hydrogen Supply System

Fuel cell vehicle hydrogen supply system is composed of hydrogen supply part, hydrogen safety part and system communication part. The hydrogen supply part is mainly composed of gas supply pipeline and related combined valves. The core of this part is to control and regulate the hydrogen pressure and flow in the hydrogen supply pipeline through key valves. The hydrogen safety part mainly includes various sensor components, which are responsible for monitoring the hydrogen concentration, pressure and flow, and reasonably distributing and installing the corresponding devices, so as to ensure the overall safety[4]. The communication part of the system is to establish CAN signal transmission and feedback control between the hydrogen supply system and the hydrogen system controller.

Working Principle of Hydrogen Supply System

When the hydrogen supply is supplied, the solenoid valve on the high-pressure hydrogen cylinder valve is opened, and then the fuel cell stack is supplied by the flow valve, the filter, the pressure reducing valve, the safety valve and the pipe solenoid valve. At the same time, the bottle vent solenoid valve in the whole system is

equipped with a PRD relief device, and there are safety protection devices such as over-current valve and safety valve on the pipeline, so as to ensure the safety of the whole system in use.

Failure Analysis of Hydrogen Supply System
Analysis Of Safety Hazards Based on Fault Tree

The purpose of analysis of safety hazards is to ensure the safety and reliability of hydrogen supply system and avoid dangerous accidents. Based on the above analysis of the structure and function of on-board hydrogen supply system, this paper summarizes the safety hazards, focuses on the analysis of faults in the hydrogen supply process, and puts forward the corresponding recovery conditions and protective measures.

The main safety hazards in the operation of the hydrogen supply system are: deflagration caused by hydrogen leakage in the hydrogen supply system, and rupture of the hydrogen storage bottle caused by overtemperature and overpressure. In the hydrogen supply system, the main components used for monitoring and protection are hydrogen supply controller and sensors. Therefore, according to the types of sensors, the faults in the hydrogen supply system are classified as follows: hydrogen leakage, high/low pressure fault, high temperature fault and component fault. Fault tree is used to analyze the faults in the hydrogen supply system.

Through analysis of fault tree, it can be concluded that the reason of deflagration caused by hydrogen leakage in the hydrogen supply system is that hydrogen gathering in the hydrogen supply system and reaches ignition energy[5]. Due to the characteristics of hydrogen, the ignition energy is extremely low when its concentration is in the range of 4%-75%, and it is easy to explode in open flame. Based on the large flammable concentration range and low ignition energy of hydrogen, there will be a great probability of deflagration when hydrogen leakage. The hydrogen pipeline includes many pipes and connections, which are the leakage sources (the probability of hydrogen leakage depends on the number of connected parts).

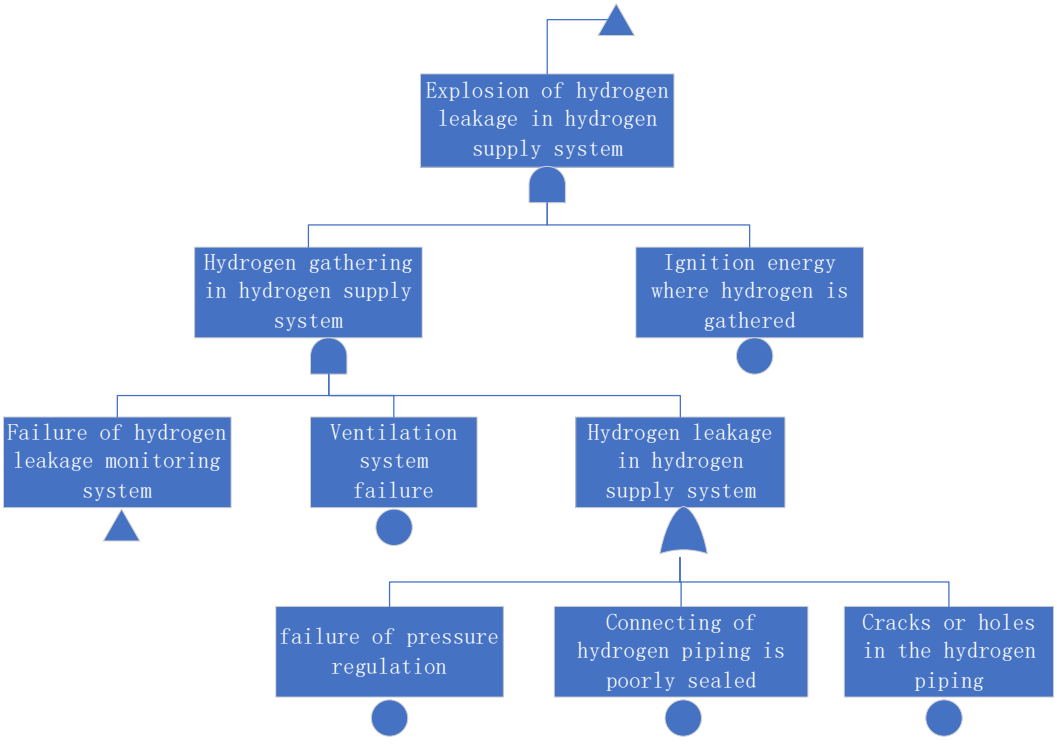

Fig. 1. Fault tree of deflagration caused by hydrogen leakage in hydrogen supply system

Through analysis of fault tree, it can be concluded that the reason for the rupture of the hydrogen storage bottle caused by the excessive temperature and pressure is the overpressure inside the tank[6]. In addition, the rupture spontaneously caused by external failures such as car accidents with collision and aging of the bottle that the safety valve can't protect will not be studied in this paper.

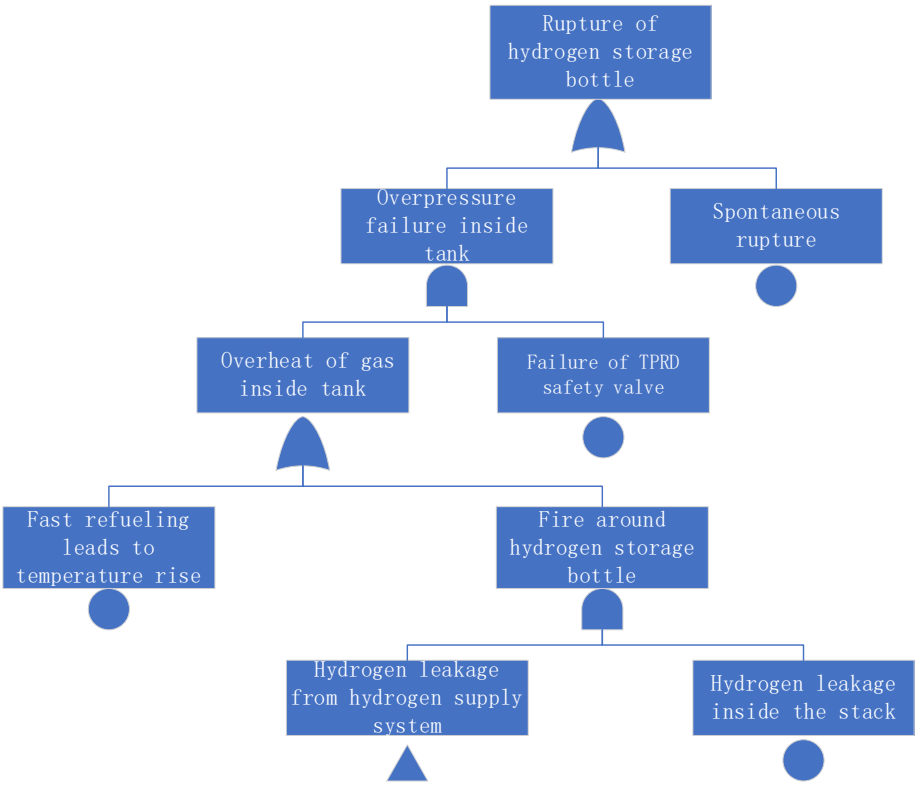

Fig. 2. Fault tree of hydrogen bottle rupture

Derivation of Fault Threshold

This part mainly introduces the composition, working range and fault threshold of the sensor.

Safety Protection of Hydrogen Supply System

Based on the above fault analysis results, the safety protection of hydrogen supply system is optimized. To ensure the reliability of on-board hydrogen system, it is necessary to protect the hydrogen supply system. Each hydrogen bottle mouth valve is equipped with a temperature sensor and a pressure sensor to measure the temperature and pressure of the bottle mouth. The pressure reducing valve in the hydrogen supply pipeline has a pressure sensor at the front and rear, which is used to measure the hydrogen pressure in the pipeline. In addition, the concentration sensor is distributed in the hydrogen supply pipeline, which is used to detect hydrogen leakage in the pipeline.

Fault Testing

In order to verify the safety monitoring function of hydrogen controller, it is necessary to carry out hardware-in-the-loop test on hydrogen controller. Test links mainly include the following: sensor signal acquisition, controller output execution command and CAN communication. The sensor signal is simulated in LabVIEW and sent it to the controller. The hydrogen controller responds after receiving the signal and transmits the response signal to the analog actuator in LabVIEW. Based on the output of actuator with different sensor signal input, judge whether the upper logic of hydrogen controller is correct. After the basic work is done, the entire in-loop test is debugged. Sensor signal input, actuator signal output and CAN communication are tested and verified.

CONCLUSIONS

Hydrogen supply system in the fuel cell vehicle is the core part of fuel cell system. In this paper, the fault tree is used to analyze the internal faults that may cause hydrogen explosion in the hydrogen supply system, and then the explosion risk assessment caused by internal faults can be obtained. Combined with the results of fault analysis, the safety protection system of hydrogen supply system is optimized. Among them, the hydrogen system controller plays an important role in ensuring the safety of the vehicle-mounted hydrogen supply system. Therefore, a test of hydrogen controller based on Lab VIEW is established, which can verify the safety status of hydrogen supply control system.

ABSTRACT

Safety study and Computational Fluid Dynamics (CFD) simulation are conducted to analyze hydrogen leakage in semi -closed space of hydrogen facilities and installation in the framework of Cervera H24NEWAGE project. The goal of this study is to evaluate the hydrogen dispersion from release sources inside the building and to give detailed analysis of gas dispersion by using CFD in all areas, especially in some areas where there are highly potential leakages and inadequate flow ventilation due to some obstacles which could impede air recirculation in the zone. This study is useful to understand the dispersion of hydrogen release inside the building in order to implement best safety engineering practice for the new hydrogen facilities. In this study, hydrogen release is calculated by using UNE 60079-10 and considering other international standards such as API 505, and EIGA Doc 15/21. CFD simulations of different combinations of hydrogen release are done by varying pressure and opening area of release source with four air ventilation systems in operation. Velocity of air and concentration of hydrogen are calculated from the CFD model to hydrogen dispersion inside the building.

Keywords: Hydrogen safety, Hydrogen leakage, CFD simulation, Air ventilation

INTRODUCTION

Hydrogen (H2) is a clean energy source and has a great potential as a key element in the world economy due to its potential applications in basic sectors such as energy, industry and transportation. Hydrogen is foreseen as a key to the energy transition, due to its high potential contribution to the decarbonization of the economy and the reduction of fossil fuels use, which allows a greater integration of renewable energies in the energy mix and an important contribution to the circular economy. However, the maturity of hydrogen technology applications is still low and future development of its implementation is needed. Therefore, a new laboratory and facilities are needed to help us to understand and develop the best safety engineering practice of its applications.

Our study consists of safety study and CFD (Computational Fluid Dynamics) modelling of hydrogen leakage from equipment and piping installations in the new CIRCE hydrogen laboratory which is carried out in the framework of Cervera H24NEWAGE project. This building has a total effective volume of 6,434 m3 (49.4 m (L) x 16.28 m (W) x 8 m (H)) which are planned to be installed in 2022-2023. It consists of three working areas which are gasification, burner, and biomass reactor unit with hydrogen bottles installation located outside the building (Fig. 1).

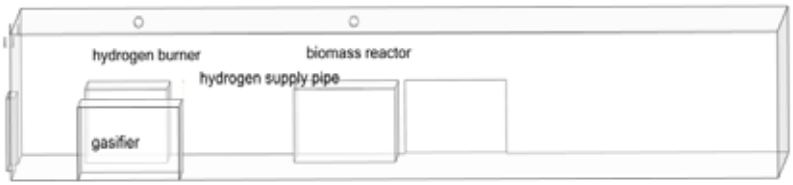

Fig. 1. 3D Model of Alfajarín Hydrogen Facilities

Hydrogen Leakage Analysis

The UNE-EN 60079-10-1 standard will be used to calculate hydrogen release from the system such as leak from piping connections, instruments, exhaust vent, safety valves considering its operating and design condition. Air recirculation and maximum hydrogen release in each block will be evaluated to guarantee that the total calculated hydrogen release in each block is below its maximum limit. Ventilation design criteria is evaluated carefully and is considered as a control measure to reduce the hydrogen gas hazard due to hydrogen release from the system. Hydrogen release from equipment and piping connections can create an explosive atmosphere if the concentration of the hydrogen exceeds 25% of the LEL which is 1% considering 4% LEL of Hydrogen. Six (6) air changes per hour is

considered as minimum requirement to guarantee adequate ventilation inside the enclosed building [1-2]. The minimum ventilation of the building will be 38604 Nm3/h (6434 m3 x 6 changes/h) and four exhaust fans of 10,000 Nm3/h will be in operation to guarantee the minimum requirement according to standard.

Release Rate and Release Characteristics

Release rate for gas (W_g) from hydrogen installation is calculated by using equations below for subsonic release (Eq.1) and sonic release (Eq. 2). Subsonic release is mainly considered in the calculation due to low discharge velocity of release rate of gas which is below the speed of sound. On the other hand, sonic release or release rate of gas with choked gas velocity is considered when the discharge velocity equal to the speed of sound which is the maximum theoretical discharge velocity [3]. Release characteristic is considered as maximum allowed concentration of hydrogen and is calculated by using Eq. 3 considering mass release of gas, density, LFL and safety factor.

$$W_g = C_d \, x \, S \, x \, p \, x \sqrt{\frac{M}{Z\,R\,T}\frac{2\gamma}{\gamma-1}\left[1-\left(\frac{P_a}{p}\right)^{(\gamma-1)/\gamma}\right]}\left(\frac{Pa}{p}\right)^{1/\gamma} \quad (1)$$

$$W_g = C_d \, x \, S \, x \, p \, x \sqrt{\gamma\frac{M}{Z\,R\,T}\left(\frac{2\gamma}{\gamma-1}\right)^{(\gamma+1)/(\gamma-1)}} \quad (2)$$

$$V_g = \frac{W_g}{\rho_g \, k \, LFL} \quad (3)$$

Variation of Hydrogen Release

The release and accumulation of hydrogen in semi-closed spaces is potentially dangerous as the hydrogen moves rapidly upwards due to the large difference of air and hydrogen density. Hydrogen dispersion in a semi-closed space with one open boundary, with uniform or nonuniform concentration distribution of hydrogen, depends on several factors such as hydrogen pressure, leak size, direction of release, and the enclosure parameters such as its volume and vent sizes [4]. Different combinations of hydrogen release pressure and source opening area are shown in Table 1.

Table 1. Variations of Hydrogen Release

Parameters	Unit	Case 1	Case 2	Case 3	Case 4	Case 5
Pressure	barg	0.10	5.00	10.00	50.00	6.00
Mass release (W_g)	kg/s/flange	1.404E-06	7.019E-05	1.404E-04	7.019E-04	8.422E-05
Volume release	L/s/flange	0.016	0.781	1.561	7.807	0.937
LFL	vol/vol	0.040	0.040	0.040	0.040	0.040
Gas density (ρ_g)	kg/m^3	0.0899	0.0899	0.0899	0.0899	0.0899
Safety factor (k)	-	0.500	0.500	0.500	0.500	0.500

CFD Modeling

The CFD model has been developed with a commercial CFD software (Ansys Fluent) and consist in a 3 million polyhedric cells that reproduce the fluid volume. Boundary conditions have been defined by imposing an outlet mass flow in the extractors and a pressure inlet in the door openings. This approach realistically models the actual building conditions. For turbulence model, two model has been tested (standard k-ε and SST k- ω). In order to characterize the leaks in the pipe joints, an opening area is created which corresponds to leakage value of each case study.

RESULTS AND DISCUSSION

The result of the CFD numerical model is shown in Fig.2 which shows the volumetric concentration of hydrogen inside the building in the range of 0-1%. In this case, ventilation system performance is evaluated to ensure that the concentration in all areas is below the maximum limit (1%).

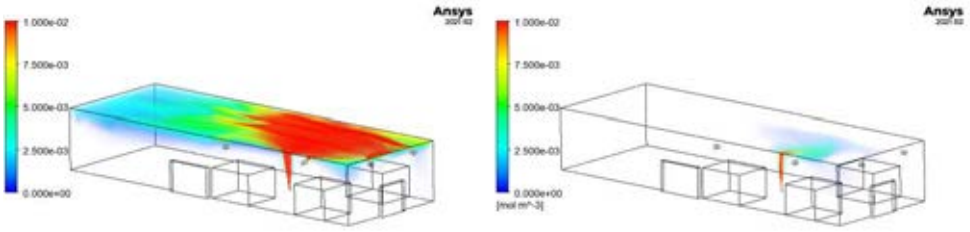

Fig. 2. Volumetric concentration of hydrogen in case 4 and 5

CONCLUSIONS

CFD is considered as a useful numerical model to evaluate air characteristics in all areas, such as velocity and gas concentration, especially in some areas where air dilution is inadequate which can't be measured easily by normal air measurement instrument. According to preliminary result of CFD model in Fig.2, hydrogen concentration inside the building is varied between 0-1% depends on number of air recirculation in each area, and in some particular areas is above than 1% which is the maximum limit off hydrogen according to UNE-EN 60079-10-1 standard. Therefore, the CFD model is useful to understand hydrogen distribution profile inside the building which will help us to design proper ventilation system in order to guarantee that hydrogen concentration inside the building in all areas less than 1%.

Moreover, a detailed study will be done with different variations of hydrogen release in order to give several recommendations concerning safety issues due to hydrogen release and to give the best recommendation based on good safety engineering practice.

NOMENCLATURE

W_g	Mass release of gas, kg/s
C_d	Discharge coefficient (dimensionless)
S	Cross section of the opening (hole), through which the fluid is released (m2) (Reference to EN 60079-10-1 2015 Table B.1)
M	Pressure inside the container, Pa
M	Molar mass of gas or vapour, kg/kmol
Z	Compressibility factor (dimensionless)
R	Universal gas constant, 8,314 J/kmol K
P_a	Atmospheric pressure, 101,325 Pa
T	Absolute temperature of the fluid, gas or liquid, K
V_g	Release characteristic, m^3/s
k	Safety factor attributed to LFL (dimensionless)
LFL	Lower Flammability Limit, vol/vol

Greek Letters

ρ_g	Gas density, kg/m^3

TOWARD THE CONTINUOUS SENSING OF LEAKED HYDROGEN BY A QUAD-ROTOR DRONE

[1]Takafumi SUGA and [1*]Kazuo MATSUURA*

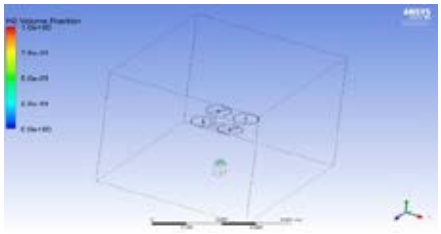
ABSTRACT

Hydrogen is expected to leak in a variety of situations, from production to consumption. To realize a hydrogen sensing system that is more flexible and quicker than conventional systems, we have proposed a new drone-based system for hydrogen sensing with a small hydrogen sensor of the semiconductor type. Initially, quad-rotor drones were thought to be unsuitable for hydrogen leak detection because hydrogen is pushed away from the drone by propeller downwash. However, recent CFD (Computational Fluid Dynamics)-analyses and experiments detecting hydrogen at a drone have shown that hydrogen leak detection is possible even under the propeller downwash. In particular, it has been found that the flow rises from the leak source to the propeller outside the propeller downwash. In this study, we investigate the mechanism of hydrogen sensing by the quad-rotor drone through direct measurement of hydrogen dispersion around the drone. For this purpose, hydrogen leak experiments were conducted and the path of hydrogen dispersion around the drone was analyzed by twenty hydrogen sensors installed on a lattice constructed around the drone. These results substantiate, for the first time as long as the authors know, the hydrogen sensing mechanism mentioned above and support that reliable drone sensing can be achieved.

Keywords: Hydrogen safety, Sensing, Drone, CFD analysis, Smoke-visualization

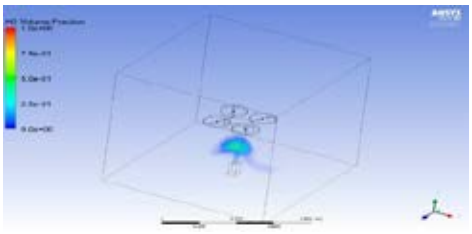
INTRODUCTION

The use of hydrogen is becoming more and more widespread in our daily lives. From production to consumption, hydrogen leakage is anticipated in various situations. Generally speaking, hydrogen sensing can be categorized as fixed measurement, portable probing and laser measurement. In the fixed measurement, the location of a hydrogen sensor is fixed, therefore some time is required until hydrogen reaches the sensor from a leak source. In the portable probing, measurement becomes difficult in the places where human access is difficult. In the laser measurement, Raman scattering method based on an ultraviolet laser is known. In this method, optical system inevitably becomes expensive. To realize a hydrogen sensing system that is more flexible and quicker than conventional systems, we have proposed a system in which a small semiconductor-type hydrogen sensor is mounted on a drone [1]. Initially, it was anticipated that quad-rotor drones were unsuitable for hydrogen leak detection because the rise-up of hydrogen from a leak source is suppressed by the propeller downwash. However, recent-CFD analysis and smoke experiments have shown that hydrogen leak detection is still possible [2]. In this study, we will measure the process of hydrogen dispersion in order to clarify the mechanism of the successful hydrogen sensing.



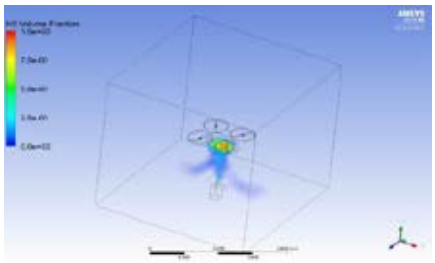
EXPERIMENTAL METHODS

Drone-based hydrogen sensing system

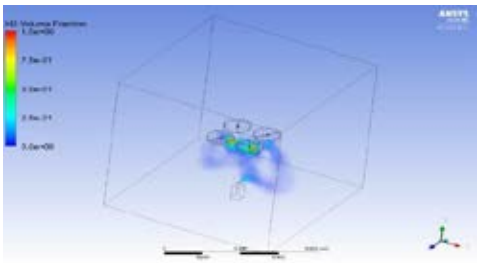


The sensor system is attached to a RC Logger's quad-rotor drone, RC EYE One Xtreme. The total length of the drone is 225 mm and the diameter of the propeller is 138 mm. The hydrogen sensor used in this project is an MQ-8 sensor from Zhengzhou Winsen Electronics Technology. This sensor is of semiconductor-type and its detection range is 100-10000 ppm. Its response time is less than 1s.

Hypothetical mechanism of the hydrogen sensing



Drone sensing has been developed to enable easy detection of hydrogen leaks even in places where detection has been difficult by installing semiconductor-type sensors on drones. Initially, quad-rotor drones were thought to be unsuitable for hydrogen leak detection because the gas could not reach the sensor mounted on the drone due to the airflow of the propeller. However, the CFD analysis shown in Fig. 1 and the smoke experiment shown in Fig. 2 showed that it is feasible.



(a) t=3.5s (0.5s after the leak start of H2)

(b) t=5s (2s after the leak start of H2)

(c) t=6s (3s after the leak start of H2)

(d) t=7s (4s after the leak start of H2)

Fig. 1. Computed hydrogen distribution

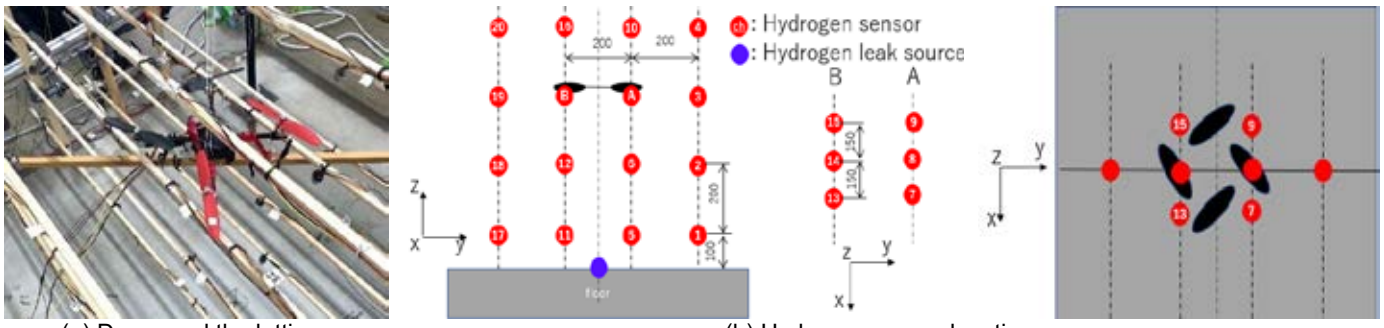


Fig. 2. Flow around the drone visualized by smoke experiment at the rotation speed of 1600 rpm (time evolves from left to right). Air stream circulation is created around the drone.

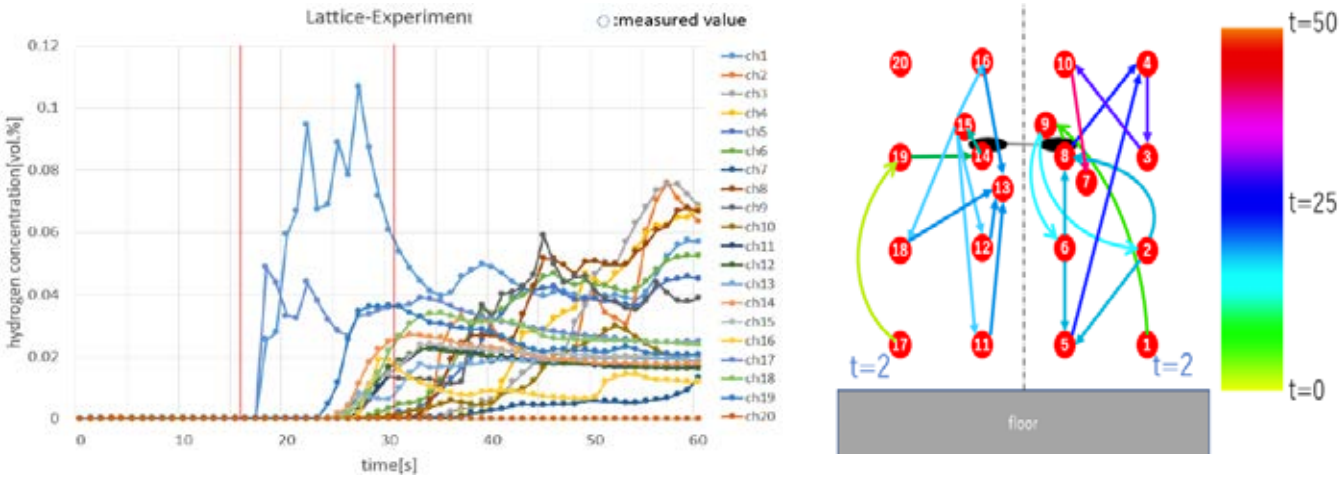
Figures 1 and 2 show CFD results of hydrogen dispersion around the drone and the flow around the drone visualized by a smoke experiment, respectively. In Fig. 1, computed hydrogen distribution for t=3.5-7 s is shown. Here, t=0 is the leak start. Hydrogen initially rises up from the leak source, and it is pushed down by downwash from the propellers. Hydrogen then passes outside the downwash and rises up again to the drone riding on circulating flows formed around the propellers. In Fig. 2, smoke is supplied from a pipe with small holes. For the purpose of clear visualization, smoke emission is terminated after a short time. Although smoke from the floor is diffused by the downwash of the propellers, flow circulation is formed due to suction from the upside of the propellers. From these results, it is considered that hydrogen from the leak source first rises to the propellers outside the region of propeller downwash, and then is sucked in and discharged from the propellers, which is the reason for the successful hydrogen detection by the present system.



Direct measurement of hydrogen dispersion by a sensor array

In order to understand the actual path of hydrogen a sensor arrays was constructed as shown in Fig.3. A drone was placed at 50 cm directly above the leak source, and sensors were placed on the square bars held at 10 cm, 30 cm, 50 cm, and 70 cm from the floor. 100 vol.% hydrogen leaks from the leak source at the flow rate of 5 L/min for 15 s. The propeller rotation is 1600 rpm. Figure 4 shows the results. If we focus on the left side of Fig. 4, i.e., (b) detection order, the hydrogen arrive at Channel 17, 19 and 14, and then hydrogen diffuses to various regions around the drone.

Fig. 3. Experimental apparatus for the sensor array measurement

(a) Historical H2 concentration at each sensor (b) The path of hydrogen dispersion measured by the sensors

Fig. 4. Results of the sensor array experiment

CONCLUSIONS

A system called drone hydrogen sensing was proposed . The drone sensing was found to be feasible through the CFD analysis and smoke experiments, and a hypothesis was formulated about the detection mechanism. To corroborate the hypothesis, the process of hydrogen dispersion around an operating quad-rotor drone was measured by the sensor array consisting of twenty hydrogen sensors placed on a lattice constructed around the drone. Hydrogen from the leak source first rises to the propellers outside the propeller downwash and then is sucked in and discharged from the propellers. The present results, for the first time as long as the authors know, substantiate the previously-proposed mechanism of hydrogen sensing by a quad-rotor drone.

ABSTRACT

Demand for hydrogen fuel increases with the introduction of fuel cell electric vehicles, giving increased pressure to minimize refueling station footprints and lower costs while maintaining safety and performance. Compressed gas hydrogen (H_2) storage is a viable approach to assuring sufficient hydrogen capacity at commercial fuelling stations. Due to the high pressure at which hydrogen is usually stored and dispensed, consequence analysis for risk assessment and power reduction is very crucial. In this regard, the present study aims at simulating hydrogen dispersion along with consequence analyses for such events as jet fire using ALOHA model. Dispersion consequence modeling was performed, followed by the evaluation of the effect of environmental (i.e., stability, ambient temperature, surface roughness, wind speed, and humidity) and process (i.e., vessel temperature and pressure, and leakage diameter) parameters on maximum size flammable vapor cloud and maximum level jet fire radiation on the ground. The size of flammable vapor cloud (consequence dispersion index) and the maximum flux of radiation were affected by process parameters more than ambient parameters. Leakage diameter was found to have the highest impact on the operational parameters.

Keywords: dispersion hydrogen, consequences, ALOHA

INTRODUCTION

Hydrogen is a promising energy carrier. However, hydrogen has a wide flammable range of 4–75 vol.% (in air) and a very low ignition energy of 0.019 mJ. The primary issue of hydrogen utilization is safety in various scenarios for the coming hydrogen economy. This work focuses on hydrogen leakage, which is typically induced by structural failure in refueling stations and transit vehicles, with attention to eliminate public concern and provide references for design, legislation, and standards. Rodionov et al. [1] presented a risk assessment of the hydrogen explosion related to a hydrogen-driven engine car. From the work, it stated that hydrogen explosion in open and semi-confined environments has a high level of risk with potential injuries to people and damage to cars and area of the hydrogen explosion. Hydrogen explosions in a confined environment have a low probability, but they can cause the most severe consequences to people, properties, and the area of the accident. For the safe design of retail facilities, through the development of appropriate codes, it is essential to understand all the hazards that could arise following an accidental release of hydrogen and to have data to allow the appropriate standards to be developed. These data can be also used to develop and validate models used in quantitative risk assessment tools [2-3] and tools based on computational fluid dynamics (CFD) [4] or tool based on integral models e.g. DEGADIS,SLAB, PHAST, HGSYSTEM, and ALOHA. The present study was formulated in order to determine the consequences caused by hydrogen dispersion, adopting ALOHA software. Variables such as wind speed and the leak hole diameter were selected as the factors to simulate the consequences of hydrogen storage leakage accidents. The impacts of each variable on accident consequences were analyzed for obtaining the reasonable and effective reference in actual accidents and conducting fire risk assessment.

SIMULATION METHODS

The model of dispersion chosen for the purpose of this research is the ALOHA model, which has been built upon the Gaussian dispersion model of continuous, buoyant air pollution flumes that capable to simulate the accidental release of hazardous substances and the dispersion of chemical vapor. For this work, hydrogen refueling station (HRS) facilities with storage involving compressed gas hydrogen have been chosen as the subjects of simulation. Suppose leakage occurred at Pasir Gudang highway, in Malaysia with longitude and latitude of 1.4825°N, 103.8811°E. The initial condition of the simulation and for the potential incidence of release, two hypothetical scenarios (I and II) have been created with environmental configurations as shown in Table 1.

Table 1 Initial condition and Potential incidence of release

Potential release	Scenario I: Rupture in tank at a refueling station (HRS)	Scenario II: Rupture of storage hydrogen tank in a car
Simulation scenarios	**a) Pipeline** • Diameter = 0.15, 0.20 and 0.30 m • Pipe length = 200 m • Pressure in pipe = 70 bar • Wind speed: 2 and 8 m/s from North • Ambient temperature = 33°C • Humidity = 46 % **b) For storage tank** • Direct source of hydrogen (worst case scenario) • Leak hole diameter of 15 cm • Volume: 300 litre • Uncongested area of hydrogen refueling station • Vessel pressure = 500 bar	Use Toyota Mirai as model for the simulation • Moving car – possible being hit at back (25-L hydrogen storage tank) • Possible rupture of all connected storage tanks (Total volume is 141 litre) • Storage pressure = 700 bar • Car moving in semi-confined area, e.g., tunnel • Car parked in a confined area and congested area, e.g., multilevel parking

RESULTS AND DISCUSSION

The main consequences of hydrogen leakage in this work are jet fire (radiation intensity) , flammable cloud and blast overpressure of vapor cloud explosion. Table 2 summarizes the maximum distance from the maximum jet fire, maximum flammable vapor cloud and blast overpressure when hydrogen leaks at different wind speeds i.e. 2 and 8 m/s. It can be depicted that the effect of the wind speeds on from the hydrogen leakage sources is minimum at the stable climate condition. However, when the leak hole diameter pipe increases in case of Scenario Ia, the maximum distance from flammable vapor cloud and maximum radiation level increase with a higher leakage diameter due to an increased release rate and an increased amount of hydrogen. For instance, from 15 to 30 cm leakage in pipe, the maximum distance from flammable vapor cloud and the thermal radiation jet fire increases ~ 2.3 – 2.8 times.

Table 3 Threat zones of hydrogen release computed in the ALOHA simulation at wind speed of 2 and 8 m/s.

8 m/s wind speed							
	Scenario Ia: Dispensing pipes at the HRS				Scenario Ib: Leaks from the storage tank		
Leak hole diameter	**Thermal radiation threat zone**			**Leak hole diameter**	**Thermal radiation threat zone**		
	10.0 kW/sq.	5.0 kW/sq.	2.0 kW/sq.		10.0 kW/sq.	5.0 kW/sq.	2.0 kW/sq.
15 cm	47 m	66 m	102 m	15 cm	12 m	16 m	25 m
20 cm	67 m	93 m	144 m				
30 cm	107 m	150 m	233 m				
	Flammable threat zone				**Flammable threat zone**		
	60 % LEL	10% LEL			60 % LEL	10% LEL	
15 cm	538 m	1600 m		15 cm	N.A	118 m	
20 cm	817 m	2500 m		Direct	N.A	110 m	
30 cm	1500 m	5000 m					
2 m/s wind speed							
Leak hole diameter	**Thermal radiation threat zone**		**Thermal radiation threat zone**				
	10.0 kW/sq.	5.0 kW/sq.	2.0 kW/sq.		10.0 kW/sq.	5.0 kW/sq.	2.0 kW/sq.
15 cm	47	65	101	15 cm	11	16	25
20 cm	66	92	143				

30 cm		107	149	231			
	Flammable threat zone				**Flammable threat zone**		
	60 % LEL	10% LEL			60 % LEL	10% LEL	
15 cm	5000 m	>10 km		15 cm	N.A	118 m	
20 cm	8900 m	>10 km		Direct	N.A	110 m	
30 cm	> 10 km	> 10 km					

For Scenario II, it can be said that the congested situation gave higher maximum distance of blast overpressure (0.55 bar) and 60% LEL flammable cloud i.e. 24 m and 97 m , respectively. It can be explained as; the multilevel parking and available cars can represent congestion and if engulfed by a vapour cloud, can lead to significant flame acceleration. The turbulent energy created by the congestion has a greater effect on explosiveness than does the total amount of leakage or premixed volume [6]. Hence the implication is that it is not necessary to release large quantities of hydrogen to obtain high overpressures on ignition. A release of relatively small quantities with rapid ignition may give a severe event.

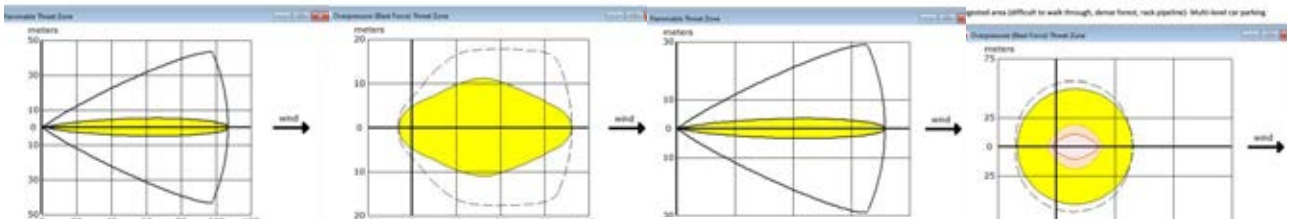

Fig. 2 Threat zones of hydrogen release from the vehicle storage leakage at total rupture for uncongested scenario (two from left) and congested area (two from right)

CONCLUSIONS

The current study evaluates parameters affecting the hydrogen dispersion and ignition using ALOHA model. It can be said that wind speed (climatic factor) gave a minimum change on maximum distances from the consequences scenario, however, the process condition i.e., leakage hole diameter showed a significant factor determining the maximum distance from the radiation intensity and blast overpressure. Likewise, congested area also plays vital impact on the resultant overpressure in case of total rupture of vehicle hydrogen storage.

ABSTRACT

When it comes to storing and transporting hydrogen, safety is key. Using Computational Fluid Dynamics (CFD) simulations in the design and verification of hydrogen storage and transportation devices has become the norm. Accurate CFD models for explosions and hydrogen venting involve complex meshing solutions applied in several iterations to refine and accurately capture the flame and shock positions. To this end, the current work builds on the study of the deflagration-to-detonation transition (DDT) phenomena by proposing and validating against experiments a novel simulation approach. This approach couples automated mesh generation and mesh refinement techniques with detailed chemistry to reduce the overall time to solution. The proposed method is coupled with different combustion modeling approaches, including the eddy dissipation concept and the homogeneous reactor model, as part of the validation study. The numerical simulations are centred around the analysis of DDT in hydrogen-rich enclosures that include a number of obstacles arranged in either a symmetrical or staggered manner. The influence of the layering of the gas species inside the enclosures that leads to homogenous or inhomogeneous conditions is discussed in parallel to the effects of the overall hydrogen fraction.

Keywords: Hydrogen Safety, Deflagration-to-Detonation Transition, CFD.

INTRODUCTION

The growing use of hydrogen as a viable source of energy in many sectors of our society puts greater demand on engineers to evaluate and design systems that have safety as one of the key criteria. In accordance with [1], the 1st priority of research topics related to "Accident Physics of Gaseous Hydrogen" is the "*premixed combustion associated with large scale problems with obstacles, flame acceleration and particularly deflagration-to-detonation-transition (DDT)*". DDT phenomena have long been of interest [2], and CFD is a valuable tool to analyze such complex physics. However, CFD often requires a high degree of expertise and several iterations for the user to build a model that is able to provide results with the desired accuracy. In order to address this issue, we propose and validate against experiments [3, 4 & 5] a novel simulation approach that reduces the number of mesh iterations and tuning model parameters. The DDT experimental setup used for validation consists of an enclosure (5400mm x 60mm x 300mm) that includes 7 rows of obstacles and an ignition source located at the center of the left-most wall; the obstacles produce a blockage ratio of 60% as shown in Fig. 1. The proposed method relies on automatic mesh generation and Adaptive Mesh Refinement [6] based on the local flow conditions. As shown by [4, 7 & 8], the combustion modelling and its related species reaction mechanism are other important aspects that enable the user to further improve the accuracy of the CFD model. To support this, two different combustion modelling approaches, the eddy dissipation concept (EDC) and the homogeneous reactor model (SAGE) [9, 10], are used. Following the validation of the proposed method, the effects of the existing gas layering and overall hydrogen concentration on DDT are analyzed. The last step involves the analysis of the geometrical layout of the obstacles for different blockage ratios and the effect on DDT [11].

CFD MODEL

The present work uses version 3.0.24 of CONVERGE CFD software, a cell-centered finite volume solver [6]. Here, CONVERGE solves the unsteady compressible Navier-Stokes equations using the Pressure-Implicit with Splitting of Operator (PISO) algorithm, coupling the energy, continuity, and species transport equations with the Redlich–Kwong equation of state. The momentum, continuity, species and energy equations are discretized using a second-order upwind scheme (MUSCL) based on the minmod limiter. The checker-boarding effect of the pressure-velocity coupling on collocated grids is mitigated through the use of the Rhie-Chow interpolation scheme. The turbulence is modelled with the Large Eddy Simulation (LES) approach using the Consistent Dynamic Structure model [12].

An automated mesh generation algorithm based on a modified Cartesian cut-cell approach is performed at runtime within the solver. In addition, the mesh is adjusted via an Adaptive Mesh Refinement (AMR) method during the simulation, introducing local on-the-fly grid refinements where gradients of selected variables exceed a certain user-specified threshold. This feature helps to remove the mesh generation iterations, which is particularly critical in cases dominated by strong gradients (e.g., shocks and flame front) and with a highly transient nature, as with DDT phenomena.

The combustion is modelled through different approaches: EDC and SAGE. The EDC model integrates the detailed chemistry into turbulent flows by assuming that reactions are happening at a scale based on the turbulence properties and that the reaction rate is controlled by the turbulence mixing. Therefore, the creation of new species and energy release/consumption source terms include turbulence quantities. For this reason, the Realizable k-epsilon turbulence model is used.

SAGE is a detailed chemical kinetics approach based on the homogeneous reactor model. With SAGE, the chemical reaction rates and the turbulent mixing directly determine the laminar and turbulent flame speeds. Adopting SAGE in the LES framework implies the usage of finer meshes to properly resolve the flame and turbulent structures. However, since these features are highly unsteady and localized, AMR proves to be an effective tool to limit the cell count [11].

Fig. 1. Model used for DDT simulation validation; ignition source shown in red.

RESULTS AND DISCUSSION

The validation geometry is shown in Fig. 1, and conditions are taken from [3, 4 & 5]. For the sake of brevity, only the results obtained with SAGE are shown here. In Fig. 3, the inhomogeneous and homogenous cases with 30% hydrogen molar fractions are computed and validated for the flame tip position and flame tip velocity. A reasonably good agreement with the experiments is observed for different hydrogen concentration and distribution, showing the transition from deflagration to detonation. As shown here, the transition from deflagration (where the flame tip proceeds with relatively low velocity) to detonation (where the front proceeds at few thousands meters per second) is happening sooner and more abruptly in the homogenous mixture, although higher flame tip velocities are obtained in the inhomogeneous mixture once the detonation is achieved. This seems to be in line with Chapman-Jouguet detonation speed [2, 4] and can be explained by the flame tip moving upwards in the channel, where the hydrogen mixture is higher on average than in the homogenous case with the same overall hydrogen concentration (see Fig. 2). In cases with a leaner hydrogen-air mixture (20% hydrogen concentration), the opposite trend has been observed. For reference, the theoretical Chapman-Jouguet detonation speed computed for a 30% hydrogen concentration is of the order of 2560 m/s. This seems to be well predicted by the simulation with the value of 2240 m/s. Gravity plays a larger role in the asymmetry of the burnt gas than in the flame front even in the homogenous mixture (Fig. 2). In these reacting flows with strong gradients, the numerical simulation is able to accurately account for the Richmeyer-Meshkov and Kelvin-Helmholtz instabilities. These are key ingredients in the shock-flame interaction, and this is where LES provides a more suitable modelling framework compared to URANS.

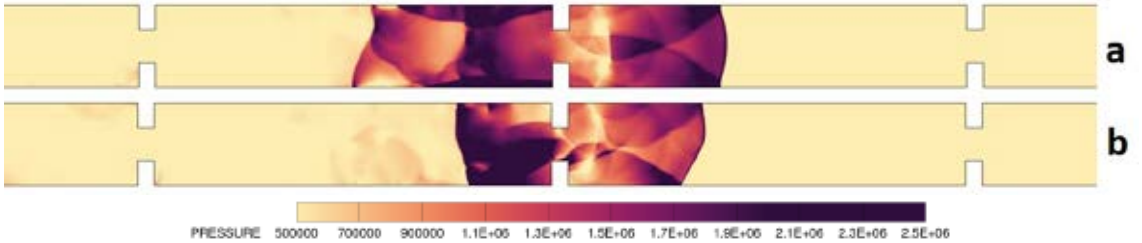

Fig. 2. Pressure [Pa] contours in the (a) homogeneous and (b) inhomogeneous mixture.

CONCLUSIONS

In this work, a novel simulation approach is proposed and validated against experiments for simulating hydrogen DDT phenomena with minimal user tuning required. Different combustion modelling approaches are investigated, as are the effects of the hydrogen-air mixture variation and the geometry modification on DDT.

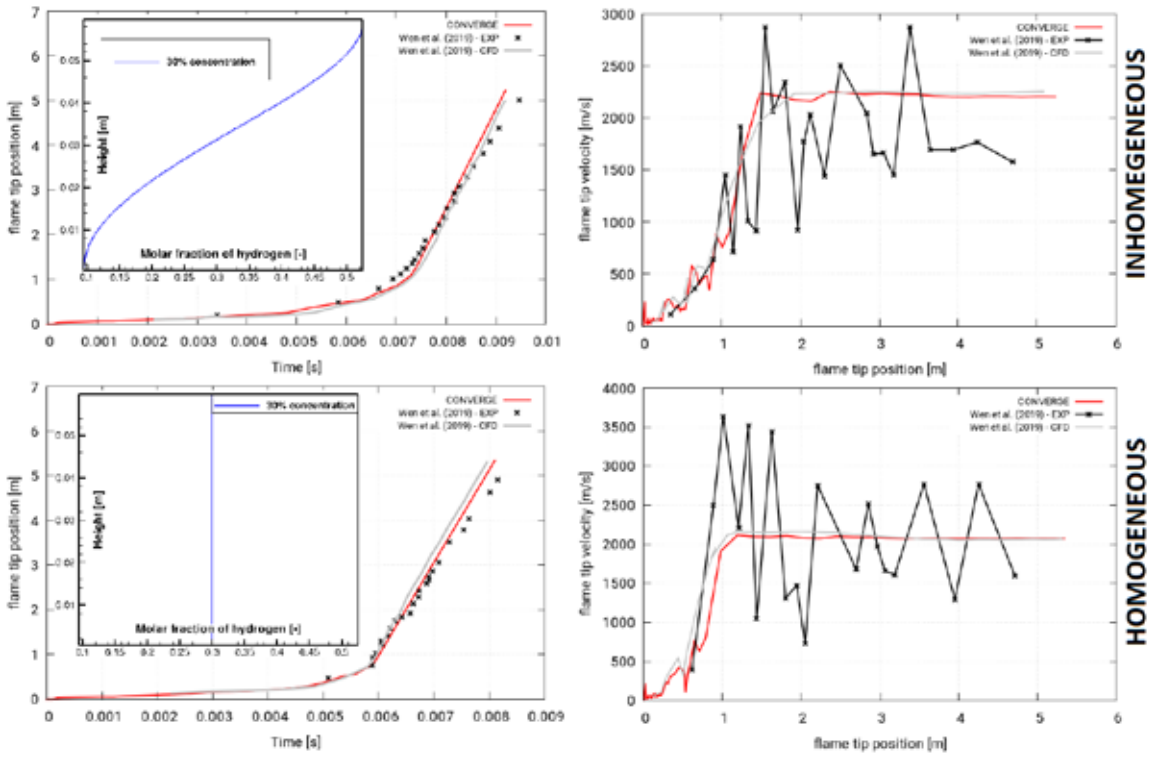

Fig. 3. Validation results against inhomogeneous and homogeneous hydrogen-air mixtures; experiments from [3, 4].

ABSTRACT

Safety and reliability are the major challenges to face for the development and acceptance of hydrogen technology. It is therefore crucial to study deeply material compatibility, in particular polymer materials that are directly in contact with hydrogen. This paper presents an experimental study on the fretting wear behavior of two types of cross-linked hydrogenated acrylonitrile butadiene rubbers against 316L steel ball in hydrogen environment. Furthermore, aging experiments were conducted for 7 days under static conditions in 100 MPa hydrogen. The influences of hydrogen pressure as well as the aging exposure on the fretting behavior are discussed by means of surface analyses and well as material properties.

Keywords: Fretting wear, elastomers, hydrogen, high-pressure

INTRODUCTION

The development of an infrastructure for the safe and reliable storage, handling and delivery of hydrogen is crucial for the expansion of hydrogen technology in the transport and industrial sector. Thereby, many polymeric materials that are directly in contact with hydrogen play a vital role in particularly in components such as seals, coupling systems and friction stressed surfaces in regulating and shut off valves [1]. It is therefore necessary to study the effects of hydrogen environment on friction and wear of polymers. Previous works on the sliding performances of polymeric materials pointed out the effect of polymer structure, fillers, temperature and counterface material in hydrogen environment [1-2]. Further studies in high-pressure hydrogen indicated the influence of fillers and fibers on the reciprocating behaviour of polymer and rubber materials [3-5]. For high pressure application, it is widely recognized that the main effects are swelling and blistering of rubbers due to rapid gas decompression. This can inevitably influence the tribological behavior of the polymers. Therefore, the focus of this study is to investigate the fretting behaviour of HNBR grades in hydrogen at different pressure up to 10 MPa compared to air and after hydrogen exposure in 100 MPa. For this purpose, aging experiments in 100 MPa hydrogen were conducted for 7 days under static conditions at the competence center H2safety@bam.

MATERIALS AND METHODS

Two different types of crosslinked elastomers provided from Arlanxeo Deutschland GmbH were investigated (Table 1). The mechanical properties of the rubber materials were examined before and after hydrogen exposure at 100 MPa, 120 °C and 7 days with dynamic mechanical analysis, tensile and hardness measurement.

Table 1. Composition of the HNBR investigated

Material	Fillers
HNBR 1	carbon black
HNBR 2	carbon black, polyamide

Friction tests were performed in a fretting tribometer developed at BAM for hydrogen environment up to 10 MPa. The upper specimen is a 316L stainless steel with a diameter of 6.0 mm. The lower specimen is the rubber fixed on a steel flat which is driven by a voice coil to make the reciprocating motion. The normal load was set to 5 N, the frequency 10 Hz and the stroke 2 mm. Before the tests, the elastomers were cleaned and exposed to dry heat at 60 °C for 48 hrs. This step is an essential pre-conditioning step for the removal of moisture content and outgassing of the samples that otherwise might have affected the properties of the hydrogen exposed samples. Tests were performed at room temperature in air and in hydrogen up to 10 MPa.

RESULTS AND DISCUSSION

Tribological tests revealed that hydrogen environment doesn't significantly affect the friction behaviour at normal pressure, but that the wear of the polymer decreases with increasing hydrogen pressure. Experiments performed

just immediately after hydrogen exposure at 100 MPa indicated however significant changes on the fretting behavior. Figure 1 show the friction curves of HNBR2 in air and at 10 MPa before and just after hydrogen exposure at 100 MPa. Comparing to air, the fretting behavior of HNBR2 in hydrogen is not affected by the environment. Before exposure, the fretting loop describe a slip motion between the steel ball and the polymer plate. After high pressure hydrogen exposure, the fretting process is characterized by increased adhesion due to elastic deformation, leading to partial slip. This could be explained by a decreased hardness of the elastomer measured immediately after high-pressure hydrogen exposure.

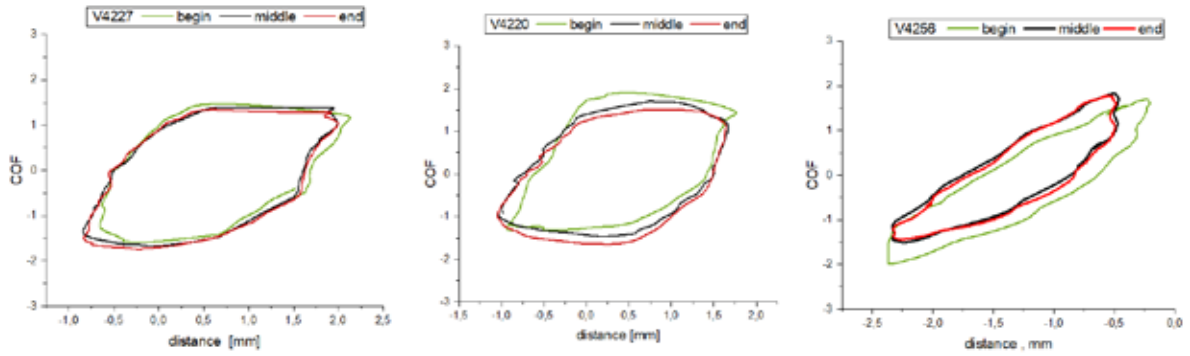

Fig. 1. Coefficient of friction of HBNR2 in air (a) and in H_2 at 10 MPa before (b) and after (c) H_2 exposure at 100 MPa

CONCLUSIONS

This paper presents an experimental study on the fretting wear behavior of two types of cross-linked hydrogenated acrylonitrile butadiene rubbers against 316L steel ball in hydrogen environment. Furthermore, aging experiments were conducted for 7 days under static conditions in 100 MPa hydrogen. Results reveal that hydrogen exposure has a significant influence on the fretting behavior of HNBR grades, changing the fretting process from gross slip to partial slip immediately after exposure at 100 MPa. This can be related to increased deformation due to decreased hardness of the elastomers.

ABSTRACT

In this study, ZnO nanorods, functionalized with Cr, Co, Ni and Cu metal nanoparticles are synthesized and the structural, electrical and hydrogen gas sensing properties are examined. ZnO nanorods with approximately 90 nm in diameter and 1 µm in length are produced by using hydrothermal method on ZnO seed layer coated glass substrate. Then Cr, Co, Ni and Cu metal acetate solutions are separately coated on ZnO nanorods by using spin coating method. It is obtained from structural characterization that the fabricated bare and metal functionalized ZnO nanorods are vertically aligned and have c–axis orientation. The FESEM images show metal nanoparticles with size below 20nm on ZnO nanorods. The electrical and hydrogen gas sensing characteristics of gold electrodes coated bare and metal functionalized ZnO nanorods are measured from room temperature to 200°C. The highest sensitivity and good selectivity were observed for Ni nanoparticles decorated ZnO nanorods.

Keywords: ZnO nanorods, Hydrogen, Gas Sensor, Nanoparticle, Decoration

INTRODUCTION

The increase in the amount of the using fossil fuels with the industrial revolution leads to the release of harmful gases to nature, negatively affecting the environment and human health. However, most of our energy today comes from fossil fuels. The use and dissemination of hydrogen gas as a primary energy source will enable both the elimination of the effects of global warming on humanity and the reduction of foreign dependency to meet the energy needs of countries. Fuel cells come to the fore in the use of hydrogen as an energy source. Hydrogen-based fuel cells generate electrical energy as a result of the chemical reaction between hydrogen molecules and oxidizing molecules. Although there are various studies and commercial applications on this principle from the past to the present, the energy shortages experienced reveal the value and necessity of using hydrogen energy. Despite its potential in the use of hydrogen as energy, it must be constantly monitored for gas leaks, as it is an odorless, tasteless and colorless gas and is explosive and flammable if it has a concentration above 4% in the air [1-3].Semiconductor metal oxide nanomaterials have been used as a sensing layer in the detection and monitoring of pollutants, inflammable and explosive, volatile organic compounds (VOCs), and toxic gases for many years due to maintaining stable structures against to harmful physical effects of ambient as temperature, humidity, pressure, and corrosion [4]. Zinc oxide (ZnO), tungsten oxide (WO_3), Tin oxide (SnO_2) and titanium dioxide (TiO_2) and have attracted the attention of researchers with their high sensitivity and fast response time, especially in sensor studies, due to their wide electronic band gap and d-symmetry of their valence orbits [5]. In gas sensor studies based on semiconductor metal oxide nanostructure, ZnO nanorods are frequently preferred because they can be synthesized with easy and low production cost techniques, and their electronic and chemical properties can be changed by the use of doping or heterostructure [6,7].

In this study, the changes in electrical and gas sensing characteristics of hydrothermally fabricated ZnO nanorods with metal nanoparticles were investigated. The selectivity properties of the sensor device developed with the decoration of metal nanoparticles differed. In addition, the gas sensing mechanisms of the developed metal-decorated nanorods are explained.

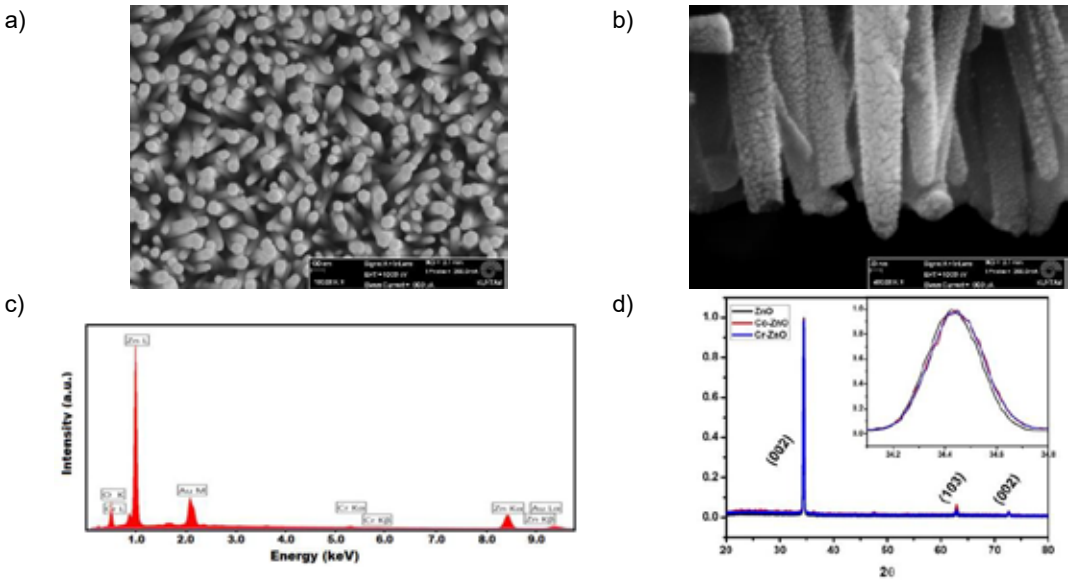
MATERIALS AND METHODS

The production of vertically oriented metal nanoparticle decorated ZnO nanorods on a glass substrate was carried out in three stages. The production steps are respectively forming the ZnO seed layer on the glass substrate, growing the ZnO nanorods, and decorating the metal nanoparticles with the sol-gel technique. Further information about ZnO nanorods fabrication with hydrothermal techniques was given in our previous works [8]. Fabricated ZnO nanorods were decorated with different metal nanoparticles as chromium (Cr), cobalt (Co), Nickel (Ni), and copper (Cu) for investigating selective detection of H_2 sensing with sol-gel techniques. For these purposes, acetate solution was prepared for each metal decoration and coated on the ZnO nanorods by using spin coating techniques at 2500 rpm for the 30s. The

coating process was repeated five times and then annealed at 300°C for 1h. The structural, morphological and composition of metal nanoparticle decorated ZnO nanorods were examined with X-ray diffractometer (D/MAX 2200) field emission scanning electron microscopy (FESEM, ZEISS ULTRA PLUS) and Energy Dispersive X-ray spectroscopy (EDX), respectively.
Gold (Au) interdigital transducers were coated on the surface of the metal nanoparticle decorated ZnO nanorods for electrical and gas measurements by using thermal evaporation systems. Current versus voltage measurements between -1V and +1V were realized for dc electrical characterization under dry airflow. Gas sensing measurements were realized in dry airflow in the homemade gas tight measurement cell. The fabricated ZnO nanorods were tested to the various concentration of the H_2, ethanol, and chloroform (1000 ppm to 5000ppm) for understanding sensing properties and especially selective detection of the H_2.

RESULT AND DISCUSSIONS

The morphologies of the ZnO nanorods and metal nanoparticle decorated ZnO nanorods were studied by using SEM. Fig 1a shows the SEM images of Cr nanoparticles decorated ZnO nanorods. All surfaces were covered with hexagonally shaped and vertically aligned ZnO nanorods and average diameters were approximately 90nm. Similar results were observed for all samples. To determine the decoration of the nanorods, cross-sectional SEM investigations were carried out at high magnification in Fig 1b. Facet surfaces of the ZnO nanorods were covered with the Cr nanoparticles. The content of the nanoparticle on the ZnO nanorods was investigated by EDX analysis (in fig 1c). In EDX spectra, Cr peaks with lower intensity were observed than Zn and O due to the concentration of the Cr atoms. Afterward, an XRD analysis was performed. Although there was no significant difference in the diffraction graph obtained from the analysis at first when the 002 peak was examined closely, the presence of a shift towards the right was detected. The presence of shifting in the diffraction angle is due to the effect of Cr and Co atoms placed around ZnO.



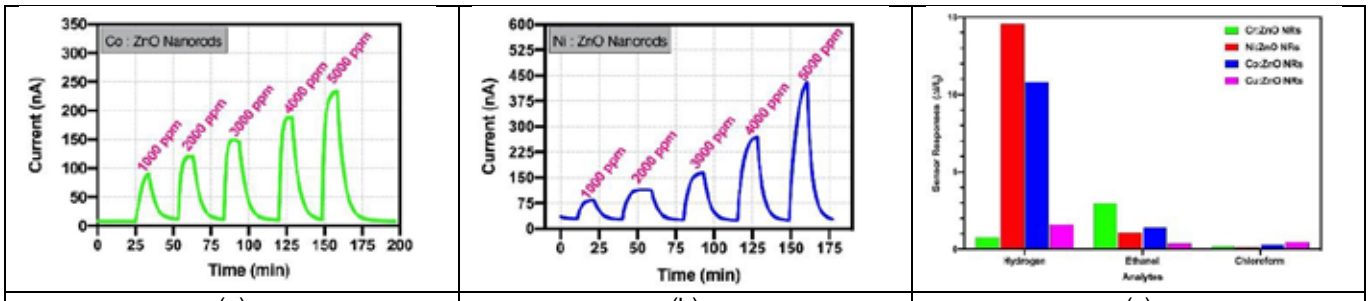


Fig. 1. a) SEM image of ZnO Nanorods, b) cross sectional and high magnificated SEM image of Cr nanoparticle decorated ZnO nanorods, c) EDX spectrum of Cr nanoparticle decorated ZnO nanorods and d) X-ray diffraction at 002 plane of bare ZnO Co and Cr decorated ZnO nanorods

Like all metal oxides with a wide electronic band gap and used as the gas sensing element, it produces a response against all analytes tested in ZnO. Although this provides a great advantage in sensor applications, it also leads to a decrease in selectivity. It is very important that the warning, which will indicate the dangerous situation, is reliable, especially when it is desired to be used in the monitoring of explosive and flammable gases. For this reason, the use of doping and heterostructures to increase the selectivity of metal oxides is a frequently encountered situation in the literature. Metal nanoparticle decorated ZnO nanorods were tested to the H_2, ethanol, and chloroform in various concentrations at 200°C under biased at 1V depending on increasing the sensitivity of the sensitive materials. The gas sensing mechanism of semiconducting metal oxide relies on a chemical reaction between oxygen ions absorbed on the metal oxide surface and target analyte molecules [3]. H_2, ethanol, and chloroform are reducing gases and therefore the current is expected to decrease or the resistance to increase. Current versus to time graphs of Co and Ni decorated ZnO nanorods were given in Fig 3a and 3b, respectively. When H_2 gas is purged into the measurement cell, the current of the sensing materials increases very rapidly and reached a steady-state level of nearly 6 min. Similar sensing responses were observed for other decorated sensor devices and also tested analytes. At this point sensor responses

are so important to understand selectively detection of the H_2 gas. Sensor responses of the metal nanoparticle decorated ZnO nanorods were tested to target analytes for 5000 ppm concentration in dry air ambient was given in Fig 3c. According to Fig. 3c, Ni nanoparticle decorated ZnO nanorods show better sensitivity for H_2. On the contrary, better ethanol sensor responses were observed for Cr decorated ZnO nanorods.

(a) (b) (c)

Fig. 1. Current vs time graphs of a) Co and b) Ni metal nanoparticle decorated ZnO nanorods exposed to H_2 and c) Sensor responses all fabricated samples versus to tested analytes for only 5000ppm

CONCLUSIONS

Gas sensing properties of ZnO nanorods decorated with metal nanoparticles were investigated in terms of selectivity and sensitivity properties. Among the decorated ZnO nanorods, it was determined that the sensitivity of Ni nanoparticles especially to hydrogen gas is higher than other metal nanoparticles. However, it was observed that the sensitivity values of the sensors developed by the exchange of metal nanoparticles differed against the other analytes tested, and it was determined that the selectivity was increased. On the other hand, it was observed that nanoparticle decoration was provided on the lateral surfaces of the nanorods with the sol-gel method, and an improvement in the physical properties of the base metal oxide was achieved.

ABSTRACT

In this study, the effects of various metal electrodes and various crystal structures on hydrogen (H_2) gas sensors based on titanium dioxide (TiO_2) nanotubes were investigated. For the production of TiO_2 nanotubes, anodization method consisting of an electrolyte containing 0.5wt% NH_4F in 85% pure glycerol solution was applied. Scanning electron microscope (SEM) images of the obtained TiO_2 nanotubes were examined. In order to see the effect of different crystal structures of TiO_2, amorphous, anatase and rutile phases were obtained by annealing of samples. Each of the Ti/TiO_2 nanotubes/metal (Pd, Pt, Au, and Ag) gas sensors, obtained by coating with palladium (Pd), platinum (Pt), gold (Au) and silver (Ag) electrodes, was tested at room temperature at 1% H_2 concentration depending on three different phases.

Keywords: Titanium dioxide, nanotubes, hydrogen sensor, anodization, metal electrode

INTRODUCTION

Nowadays, H_2 has many industrial applications because it is environmentally friendly and low cost applications [1]. However, if the hydrogen concentration in the air increases, it can be flammable and explosive by mixing with oxygen. Therefore, there is a need to produce H_2 sensors with good sensitivity and selectivity to detect H_2 concentration before it reaches dangerous levels [2]. Many different technological methods such as catalytic, thermal conductivity, electrochemical, resistance based, work function based, mechanical, optical and acoustic are used in the production of H_2 sensor [3]. Titanium oxide (TiO_2), one of the metal oxides, has long been used in functional devices and gas mixture detection research due to its excellent thermal, synthetic and mechanical properties [4]. TiO_2 has three natural polymorphs: rutile, anatase and brookite [5]. TiO_2 can be produced in nanostructures (nanoparticles, nanorods, nanowires, nanotubes, etc.) with different surface-volume ratios and sizes [6]. TiO_2 nanotubes draw attention especially in gas sensor applications with their large surface-volume ratio and advantageous dimensions [7]. The fact that TiO_2 nanotubes can be easily produced by anodization method and their size can be adjusted depending on the anaodization parameters has enabled measurements at low temperatures and different gas concentrations in gas sensor research [8].

In recent years, TiO_2 nanotubes, which have been synthesized using various methods, have been shown to have different properties such as selectivity, response time, sensitivity, etc. against H_2 gas. The effects on the parameters are investigated. In order to produce TiO_2 nanotube-based H_2 sensors by anodization method, electrolytes consisting of hydrofluoric acid (HF) mixture, glycerol-based electrolytes, H_2SO_4-HF mixture solutions, NH_4F solutions in ethylene glycol (EG) were used [9]–[11]. Among these methods, TiO_2 nanotubes produced using glycerol-based electrolyte, high aspect ratio, arrangement, and response to H_2 gas attract attention.

To measure the current-voltage (I-V) change, metal electrodes such as Pt, Pd, Au, Ag etc. were coated on nanotubes. However, the sensing properties of these metals and various crystal structures against H_2 flow at different concentrations have not been compared.

MATERIALS AND METHODS

The high purity titanium foils with a thickness of 0.1mm, which we used to produce TiO_2 nanotubes, were cleaned by ultrasonic processes in acetone, isopropyl alcohol and deionized (DI) water in 15 minutes, respectively. Electrolyte solutions were prepared at 20 ^{0}C with 99.5wt% glycerol (85% purity) and 0.5wt% NH4F in a magnetic stirrer. In the anodizing process, a two-electrode system with DC power supply (20 V) and platinum gauze (99.9%, Sigma-Aldrich) as the cathode was applied for 120 minutes. After the production of TiO_2 nanotubes was cleaned and dried, SEM images (Fig. 1) were taken to examine their morphological structures. Then, TiO_2 nanotubes were annealed at 300 and 700 ^{0}C in dry air flow for 3 hours.

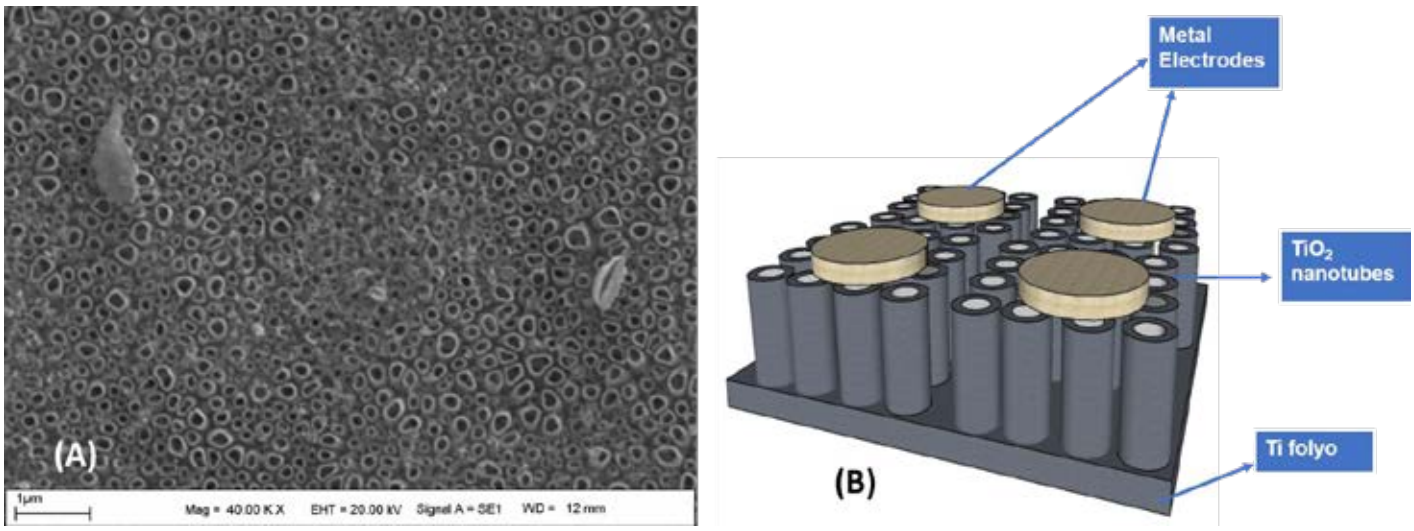

Figure 1. (A) SEM images of TiO_2 nanotubes, (B) schematic representation of TiO_2 nanotubes based gas sensors

Pd, Pt, Au and Ag electrodes were coated on unannealed, 300 and 700 ^{0}C unannealed TiO_2 nanotubes with 100 nm thickness by DC magnetron sputtering method using shadow mask. Thus, a total of 12 sensor structures were produced as in Fig. 2. Metal coatings of Pd/TiO_2 nanotube/Ti, Pt/TiO_2 nanotube/Ti, Au/TiO_2 nanotube/Ti and Ag/TiO_2 nanotube/Ti structures were used as upper electrode and Ti was used as lower electrode to take I-V measurements.

RESULTS AND DISCUSSION

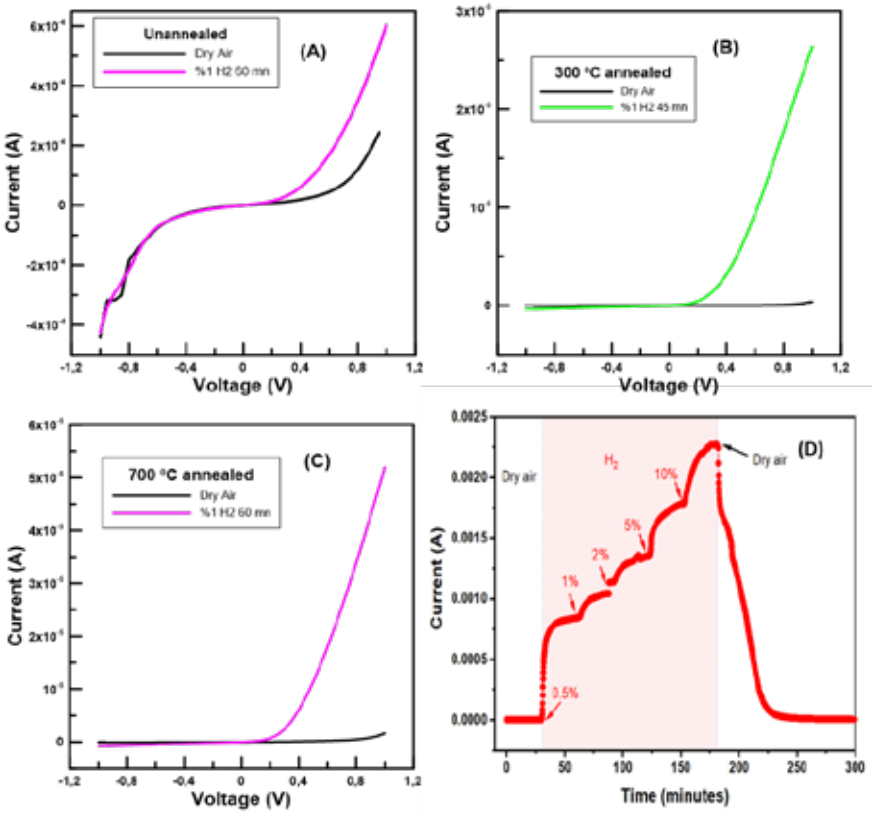

Figure 2. Current-voltage variation of Pt/TiO2 nanotubes/Ti devices (A) unannealed, (B) annealed at 300 and (C) 700 ºC (D) The current versus time for Pd/TiO2 nanotubes/Ti devices annealed at 300 ^{0}C by exposing various concentration of H_2

To explain the concentration due to H_2 gas sensing behavior on Pt/TiO_2 nanotubes/Ti sensor device structure, voltage applied current was measured in dry air and at a concentration of 1% H_2. Fig. 2A, B and C shows the current variation of the unannealed and annealed at 300 and 700 ºC of Pt/TiO_2 nanotubes/Ti devices. The response of the sensors to the gas can be calculated as follows;

$$\text{Sensor Response (R)} = \frac{\Delta I}{I_A} = \frac{I_H - I_A}{I_A} \quad (1)$$

where I_H is the current after the sensor is exposed to H_2, and I_A is the baseline value of the sensor exposed to dry air**.** The variation of the current as a function of time when exposed to various H_2 concentrations (1, 2, 5 and 10%) of Pd/TiO_2 nanotubes/Ti sensor device annealed at 300 ^{0}C is shown in Fig. 2D.

CONCLUSIONS

As a result, the production of TiO_2 nanotubes formed by anodic oxidation method on titanium foil has been completed. The effect of the crystal structure on the H_2 sensing properties of metal electrodes and TiO2 nanotube-based sensors was investigated. Unannealed, annealed at 300 and 700 ^{0}C, TiO_2 nanotubes exhibited Schottky-type behavior in I-V measurement in dry air condition and 1% H_2 environment. The measurements obtained show that the most ideal result belongs to the Pt electrode coated device annealed at 300 ^{0}C.

ABSTRACT

International Atomic Energy Agency (IAEA) specifies the principal requirements for the protection and mitigation strategies of safety-related plant components, within the vicinity of the nuclear plant. However, safety issues related to pressurized hydrogen release are of concern since a small leak in a hydrogen system could ignite easily, support a flame that is difficult to detect, and lead to catastrophic fire and explosion. In this work, three correlations used to determine the vapor cloud explosion prediction, i.e., Trinitrotoluene (TNT), TNO Multi-energy and Baker-Strehlow-Tang (BST) to estimate the failures and consequences of the accidental release of hydrogen in a hypothetical nuclear power plant. The data was compared to simulation results from FLACS dispersion model. It was shown that the consequential damage of explosion overpressure is strongly dependant on the global load of flammable gas volume and plant layout. In this work, 5000 m^3 of hydrogen explosion is sufficient to produce blast load wave for total plant destruction. It can be said that, for a safety consideration, a physical distance of 200 m between the explosion source and the target outer walls could be sufficient to protect against the explosion hazards.

Keywords: Blast Load Wave, Failure And Consequence Analysis, Hydrogen Explosion, Nuclear Plant, Safety Distance

INTRODUCTION

A large quantity of hydrogen gas is used in the nuclear plant to cool the unit generators and for binding the oxygen present in the exhaust gas systems. Hydrogen gas when is released under suitable conditions could form the dangerously explosive atmosphere in its vicinity. If ignited, could form a dangerously explosive atmosphere that could lead to catastrophic fire and explosion as evidently seen at the Muskingum River Power Plant in 2007 [1]. The consequences of VCEs on the nuclear island pose to substantial consequences on domino effect condition; high explosion overpressure, thermal radiation from the fireball, toxic gas dispersion and effect of explosion-generated fragments. The effect of overpressure is of greater interest rather than that of thermal radiation and the fragments. The explosion overpressure and blast waves could propagate several kilometres and could affect the functions of multiple redundant engineered safety systems. The severity of the resulting explosion is determined by the level of congestion and hence, the layout of structures in the plant, as a subsequent would give significant effect on the magnitude of severity in case of fire and/or explosion. Building structures, storage tanks and piping in the NPP will act as obstructing objects during explosion and tend to induce turbulent flow followed by the increase in pressure and impulse, capable of destructing nearby structures and causing the fatal damage. However, the sitting analysis of facilities is usually focused on the potential impacts of VCEs to building within the vicinity areas rather than the fatal damage. This study aims to investigate the physics and dynamic mechanism of hydrogen gas explosion as function of site distances by analysing the minimum standoff distance of central gas storage depot to other building structures, such that in an accidental release, the nearest building obstacles will not provide sufficient confinement that will generate higher explosion pressure and impulse that could lead to a progressive collapse of structures or pose serious threat to the safe operation of the plant. This is crucial particularly for multinuclear power plants that are under constructions around the world and the ones to be constructed in the feature. Therefore, in this work, energy-based analytical methods (Equivalent TNT mass method [2], TNO multi-energy method [2][3][4] and Baker-Strehlow-Tang method [2] and Computational Fluid Dynamics (CFD) FLACS simulation [5] were employed to estimate the blast load and impulsive loadings from VCEs. These methods were analysed and compared for the consequences analysis of explosion incident. The prime focus of this present paper is to determine the appropriate safety distance (as a countermeasure against the effects of explosion) such that an inherently safer operation of the NPP can be maintained during an explosion incident.

HYPOTHETICAL SCENARIO

In the accident scenario, it is considered that during delivery of hydrogen at a gas storage depot, a hydrogen relief device failed, causing a leak and ignition of the flammable cloud. Fig. 1. shows the plant layout for the multi-nuclear reactor site. A flammable hydrogen cloud of approximately 5003 m^3 is involved in a detonation type explosion. With the total of fuel dispersed, it is assumed that the overpressure produced would reach the surrounding building structures and the magnitude of explosion pressure received could challenge the safety functions of the components that were housed in such buildings.

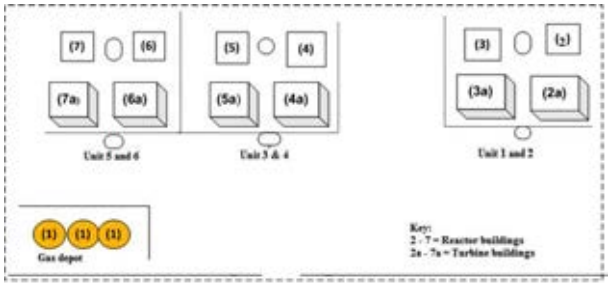

Fig. 1. The plant layout

RESULTS AND DISCUSSION

The effect of explosion overpressures and impulse loading as a function of separation distances

The functional relationship between overpressures and distance from the explosion position for the three empirical models is presented in Fig. 2a. The graph shows that TNT method predicts higher overpressure, as compared to that of TNO multi-energy and BST methods. The estimated overpressures shown in this graph are significantly higher, especially at a shorter distance (< 200 m) due to the deflagration to detonation transition alike phenomenon when hydrogen dispersed and exploded. The blast pressure measured at a detonation distance of 100 m for TNT, TNO, and BST were 2.19 bar, 0.17 bar, and 0.20 bar respectively. The damage corresponding to these overpressure levels are considered unbearable for most building structures. Accordingly, at a detonation distance of 150 m, the overpressures were 0.87 bar, 0.12 bar, and 0.14 bar, respectively.

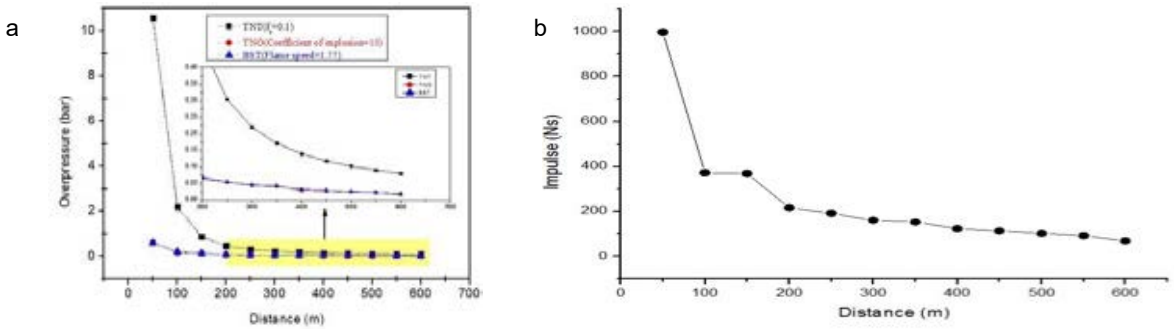

Fig. 2. (a) Overpressure and (b) impulse blast loading as a function of separation distance

Impulse load acting on structures may lead to the development of higher strain rates in reinforced concrete and its significant value may lead to substantial threat on structural integrity and safety function as indicated in [6]. At a longer distance of about 200 m, the impulsive loading is 215 Ns as shown in Fig. 2b. This value may not constitute much safety threats on surrounding buildings and relevant safety components exposed in the open.

Comparison of safety distance predicted by CFD and theoretical models

Table 3 presents a summary of overpressure estimation at some preselected locations by various models. As expected, the TNT method predicts higher overpressure loadings as compared to other two methods at the same distances. The discrepancies in the measurement between the TNT and other two models may be attributed to the differences in their formulation theories and assumptions adopted for a given scenario. It also indicates that FLACS CFD is grossly under-predicted explosion overpressure for the same detonation distances ~ 6 times lower than the computed data from the TNO and BST while an underprediction of ~59 – 79 is observed for the TNT measurements. The computed impulse from the TNO and BST measurements are ~2 times higher than that obtained with CFD technique [5].

Table 3: Overpressure estimation of VCE by various models

Method	Distance (m)	Overpressure (bar)	Impulse (Pa.s)
TNT	10	-	-
	60	7.10	-
	110	1.76	-
Baker–Strehlow–Tang	10	-	-
	60	0.50	970
	110	0.18	371
TNO (multi-energy)	10	-	-
	60	0.48	987
	110	0.18	360
CFD method	10	0.25	1240
	60	0.09	527
	110	0.03	220

CONCLUSION

This study presents the consequence analysis of VCE involving hydrogen gas dispersion in the vicinity of NPP, adapting the empirical correlations and FLACS CFD model. It can be said that empirical models predict higher value of impulse loading, however, the underpredicted values of FLACS model is not the preferred choice for the safety gaps studies, particularly at a far-field. It is also shown that the magnitude of explosion overpressure generated from the incident may affect other structural components and items exposed during VCEs within the radial distance of 100 m. Using a conservative value of 0.068 bar as the limiting overpressure on structures as in USNRC Regulation, the findings show that a minimum distance separation of 200 m between a gas storage depot and adjacent buildings could be sufficient to provide protection against the impact of explosion pressure waves from the postulated accident.

ASPECTS OF RISKS USING MAGNESIUM HYDRIDE FOR ZERO EMISSION MOBILITY

[1*] *Bjørn Axel Gran,* [2] *Kjell Løvold,* [3] *Stefano Deledda,*
[1] Institute for Energy Technology, Norway

ABSTRACT

The maritime sector has an increased focus on zero emission mobility solutions. One new initiative using hydrogen, is based upon storing hydrogen as magnesium hydride (MgH_2). Since in a such solution, continuous heating is required to desorb H_2, hydrogen storage in MgH_2 is considered a safer solution compared to compressed or liquified H_2. Indeed, if by accident there is a rupture of the metal container, the endothermic desorption of hydrogen will cool down MgH_2 and, as soon as heating is stopped, no hydrogen will be released. Institute for Energy Technology (IFE) was asked by a client to evaluate the safety benefits of magnesium hydride. This included to conduct a preliminary risk assessment and comparing the findings with similar risk assessments on the use of hydrogen and ammonia solutions related to use as a maritime fuel. The work also included compiling an overview of applicable rules and guidelines applicable in Norway, and an overview of relevant past incidents. This paper summarises on that work. One conclusion from the work is that the risk and safety assessments should not only include technical aspects, but also human, organisational and operational factors.

Keywords: Magnesium Hydride, Hydrogen Storage, Risk Assessment, Human Factors, Organisational Factors

INTRODUCTION

The regulator for most land facilities handling dangerous substances in Norway is the Directorate for Civil Protection (DSB) which provides guidance on how to address risk, vulnerability and emergency preparedness. Two main principles to follow are individual risk criteria defined through zones, and to apply the ALARP (As Low As Reasonably Practicable) principle. The ALARP principle says that the risk shall be reduced to the lowest level that can be achieved with reasonable effort. These principles are also applicable all over Europe.

When designing vessels fuelled by flammable gaseous fuels like hydrogen “the International Code of Safety for Ships using gas or other low-flashpoint fuels” (the IGF Code) gives the applicable rules [1]. The HyLaw Online Database [2] has a good overview of relevant legislation for most parts of Europe. The European pressure equipment directive (PED) applies to the design, manufacture and conformity assessment of stationary pressure equipment with a maximum allowable pressure greater than 0.5 bar [3]. There are no EU rules that describe exactly how one should conduct risk assessments, but the Your Europe Portal part for “Health and safety at work” recommends to [4]: (1) Collect the relevant information; (2) Identify the possible hazards; (3) Assess the risks arising from the hazards; for example, estimate the probability and severity of the consequences and decide whether the risk can be tolerated; (4) Plan actions to eliminate or reduce risk and (5) Document the risk assessment.

Lloyd’s Register Consulting issued in 2019 a report for DSB [5], providing guidance for performing facility risk assessments which is in line with the ISO 31000:2009 standard. In 2020 Lloyds Register Consulting issued a report for the Ocean Hyway Cluster on the use of hydrogen and ammonia infrastructure [6]. That report discusses risk aspects related to infrastructure, including production, transport, storage and bunkering, for zero emission fuels, such as hydrogen and anhydrous ammonia used as a maritime fuel. It also provides an overview of relevant historical accidents for the different fuels. For hydrogen and methane this is primarily explosion accidents, while for ammonia toxic exposure for people is the main concern. An increasing number of accidents has been seen in recent years. One pinpointed cause is the lack of experience in handling hydrogen. Another cause argued by Hydrogen Europe is that hydrogen is by many, non-technical stakeholders, considered to be safer than other fuels [7]. This is not in line with the very high reactivity of hydrogen.

Many hydrogen incidents can be found in the European Union HIAD database [8] and at the US DoE H_2 tools site [9]. Some accidents of interest are:

- The Hindenburg Disaster, 1937: 97 persons on board, filled with 15-20 tons of hydrogen, caught fire approaching the destination in New Jersey killing 36 people.

- Hydrogen explosion at the NI ammonia plant of Norsk Hydro (now Yara) at Herøya, Norway, 1985: damaging a larger plant building beyond repair and leading to severe window shattering within a 400m radius. This resulted in fatalities of two employees.
- Two explosions in pipelines at Herøya, 1986 and 1997: involved deflagration-to-detonation.
- The Challenger space shuttle disaster, 1986: besides killing all 7 astronauts, also led to the release and a fireball involving liquid oxygen and hydrogen from the failing fuel tanks.
- Hydrogen explosion accident at the Tesoro refinery near Seattle, WA, USA, 2010: high temperature hydrogen attack led to the burst of a heat exchanger during a start-up procedure, killing all 7 workers involved.
- Fukushima accident, 2011: explosions in hydrogen generated from meltdown represented steps in the chain of events.
- Uno-X Hydrogen refuelling station at Kjørbo in Sandvika, Norway, June 2019: A major release from a 950-bar tank containing less than 3 kg hydrogen ignited after 2-3 seconds resulting in a strong outdoor explosion [10]. An attempt to model possible release and explosion scenarios using computational fluid dynamics (CFD) indicates that an unconfined detonation of around 0.5kg hydrogen would be likely, and required, to explain observed effects [11].

To evaluate the safety benefits, IFE conducted a preliminary risk assessment of MgH_2 This included facilitating a Hazid meeting with stakeholders from academia and consultancy. Besides the case owner with insight in the solution, the team included an expert with insight on system and models and experts with insight in both technical and operational aspects of using hydrogen as a fuel in the maritime sector. 17 risks were identified, whereof 14 were classified in the yellow area of the ALARP and required us to evaluate mitigations. 26 mitigations were identified. If all 26 mitigations are implemented, only one risk “Exposure to heat (external fire) is not acceptable as this requires mitigations to systems outside of the scope of this assessment.

The DNV Handbook for Hydrogen-fuelled Vessels [12] points out that “*Hydrogen gas is flammable, highly explosive, and has different safety-related properties and behaviour compared with other gases including natural gas*”. Further it is also stated that “*As hydrogen is the smallest of all molecules, hydrogen gas is more challenging to contain than other gases; it has a wide flammability range, ignites easily, and may self-ignite. This combination of properties may lead to increased overall risk, unless applicable safety systems and practices concerning hydrogen are implemented*”. In view of this, the Hazid was considered to have taken an appropriate focus as it ended out with mitigations that are both technological (related to safety systems) and organisational (related to practises). The handbook also points to a number of maritime conditions, which are relevant for different solutions including magnesium hydride: (i) A ship is self-reliant on sea, (ii) Escape is not possible for crew or passengers, (iii) Safety distances are smaller on a ship than on land, (iv) Exposure to environmental conditions at sea (v) Power demand depends upon ship and operation at the ship; and (vi) Interface between storage and power generating system. It is therefore crucial to do specific risk assessments with the real volumes of potential released hydrogen, the actual safety systems and the actual safety distances on that ship. Compared to compressed gas storage, the potential volumes of hydrogen released from magnesium hydride stores are smaller. However, one question arises: is this volume small enough to not prompt unwanted consequences? When hydrogen gas can be stored in the open, it has several advantages since leakages can disperse in the open air. In the case of magnesium hydride, it might require that also the heating systems and interface to the power generating system needs to be designed on top of the ship. This may have negative impact on ship stability. In addition, there may over time be more leakages due to corrosion.

For compressed gas, there is a need of the following safety systems: tank, fuel lines, hydrogen vent systems, ventilation systems, pressure regulation unit(s), fire protection system, H_2 detection systems, safety systems (fire detection, firefighting systems, emergency shutdown systems); and structural fire protection.

Desorption of H_2 from magnesium hydride does not need any compression but requires heating. A high-pressure tank or a pressure regulation system is therefore not needed, but all the other safety systems need to be in place. In addition, there is a need of the following safety systems: heat protection systems and ignition control systems. One will in addition have a larger amount of potential leakage points that needs to be ventilated and monitored.

One observation from the Hazid is that many unwanted incidents ended in the yellow ALARP (as low as reasonably practicable) area. This could be an indication that there are uncertainties both for the frequency and the consequence assessments. Another observation from the Hazid is that all the unwanted incidents, including those that could lead to an explosion, could be mitigated. That made the risks acceptable. The identified mitigations were both related to technical aspects of the design as well as operational aspects of the use of magnesium hydride. This is at a first glance a good sign. However, the results could also be due to a misconception on the frequency estimations due to lack of

historical relevant experience and a wish of having the solution to work safe. The Hazid therefore recommended that all the risks were revaluated with specific leakage rates when concrete designs are available.

CONCLUSIONS

This paper has provided some background on rules, guidelines and historical incidents that are applicable for hydrogen-based solutions in Norway. The paper also discusses the results from a risk assessment on a magnesium hydride/based hydrogen storage solution with other risk assessments. Desorption of H_2 from magnesium requires the following safety systems: fuel lines, hydrogen vent systems, ventilation systems, pressure regulation unit(s), fire protection system, H2 detection systems, safety systems (fire detection, firefighting systems, emergency shutdown systems), structural fire protection, heat protection systems and ignition control systems. One will in addition have a larg amount of potential leakage points that needs to be ventilated and monitored. Findings from the Hazid are that there are uncertainties both for the frequency and the consequence assessments of the events, but also that all the unwanted incidents could be mitigated. That made the risks acceptable. The identified mitigations were both related to technical aspects of the design as well as operational aspects of the use of magnesium hydride. The conclusion from the Hazid supports the recommendation of doing holistic risk assessment when addressing the use of hydrogen-based solution for maritime mobility.

HYDROGEN SENSING PROPERTIES OF ULTRATHIN Pt-Co ALLOY FILMS

ABSTRACT

In the present work, ultrathin Pt_xCo_{1-x} (x=1, 0.75, 0.5 and 0.25) alloy films are fabricated using co-sputtering with approximately 2nm in thickness. The stoichiometry and structural characterization of the thin films are obtained from SEM, EDX and XPS measurements. The structural characterization of the thin films showed smooth coverage of the surface, in a fcc crystalline plane (111). The resistive properties of the films are tested towards a hydrogen gas sensor between 25 °C – 150 °C in the gas concentration ranging from 0.5% to 5%. The surface scattering phenomenon could explain the hydrogen gas sensing mechanism of ultrathin Pt_xCo_{1-x} alloy thin films. PtCo alloy thin films show better response time than bare Pt thin films.

INTRODUCTION

The use of hydrogen (H_2) as a clean, efficient, and sustainable energy source has been expanding into various fields since it will permit the reduction of the CO_2 gas generated by the combustion of fossil fuels. These fossil fuels are the main cause of the greenhouse effect [1]. Therefore, alternatives such as H_2 are seriously considered as an ideal energy source of the future [2] and will be critical enablers to achieve the European Green Deal's ambitious goals.

The H_2 has unusual properties such as a very low density, low boiling point and a high diffusion coefficient. It also possesses a low minimum ignition energy, a high combustion heat and a wide flammable range compared to other gases. The H_2 also acts as a robust reducing agent for many elements and has a high permeability through many materials, which demands special precautions in specific applications. For example, the H_2 is colorless, odorless, tasteless, and is a flammable gas, and it cannot be detected by human senses, unless it is present in high concentrations. In this regard, rapid and accurate H_2 gas measurement is essential to alert to the formation of potentially explosive mixtures with air, to help prevent the risk of an unexpected explosion. Until now, various types of H_2 sensors have been extensively studied and published [3-4], and are commonly classified into nine categories depending on their evident physical/chemical principles of detection mechanism: (i) catalytic, (ii) electrochemical, (iii) resistor based (semiconductor and metallic) (iv) work function based, (v) mechanical, (vi) optical, (vii) acoustic, (viii) thermal conductivity and more recently (ix) magnetic. One type of H_2 sensor, the resistive metallic H_2 sensor uses palladium (Pd), platinum (Pt) and their alloys as a sensitive layer. Pd based resistive metallic H_2 sensors have been intensively studied, but there are limited studies about Pt based resistive H_2 sensors [5], specially when combined with magnetic materials that can be integrated in sophisticated spintronic structures.

In this study, the changes in electrical resistivity and H_2 gas sensing properties of Pt_xCo_{1-x} thin films fabricated by the sputtering method are investigated depending on temperature, Co content in the alloy and H_2 concentration. In addition, the mechanisms of Pt_xCo_{1-x} thin films as gas sensors are explained.

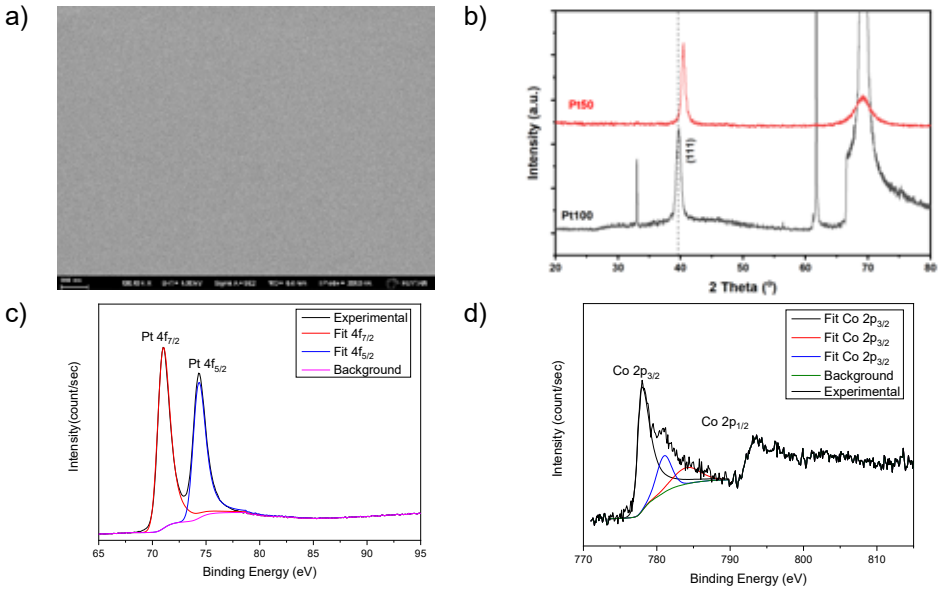
MATERIALS AND METHODS

Ultrathin Pt_xCo_{1-x} films with approximately 2 nm were deposited onto Si/SiO2 100nm substrates using a Nordiko 2000 machine. The Nordiko 2000 is a magnetron sputtering system including a load lock for sample transfer and a high vacuum chamber (base pressure 4×10^{-8} Torr) with 6 targets. The Pt_xCo_{1-x} (x=1, 0.75, 0.5 and 0.25) thin films were grown by co-sputtering from pure Co and Pt targets, in a wave-mode deposition mode, where the alloy film is achieved through sequential deposition of N layers of Pt and Co, after deposition rate calibration at 1.15 Å/s and 0.44 Å/s for Pt and Co, respectively.

Structural characterization of the film was done by field emission scanning electron microscopy (ZEISS ULTRA PLUS), Energy Dispersive X-ray spectroscopy (EDX), X-ray diffraction (XRD, Rigaku D/MAX 2200), Rutherford backscattering spectrometry (RBS), X-ray photoelectron spectroscopy (XPS, Specs-Flex) techniques.
The electrical resistance of the sensor device was measured on the top of the thin films by two silver contacts. The resistance (R_H) of the films is continuously measured under different ambient conditions. The dry air is used as a carrier gas, the H_2 concentration is changed from 0.5% to 5%, and the temperature is varied between 25 °C and 150 °C by using a heater in the measurement cell.

RESULT AND DISCUSSIONS

Fig. 1a shows the SEM image of one $Pt_{0.5}Co_{0.5}$ film sample from where one can infer the surface of the film is smooth, with no segregation of $Pt_{0.5}Co_{0.5}$. The XRD spectra of Pt and $Pt_{0.5}Co_{0.5}$ thin films are seen in fig.1b. The peak near 40° comes from (111) plane reflection, and that corresponds to a face-centered cubic crystalline structure [6]. The chemical compositions of PtCo alloy films were investigated by the XPS technique. The XPS spectra of Pt and Co from $Pt_{0.75}Co_{0.25}$ thin film sample are shown in Fig. 1c and 1d, respectively. To analyze the chemical composition of PtCo alloys, high-resolution elemental XPS spectra for Pt 4f and Co 2p regions were taken within $Pt_{0.75}Co_{0.25}$ thin film sample and it is calculated as 73:27.



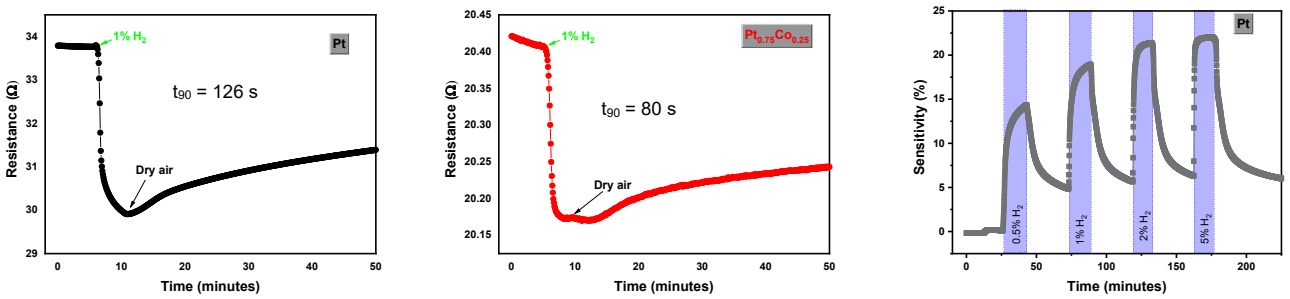


Fig. 1. a) SEM image of $Pt_{0.5}Co_{0.5}$ alloy thin film, b) XRD spectrum of Pt (Pt100) and $Pt_{0.5}Co_{0.5}$ alloy (Pt50) thin films c) $Pt_{0.75}Co_{0.25}$ alloy thin film's XPS spectra for photoemission of Pt 4f region and d) of Co 2p region.

Fig. 2a and 2b show the resistance change of Pt and $Pt_{0.75}Co_{0.25}$ thin film samples during exposure to dry air and 1% H_2 at room temperature. The resistances of both samples are decreased when the measurement cell is purged with 1% H_2. Similar behavior was reported for Pt nanowire [7,8] and Pt thin films [9,10]. After cleaning the measurement cell with dry air, the resistances of both samples increased slowly and remain larger than their baseline values for more than 40 minutes. During the resistance of Pt_xCo_{1-x} thin films measurement under dry air flow, the surface of the films is covered with adsorbed oxygen. While H_2 is exposed to the films, hydrogen atoms dislocate with oxygen atoms, and the number of electron surface scattering decreases. So the decrease in the resistances of Pt_xCo_{1-x} thin films could be elucidated with the surface scattering phenomenon. Fig. 2c shows sensitivity ($\frac{\Delta R}{R_H} x100$) as a function of time for Pt thin film sample under different H_2 concentrations at room temperature. The sensitivity is enhanced with increasing gas concentration.

(a) (b) (c)

Fig. 2. The resistance versus time graphs of a) bare Pt and b) $Pt_{0.75}Co_{0.25}$ thin film samples at room temperature. c) Sensitivity as a function of time for bare Pt thin film sample exposure to cycles of increasing H_2 concentration at room temperature

CONCLUSIONS

In this study, different chemical compositions of PtCo alloy films were prepared by sputtering deposition. XRD, XPS, SEM and RBS techniques were used to characterize for their structural and chemical compositions properties. H_2 sensing properties of the different PtCo alloys, the resistance of the films and sensitivity were measured under different hydrogen atmospheric conditions. The results were compared to pure Pt film. The hydrogen sensitivity decreases with the increasing Co ratio in the PtCo alloy films.

ABSTRACT

This manuscript presents the design and utilisation of a unique environmental chamber allowing specimens to be heated and cooled, under tensile load and controlled atmosphere, while in a neutron beam, offering a unique opportunity for in-situ neutron diffraction experiments. The chamber was built to gain insight into the impact of parameters such as tensile stress, temperature and exposed atmosphere on the hydrogen solubility of materials and on the mechanisms relating to delayed hydride cracking, hydrogen embrittlement and hydrogen ingress.

The investigation presented in this work shows the chamber's performance up to 450°C and 275 MPa applied tensile stress. The effect of tensile stresses and temperature on hydrogen solubility in Zr-2.5Nb is presented for a sample nominally charged to a hydrogen concentration equivalent of 500 wppm (mg/kg). Due to kinetic factors, no significant effect of tensile stress on the hydrogen solubility of our samples was found for temperatures up to 300°C and at tensile stresses up to 275 MPa.

Keywords: Hydrogen, tensile stress, ingress, dissolution, precipitation

INTRODUCTION

It is well known that material degradation can lead to a weakening of mechanical and structural properties. In the nuclear industry, the use of zirconium-based materials that are exposed to hydrogen can lead to failure and cracking, compromising the system's safety and functionality. Indeed, when a zirconium alloy's hydrogen concentration exceeds its terminal solid solubility (TSS), it becomes susceptible to a crack initiation and propagation process called delayed hydride cracking (DHC). [1 - 3] Therefore, knowledge of the solubility limit as a function of temperature and applied stress is critical for the development of guidelines for fitness-for-service and reactor life-extension, advanced reactor designs, as well as, in the development and validation of DHC modeling.

Since the hydride volume fraction decreases as the result of hydride dissolution when the temperature increases, a neutron diffraction peak's intensity would decrease proportionally until, at the critical temperature for dissolution, T_{TSSD}, the peak would disappear completely into the background. Conversely, on cooling from a temperature at which all the hydrides are dissolved, the intensity of the hydride peak becomes non-zero at the critical temperature for precipitation, T_{TSSP}. Thus individual hydride diffraction peaks provide an unambiguous indication of changes to the hydrides as a function of temperature. [4 - 7]

It is known that applied stress influences hydride orientation [5, 8]. The influence of stress on hydrogen solubility though, has not been extensively investigated. The unique capabilities of our chamber allow such in-situ studies and a deeper understanding of hydrogen ingress/egress needed for both energy storage and materials performance studies. The chamber can also be used to determine the effect of hydrogen concentration, temperature, composition, microstructure, surface condition, and mechanical load on materials performance using in-situ neutron diffraction measurement.

The present study is a proof of concept of our controlled environment furnace. The effect of a tensile stress on the terminal solid solubility of deuterium via in-situ neutron diffraction was examined.

EXPERIMENTAL METHODS

Controlled Atmosphere Furnace

A custom controlled-atmosphere furnace for *in-situ* neutron diffraction studies of hydrogen ingress/egress and hydride precipitation/dissolution under load was designed, fabricated, and tested. Figure 1 shows a schematic of the assembled furnace. The furnace consists of two isolated chambers, one being an inner controlled-atmosphere specimen chamber and the other being an outer vacuum chamber. The chambers are isolated in such a way that a high vacuum can be maintained in the outer chamber while controlled gas is introduced as a static pressure or flowed in and out of the inner chamber.

The furnace's outer jacket is made of 3.175 mm thick 6061 aluminum alloy and has integrated water cooling jackets above and below the specimen position. This configuration provides neutron transparency at the height of the specimen and proper cooling to the rubber O-rings, keeping them within the specification temperatures. The inner sample chamber is made of high-performance alloy Nitronic 60, also known as alloy 218, with a wall thickness of 2.03 mm. The base of the inner chamber contains the gas inlet and outlet ports, which are also used to evacuate the chamber, and thermocouple feedthroughs. Conflat (CF) vacuum seals, which use a copper gasket and knife-edge flanges to achieve an ultra-high vacuum seal, are used at the top and bottom of the inner chamber to isolate it from the outer chamber. The CF seals proved effective up to an operating temperature of 450°C at the sample position.

The specimen is connected directly to the load frame base plate and actuator via steel pull rods and interchangeable grips, such that the furnace body is not subjected to, or does not affect, the loading during tests. The interchangeable grips allow different specimen geometries to be accommodated. Stainless steel bellows of 0.254 mm thickness are used to provide a vacuum seal between the pull rods and the top and bottom flanges of the inner chamber.

When connected to the load frame base plate, the lower pull rod is stationary. The upper pull rod, however, is moveable in the axial direction, with the bellows allowing ~20 mm of travel. The upper pull rod exits the outer chamber via a guard vacuum technology. Since the up and down movement of the rod through the guard vacuum piece implies that the hole's diameter must be bigger than the rod's diameter, there is a risk that air can leak into the chamber, causing oxidation on, and therefore compromising, the heating element. A guard vacuum is used to stop these gas molecules and protect the heating element. Standard commercial vacuum and gas fittings are used throughout the furnace.

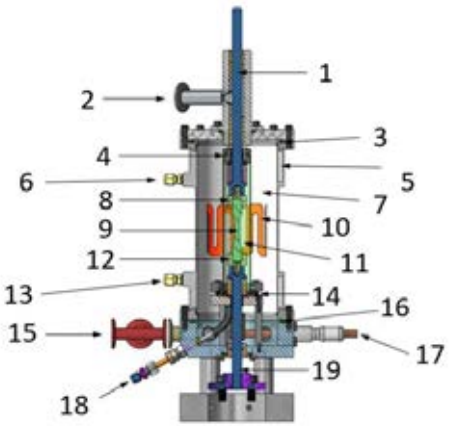

Figure 1: Schematic of controlled-atmosphere furnace. 1- upper pull rod, 2- guard vacuum pumping port, 3- upper body o-ring vacuum seal, 4- pull rod bellows CF copper gasket seal, 5- upper water cooling conduit, 6- water inlet, 7- high vacuum heater chamber, 8- upper sample jaw, 9- sample, 10- tantalum foil radiant heater, 11- sample chamber, 12- lower sample jaw, 13- water outlet, 14- sample chamber's CF copper gasket seal, 15- turbomolecular pump port, 16- lower body o-ring vacuum seal, 17- electrical feedthrough with CF copper gasket seal, 18- gas delivery to sample chamber, 19- lower pull rod

A high-current DC power supply driven by a custom temperature controller was used to operate the furnace. Feedback was provided by a thermocouple mounted adjacent to the specimen in the specimen chamber. The thermocouple was placed slightly below the neutron diffraction window to not obstruct the neutron beam.

Neutron diffraction and data analysis

Neutrons uniquely interact with hydrogen [6], scattering off the atoms strongly, both coherently, in the case of the deuterium isotope, and incoherently, in the case of hydrogen atoms. Due to this large contrast, the technique is therefore very sensitive to the presence of hydrogen and its isotopes in materials. Most neutron diffraction experiments use deuterium for crystallography purposes due to its strong coherent scattering abilities and hydrogen atoms for detection purposes due to its very large incoherent scattering cross-section, which leads to intensity loss and a higher background at very small concentrations [7, 9].

In the present context, diffraction peaks corresponding to hydride precipitates embedded in a zirconium alloy are easily distinguishable from the zirconium matrix peaks. The intensity of a given hydride diffraction peak depends on a number of factors, including the crystal structure factor, the Debye-Waller factor (related to thermal vibrations of atoms about their equilibrium positions), the crystallographic texture, the total volume of the specimen, and a variety of diffractometer parameters. [10] However, with all other parameters fixed, the intensity of a given hydride peak is predominantly a function of the hydride volume fraction in the sample.

The resulting changes in the pattern are attributable to changes in the volume fractions of the different phases present in the sample. In experiments involving changes in temperature, each pattern must first be corrected by subtracting out the changing thermal contribution to the overall level of the pattern.

Neutron diffraction measurements were performed using the L3 neutron diffractometer of the Canadian Neutron Beam Centre, located at the National Research Universal (NRU) reactor of Canadian Nuclear Laboratories in Chalk River, Ontario.

Material

The material presented in this work is a solid rod of Zr-2.5Nb having a diameter of 6.35 mm. The material specification sheet indicates that the room temperature yield strength at 0.2% offset is 485 MPa and the material's grain size is 12 μm. The crystal structure is a hexagonal close-packed structure which can change to a body-centered cubic crystal structure at temperatures over 860° C. Deuterium was introduced to different samples to equivalent hydrogen concentrations ([H_{eq}]) of 500 wppm using a gaseous technique not described here.

RESULTS

Zr-2.5Nb [H_{eq}] = 500 wppm

Specimen ZrNb02 was deuterated to a nominal equivalent hydrogen concentration of 500 wppm. The gamma hydride {202} and delta hydride {220} diffraction peaks [11], occurring at scattering angles of 89.3° and 89.6° respectively, were followed during thermomechanical cycling.

The integrated intensity vs temperature was plotted for the heating portion of cycles 2 (0 MPa), 3 (75 MPa), and 5 (150 MPa) in Figure . The intensity of the deuteride peak can be seen to shrink steadily with increasing temperature up to 420-440°C, where the peak disappears into the background. Increasing the applied stress did not appear to affect the curve significantly. This indicates that these stresses have little to no effect on the hydride dissolution temperature of Zr-2.5Nb. This experiment has demonstrated a successful preparation, operation and in-situ neutron diffraction study on a sample while simultaneously controlling the applied load, temperature and sample environment simultaneously.

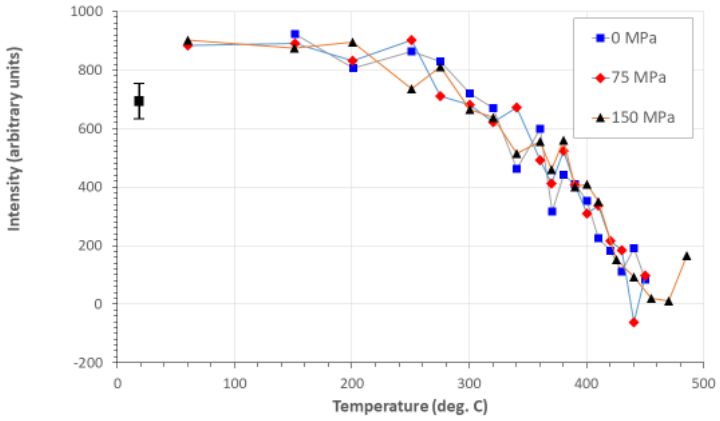

Figure 2: Hydride diffraction peak intensity as a function of temperature for specimen Zr-2.5Nb ([H_{eq}] = 500 wppm nominal) at 0 MPa, 75 MPa, and 150 MPa. The measurement uncertainty is represented by the error bar on the leftmost point.

CONCLUSIONS

Using a controlled-atmosphere furnace which allows specimens to be heated/cooled in the neutron beam while under a simultaneous tensile load, *in-situ* neutron diffraction measurements were performed on Zr-2.5Nb rods charged with deuterium to a nominal equivalent hydrogen concentration of 500 wppm.

An investigation of the effect of tensile stress on deuterium solubility, to obtain insights into the mechanism of hydrogen ingress as well as the mechanism behind DHC and hydrogen embrittlement, was performed. Samples were subjected to a series of thermomechanical cycles to investigate the effect of tensile stress on the dissolution of deuterides. No significant effect of tensile stress on the deuterium solubility of our Zr-2.5Nb rod samples was found for temperatures up to 300°C and at stresses up to 275 MPa. This is contrary to what can be found in literature [12] but it has to be noted that these temperatures are quite low for fast hydride dissolution and this result could be due to slow kinetics in this range of temperatures and applied stresses. The employment of a versatile controlled

atmosphere furnace was shown to be successful, exhibiting predictive behaviour and ease of use. The novel furnace design enables applied load control while maintaining the high vacuum seal and the sample's exposed environment.

ABSTRACT

Premixed laminar methane-hydrogen combustion contains a potential flashback risk, which may be detrimental for home appliances. The present study investigates the effect of hydrogen addition to methane-air premixed laminar flames with two-dimensional transient computations performed by the CFD code OpenFOAM. The effect of wall temperature on flame flashback propensity is examined. After a stabilized flame is achieved, flashback conditions are approached by gradually decreasing the inlet premixture bulk velocity. At flame flashback velocities, flame symmetry is found to be broken because of the oscillations at the flame leading edge. Flashback tendency is found to be increasing with increasing wall temperature and increasing hydrogen addition rate. Flashback limits for 600K wall temperature case are calculated as 0.368 m/s, 0.62 and 0.99 m/s for 0 mol%, 10 mol% and 20 mol% of H_2 additions to CH_4-air mixture respectively. For 300K wall temperature case, they are calculated as 0.165 m/s, 0.265 m/s and 0.44 m/s for 0 mol%, 10 mol% and 20 mol% of H_2 additions to CH_4-air mixture respectively.

Keywords: Laminar premixed flames, Flame flashback, Hydrogen, Numerical simulations, OpenFOAM

INTRODUCTION

The global need to reduce CO2 emissions creates great interest in the utilization of hydrogen as an energy carrier in fuel cell and combustion applications. Hydrogen-enriched natural gas could be the preparatory step for using 100% hydrogen in combustion applications, because 100% hydrogen combustion still has immature aspects for designing the required changes in the infrastructure [1].

Adding hydrogen to CH_4-air premixed combustion alters he mixture laminar flame speed, flame thickness, flammability limits, and adiabatic flame temperature. Safe hydrogen injection limits are critical for determining hydrogen blending rates into the natural gas transmission networks to create safer combustion applications in households [2]. The hydrogen-methane-air premixture contains the risk of flashback, which is the flame propagation in the upstream direction into the unburned premixture. By modifying the laminar flame speed, hydrogen addition becomes one of the many parameters affecting flashback, including burner diameter and rim temperature, burner material, wall and premixture temperatures [3-7].

The present work investigates the flashback dynamics for CH_4-air and CH_4-H_2-air premixed flames with a numerical framework for a given combination of fuel composition and bulk inlet velocity, utilizing both isothermal walls at different wall temperatures and adiabatic wall temperature condition. The computed flashback limits are compared with the experiments of deVries et al. [5] and some experimental correlations proposed in earlier studies.

MATERIALS AND METHODS

The focus of the paper is on the boundary layer flashback phenomenon in Bunsen type burners. Flashback happens when the laminar flame speed exceeds the inlet mixture bulk velocity. This is an unwanted situation may cause severe damage to the combustion system.

In the numerical calculations, the transient reacting flow finite volume solver ‘reactingDNS’ is used [8]. The reactions are solved by the reduced GriMECH 3.0 mechanism, and chemical reactions are treated with the Tabulated Dynamic Adapted Chemistry method. The experiment is modelled as a two-dimensional burner to capture asymmetrical instabilities. The experimental details can be found in de Vries et al [5]. The cold flow inlet is a fully developed Hagen-Poiseuille velocity profile, with initial temperature and pressure being 300K and 100 kPa, respectively. Three different wall temperature conditions, Tw, are explored: adiabatic and constant temperatures of 300K and 600K.

RESULTS AND DISCUSSION

The changes in the equivalence ratio with hydrogen addition are considered in the numerical calculations mimicking the experiments. Laminar flame speeds are crosschecked with Cantera and OpenFOAM to test the solver's ability to calculate the correct laminar flame speeds. Flashback limits are numerically calculated for the same fuel composition, starting from a stable flame with varying bulk inlet velocities. Flashback is considered to take place when the flame front begins to enter the burner tube and travels in the upstream direction. The inlet velocity is gradually reduced by a percentage of the laminar flame speed until flashback is observed.

The flashback dynamics are represented in Fig. 1 for a CH_4-Air mixture at 1.3 equivalence ratio and 600K wall temperature. Normalized heat release rate, which is the ratio of heat release to its maximum value, is used to trace the flame front. The stable laminar flame with the bulk inlet velocity twice of laminar flame speed, which is 0.48 m/s, is shown in Fig 1a. Bulk inlet velocity is reduced gradually to 0.368 m/s where flashback is observed. Fig 1b shows that 0.195s after setting this inlet velocity, the flame front edges start to become parallel to the burner rim and in Fig 1c, the leading edge is formed travelling in the upstream direction. The figures demonstrate the quenching distance near the left wall, and the penetration distance emergence as the flame symmetry is broken in Fig 1c and 1d. Flashback velocity is about 53% higher than the laminar flame speed with 5% accuracy. Flashback onset times provided in Fig.1 are two orders of magnitude larger than the laminar flame characteristic chemical time, estimated to 0.005 s for this flame condition.

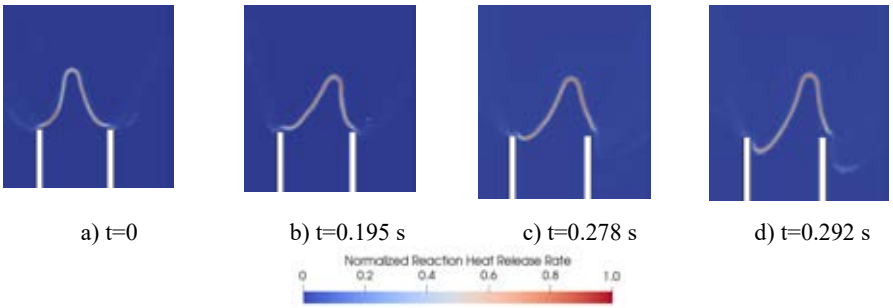

Fig. 1. Flashback dynamics represented with the normalized heat release rate contours for CH_4-air mixture at Φ=1.3 and T_{wall}=600K

Hydrogen addition impact is demonstrated in Fig.2. Fig. 2a. shows the stationary laminar premixed flame with 20% hydrogen addition (volume %) to the CH_4-Air mixture at 600K constant wall temperature. Flashback is observed with the decrease of bulk inlet velocity from 1.1 m/s to 0.99 m/s, which is 5% of the laminar flame speed. Flame symmetry is broken in Fig 2b and in Fig 2c, leading edge formation can be observed. The flame starts to travel upstream in Fig 2d.

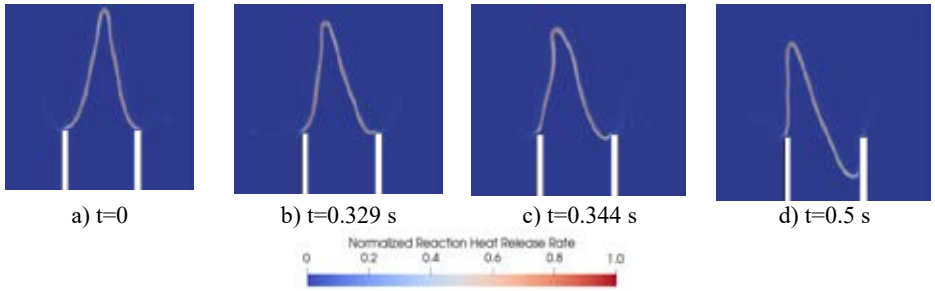

Fig. 2. Flashback dynamics represented with the normalized heat release rate contours for CH_4-air flame at Φ=1.216 with 20% H_2 addition for T_{wall} = 600K

Additional computations not presented here, show that the boundary layer flashback propensity is enhanced with increasing wall temperature. Also, when the adiabatic wall boundary condition is used, no quenching distance or leading-edge formation is observed, and the reactions occur almost at the wall. The computed flashback limits are compared in Figs. 3 with the measurements of deVries et al. [5] and with the correlations based on the critical gradient concept [3,6-7]. U_f is the experimental flashback limit that is observed when the flame just enters the burner tube.

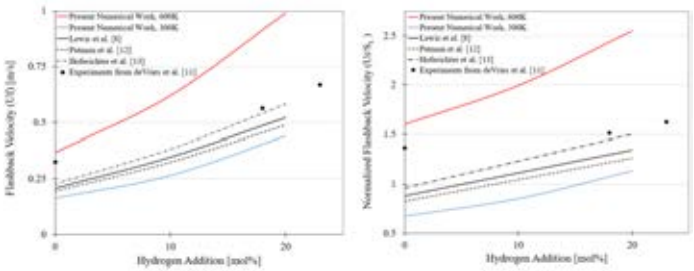

Fig. 3. Comparison of experimental and calculated flashback limits.

In Figs. 3, flashback is observed below the curves. Fig. 3a presents the absolute values of the critical flashback velocity while Fig. 3b represents the same data normalized by the computed laminar flame speed S_L for each mixture condition. With the addition of hydrogen to the premixture, flashback limit is increased for numerical, theoretical, and experimental results. Flashback velocity calculations are claimed to have an accuracy of 5%. For 600K wall temperature, the flashback velocity limits are calculated as 0.165 m/s for 0 mol% H_2, 0.265 m/s for 10 mol%H_2 and 0.44 m/s for 20 mol% H_2 addition to CH_4-air mixture. In the 300K wall temperature calculations, the limits are found as 0.165 m/s, 0.265 m/s and 0.44 m/s for 0 mol% H_2, 10 mol% H_2 and 20 mol% H_2, respectively. The experimental results lie in between our numerical results for constant wall temperatures set at 600K and 300K. The results of deVries et al. [5] are higher than the model predictions for all hydrogen addition rates for 300K wall temperature. This can be related to the quartz burner with low thermal conductivity used in the experiments. The normalized critical flame flashback velocity is above 1 for the experimental results and increases with the addition of hydrogen. All correlations and computations for 600K constant wall temperature show the same trend, especially above 10 % molar H_2 addition rate. The results imply that the simple interpretation of boundary layer flame flashback as only correlated to the laminar flame speed, should be further investigated for flames of methane-hydrogen mixtures.

CONCLUSIONS

Boundary layer flame flashback dynamics of hydrogen added methane-air laminar flames are investigated and flashback limits are determined numerically. The flashback limits are globally following the experiments and past correlations. The main contribution of the present full numerical simulation of the laminar flame flashback process in a simple burner configuration is the detailed information that can be obtained concerning the flashback dynamics without strong modelling hypotheses. For future work, the conjugate heat transfer approach should be included to model the burner wall temperature transiently since it affects the flashback limits substantially. Also, the Soret diffusion effect should be included in numerical calculations, especially for hydrogen mixtures.

ABSTRACT

In the exercise of developing a German Roadmap for Hydrogen Regulations, Codes and Standards (RCS), the identification of current developments and existing gaps and the preparation of recommendations has been performed. The following ongoing international RCS activities were reviewed: ISO, IEC, CEN, CENELEC, EU and UN ECE / WP29. Focus was primarily on hydrogen and fuel cell applications for road transport and stationary applications and to a lesser extent on trains / airports.

It became obvious that the development of standards and regulations and in particular the coordination between the two is complex and requires a concerted approach and substantial efforts. For this reason, a roadmap strategy paper has been prepared, in which a roadmap and timeline has been developed. As an appropriate instrument to achieve a successful implementation of all regulatory and normative requirements while involving all actors and stakeholders, the establishment of an H_2 RCS coordination platform has been considered.

Keywords: RCS Roadmap, RCS Platform, AFID, GTR13

INTRODUCTION

The efficient and cost-effective realization and implementation of hydrogen and fuel cell technologies in the existing energy and transport systems requires appropriate laws (regulations), standards and processes ("Regulations, Codes and Standards" - RCS). Almost all relevant regulations that are applicable to hydrogen and fuel cells in Germany today are based on or must be adapted to European legislation (directives or regulations). Likewise, the essential part of the standards used today is or will be harmonized with international (ISO, IEC) or European (EN) standards. New standards are essentially developed only within the framework of ISO, IEC or CEN, CENELEC. For example, in 2017, approximately 75% of the new standards relevant for Europe were international and only 20% European standards.

H_2 and FC technologies are developed worldwide, especially in Asia and North America. This influence is also reflected in important regulations and standards for hydrogen (H_2 RCS). Due to the path of regulatory development via the New Legislative Framework adopted by the European Commission in Europe, the relevant actors have to anticipate, synchronize and harmonize the development of standards and regulations and thus an increased representation of German experts is required in all relevant international standardization committees. In order to ensure the representation of Germany's interests in the future, consequently a more active participation in committee work is required, in particular by the EU, UNECE, ISO, IEC, CEN, CENELEC.

The development of standards and regulations and in particular the coordination between the two is complex and requires a concerted approach and substantial efforts. For this reason, a roadmap strategy paper has been prepared, in which a roadmap and timeline has been developed [1], how the necessary RCS coordination efforts will be implemented and then continuously pursued. The progress of this implementation must be regularly reviewed and, where appropriate, be adapted to changing requirements.

As the topics with the biggest needs for action have been identified the following ones:

- The revision and further development of the AFID, the GTR 13, the ADR as well international H_2 / fuel cell standards.
- Regarding the development of hydrogen and fuel cell standards international bodies of ISO/TC (197, 158, 58, 22), IEC/TC (105, 31) and the European technical committees of CEN / CENELEC are of special relevance for participation
- A stronger influence by or participation of Germany and Europe in these regulatory and standardization activities is urgently required.

In the following the most important needs for action as displayed in the *German H_2-Roadmap 2025* are visualized:

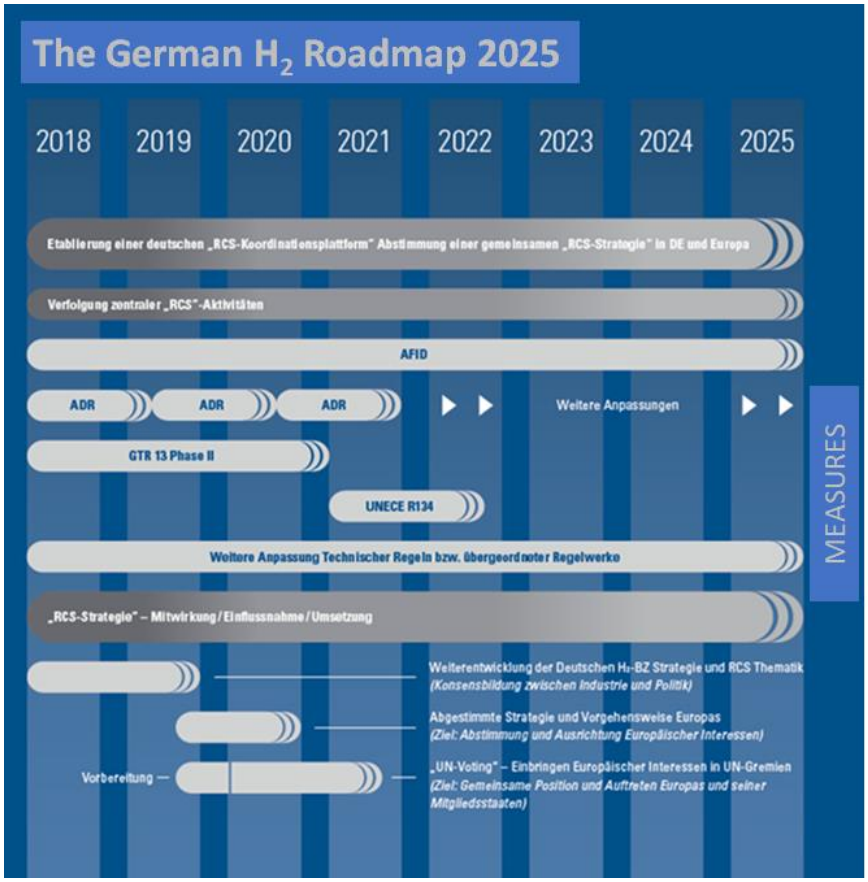

Fig. 1. Identified Need for Action in the German H_2-Roadmap 2025 [1]

The topological integration of the German legislation into the European and international regulatory framework is shown in Figure 2:

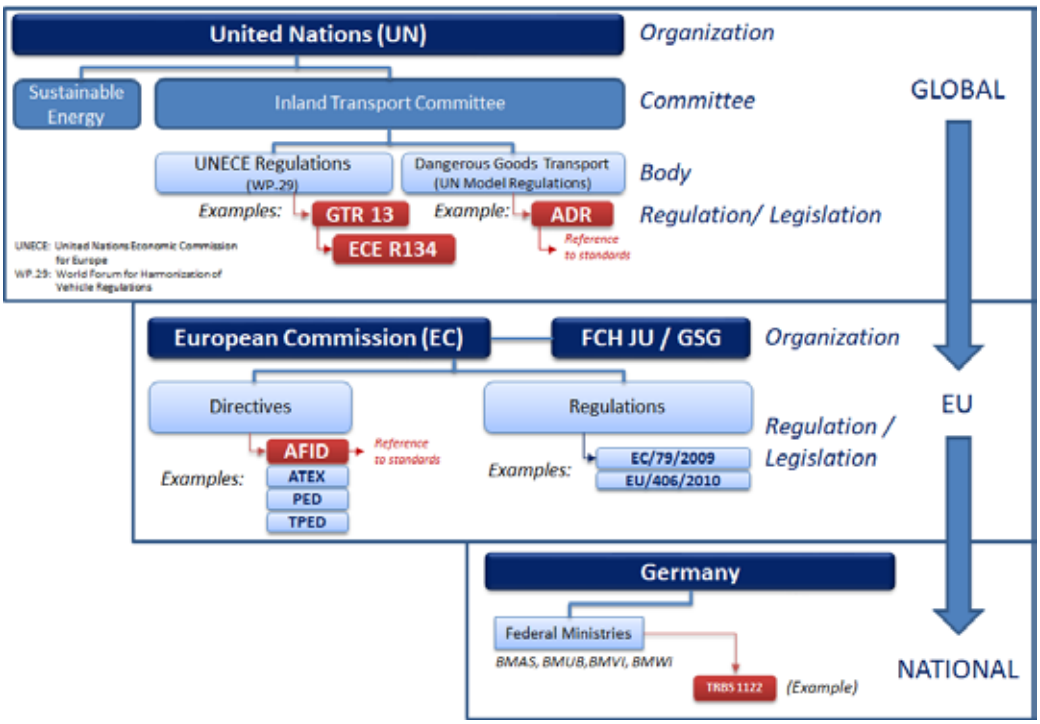

Fig. 2. Topological integration of the German legislation into the European and international [2]

Figure 2 indicates that according to Germany legislation technical rules for operational safety (TRBS) that reflect the state of the art and ensure the implementation of the Ordinance on Industrial Safety (BetrSichV as issued the German Federal Ministry of Labor and Social Affairs have to be complied with additionally to international and European framework legislation.

CONCLUSIONS

As an appropriate instrument to achieve a successful implementation of all regulatory and normative requirements while involving all actors and stakeholders, the establishment of an H_2 RCS coordination platform has been considered. Major tasks of this platform include, but are not limited to:

- Observation of priority developments & trends
- Development of a unified position / vote in RCS matters within Germany
- Regular consultation / harmonization with the actors in Germany (representatives of industry, relevant networks and other experts)
- Development of a unified position / vote in RCS matters within Europe
- Coordination of RCS activities with the FCH JU in Europe;
- Cooperation with the European Government Support Group (GSG) to achieve a agree on common positions among the EU member states
- Influence of/ participation in European (CEN / CENELEC) and international (ISO / IEC) standards development

ABSTRACT

Renewable hydrogen, when combined with large-scale underground storage in aquifers, depleted fields, or salt caverns, enables energy transport over time while balancing the impacts of variable energy production from renewable sources. Although hydrogen storage in salt caverns has been practised since the 1970s in Europe, it has not yet been implemented anywhere in depleted fields or aquifers. The HyStories [1] project aims to provide technical developments applicable to depleted aquifers or fields, to conduct techno-economic feasibility studies and to provide information on underground hydrogen storage to decision-makers in administration and industry. In this context, the legal framework for underground hydrogen storage at European level was analysed in terms of the existence, or otherwise, of regulatory barriers, as well as the extent to which these barriers may affect the development of underground hydrogen storage projects. The starting point of this analysis of the legal framework for UHS was the existing national regulations for the mature underground natural gas storage industry and more than 39 experts from 17 different countries were involved in the project. Thus, this study compares the different country-specific approaches and offers a series of recommendations to avoid legal barriers to the deployment of UHS in geological formations across Europe.

Keywords: Hydrogen, Underground, Storage, Regulatory

INTRODUCTION

The Hystories project [1] aims provide insights on underground hydrogen storage (UHS) in aquifers and depleted fields for decision-makers in government and industry through technical developments, and techno-economic feasibility studies. This work has considered a geographical boundary of EU-27 + UK, and has shown that the regulation, legislation, standards, and permissions of the Member States involved in the HyStories project through partners, third parties and the Advisory Board [2].

Currently, there is no uniform set of laws on natural gas storage for most natural gas storage facilities located in Europe. The legal framework in different countries may be part of mining legislation, energy legislation, construction legislation, environmental legislation, labour protection legislation, health and safety regulations or similar associated legislation. Therefore, the starting point for the present analysis of the legal framework for large-scale hydrogen storage is therefore the existing rules for the advanced natural gas industry.

METHODOLOGY

Reviewing applicable legislation for UHS at the European scale is challenging since each country has its own, in its own language. To gather as much information as possible on the legal situation of underground storage of natural gas and hydrogen in the European context, a survey was launched to Hystories 7 partners and 17 third parties (so 24 institutions involved in hydrogen and/or underground storage from 17 countries), plus Hystories Advisory Board comprising 13 companies (large European gas storage operators, TSO, or manufacturers). From this survey, twenty-three entities provided relevant information for the study.

The survey consisted in 9 questions organised in 4 different sections: Survey Data, Regulatory framework, Standards related to the integrity of underground storages, and wells and Other related issues. Figure 1 shows the breakdown of the 39 responses per country (17 different countries).

Furthermore, to collect the complete list of permits required to develop an underground gas storage today, a questionnaire was developed, completed, and reviewed by experts from France, Germany, Spain, and Poland.

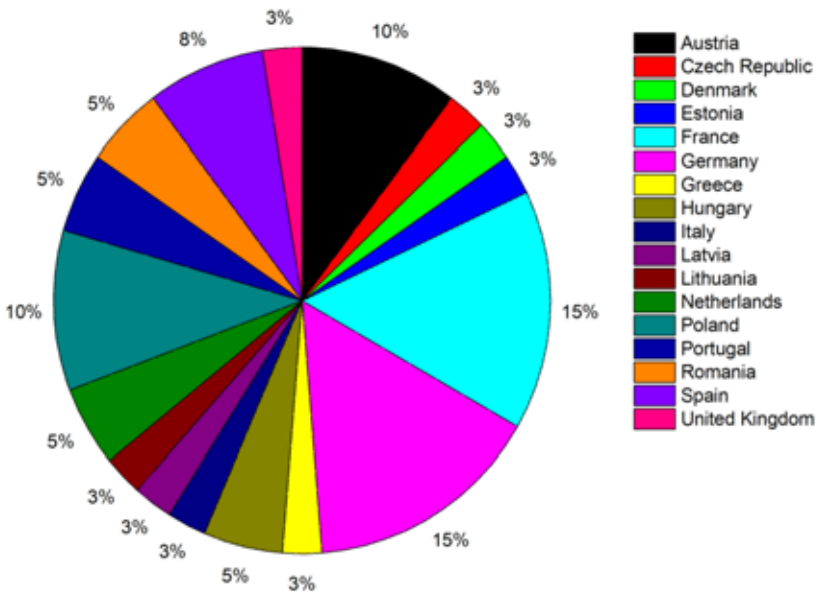

Figure 1.Percentage of responses obtained in the survey for each Member State. Source: FHA.

Regulation

R*egulation* is generally understood as a market concept in the natural gas sector: it is regulated in Europe by common directives that aim at unifying the natural gas market, specifically by the Directive 2009/73/EC [2] and the Regulation (EC) No 715/2009 [3]. The European Commission published the revision of both directives including hydrogen, called the "Hydrogen and Decarbonised Gas Market Package", at the end of 2021 [4].

Thus, the *Proposal for a Directive of the European Parliament and of the Council concerning common rules for the internal markets in natural and renewable gases and hydrogen* [5] in its measure 71 provides that hydrogen networks should be subject to third party access to ensure competition and a level playing field in the hydrogen supply market. Regulated third party access based on regulated access tariffs should be the default rule in the long term. To ensure the necessary flexibility for operators and to reduce administrative costs during the growth phase of the hydrogen market, Member States should have the option to allow the use of negotiated third-party access until 2030.

In addition, specifically for UHS in point 72, it is clarified that since the availability of large-scale underground hydrogen storage facilities is limited and unevenly distributed across the Member States and because of the potentially beneficial role for the functioning of the hydrogen transport and markets, access to such large-scale underground storage facilities should be access to such large-scale underground facilities should be subject to regulated third party access to ensure a level playing field for market participants.

Legislation

The starting point for the analysis of the UHS legal framework are the existing national laws for the natural gas storage industry. Depending on the country, the legal framework for underground natural gas storage in European countries is involving mining legislation, construction legislation, environmental legislation, labour protection legislation, health, and safety regulations and/or other similar associated legislation. This study compiles the detailed legislation for the seventeen countries shown in Figure 1 from the responses of national experts. In particular, the information provided concerns the legislation in force in each country for natural gas underground storage facilities, the bodies responsible for granting permits, the opinion on the need to adapt Directive 2012/18/EU [6] or other industrial safety standards applicable to hydrogen storage, as well as the existence of specific regulations for natural gas and, finally, the possible existence of hydrogen underground storage facilities that have gone through the permitting process.

Standards

Two different sets of standards related to the natural gas industry have been compiled. On the one hand, the standards developed by the International Organization for Standardization, ISO, for underground gas storage facilities, and on the other hand, different technical standards from usually international reference bodies or institutes, SMRI for instance, in relation to the operation and safety of underground gas storage facilities.

Permits

The current permitting requirements for developing underground gas storage were reviewed by experts from France (Geostock, Teréga), Germany (Uniper, Storengy Deutschland), Spain (FHa, Enagas), and Poland (MEERI-PAS, Gaz System) for these four countries. As a result, four tables with details of the procedures have been developed.

RESULTS AND DISCUSSION

Hydrogen is currently defined in most European regulations as a chemical product and not as an energy carrier, which raises legal barriers to developing business models based on renewable hydrogen as an energy carrier. In this respect, discrepancies at the European level on the approach and on the allowable concentration of hydrogen in the natural gas network are an inherent barrier to the development of hydrogen as an energy carrier, whether it is to be injected in the existing underground gas network, or in a new pure hydrogen one. On the other hand, regulatory barriers for underground hydrogen storage can be regional or national regulations that aim at curbing any activity in the underground, not only exploitation but also geological exploration or characterisation. In addition, it has been identified that in some Member States, the current legislation does not cover underground storage facilities for the power industry. Finally, the storage of natural gas in certain Member States can be decided independently of the claims of landowners. This is currently not possible for any other type of product, such as hydrogen, and represents a major barrier for underground hydrogen storage. Regulations that have enable Europe to have a natural gas transportation and storage network today need to be reviewed and adapted for hydrogen.

CONCLUSIONS

As a conclusion to this study, a ranking of countries according to the status of their UHS legislation at the time of this study, September 2021 has been elaborated.

The United Kingdom, Denmark, Germany, and Austria rank first for having UHS legislation in place. It should be noted that in the German case, the legislation in force is for underground storage of chemicals, not for specific UHS, and in the Austrian case only scientific research cases would be included.

Secondly, France and the Netherlands, are developing specific legislation for UHS.

Finally, Czech Republic, Estonia, Greece, Hungary, Italy, Latvia, Lithuania, Poland, Portugal, Romania, Spain do not have UHS legislation under development, although for the Portuguese and Spanish case, UHS is mentioned in their national hydrogen strategies.

ABSTRACT

Gas networks play a vital role in the global energy infrastructure. In Ireland, the natural gas transmission pipelines transport about 50 GWh, twice as much energy as power grids. The gas grids provide a reliable and secure energy supply for electricity generation as a backup when renewable energy is not available. The European Commission in the Green Target Plan set out the goal of net-zero carbon by 2050. The decarbonisation of gas networks incorporating hydrogen generated from surplus renewable power is a potential solution for the storage of excess renewable energy especially so in Ireland with huge available wind resources. The main objective of this research is to ensure a reliable and safe supply of adequate energy to residential end-users while decarbonising the gas network. Dealing with varying hydrogen blends poses significant challenges for gas network operators to ensure hydrogen concentration meets the limits of end-user devices. This experimental research investigates the effects of various hydrogen concentrations on common existing end-user devices found in the Irish gas network. The project examines the potential range of hydrogen blends that may be incorporated into the Irish gas network from 2-20% Hydrogen. This research work provides a detailed account of the tests and experiments carried out as part of this project in the UCD Integrated energy Lab and the Hydrogen Innovation Centre of Gas Network Ireland. This includes modelling of pressure drop in an example of distribution pipe rig, combustion and ignition temperature, and comparing the accuracy of meters before and after blending hydrogen through the pipelines. This study investigates how much the addition of hydrogen impacts the operation of appliances in the residential segment, also provides reference data for all relevant parties. The outcomes from this practical research allow for a complete costing of the necessary network and appliance upgrades to accommodate blended hydrogen in the gas network.

Keywords: Green Hydrogen, Gas Networks, Energy Storage, Hydrogen Blend

INTRODUCTION

In recent years, the development of renewables in energy systems has been targeted in many countries to support decarbonisation objectives. The European Green Deal frames Europe's response to climate change challenges and commits to delivering net-zero greenhouse gas emissions at the EU level by 2050 and an EU-wide GHG emissions reduction target of at least 55% for 2030 [1]. In line with EU ambition, the Irish Government's Programme, Our Shared Future commits to achieving a 51% reduction in Ireland's overall GHG emissions from 2021 to 2030, and to achieving net-zero emissions no later than 2050 [2]. A roadmap has been developed through Ireland's Climate Action Plan 2021 to put Ireland on a low-carbon trajectory to meet future targets in 2030 and 2050. These are challenging targets, in particular as Ireland has already missed targets for 2020. According to Ireland's Environmental protection Agency (EPA) report, since 2011 the rate of emissions has deviated upwards with an overall peak in 2018. However, this figure had a modest reduction from 2008 to 2011. Transport and industries are segments that represent 18% and 15% in generating emissions respectively in the same period.

Ireland's gas network provides almost one-third of all primary energy [3], 40% of heating and more than half of Ireland's electricity generation. Ireland's gas transmission system is among the most developed gas networks in EU countries and it can make a significant contribution to decreasing emissions by providing a more sustainable and secure transition to a clean energy future. Natural gas is a cleaner alternative to conventional hydrocarbons such as oil and coal and can replace these fuels in heat and power generation. The gas network can also transport renewable gas such as green hydrogen and biomethane for long-term energy sustainability and decarbonisation of the gas supply.

Hydrogen and decarbonising gas systems

The future decarbonised energy systems using hydrogen can be obtained in the following ways: 1. Using the process of steam methane reforming with a carbon capture unit to produce blue hydrogen, 2. Generating green hydrogen from renewable electricity through an electrolysis process that doesn't produce GHG emissions. Also, it can capture

the excess renewable energy which would be otherwise lost [4]. Hydrogen is flammable with a considerable calorific value which can be burned in different segmental of end-users. Hydrogen can be injected into the conventional gas pipelines usually in low percentages up to 20% volume. Ireland has one of the best wind resources in Europe and has significant potential for wind generation which can be expected to exceed end-users demands. With the current levels of wind generation on the island of Ireland, the power system operators sometimes curtail renewable power due to electricity grid limits and constraints. As the long term Irish target plan is to install more wind farms, this can increase the surplus renewable power. Therefore, finding an alternative use of this excess energy will improve the operation of the energy system. The production of hydrogen using electrolysers is a potential solution that provides an important opportunity to convert this excess renewable power to green hydrogen which can be injected into the gas pipelines.

Long term storage

The use of new technologies such as Power to Hydrogen (P2H) can be a potential solution to develop a more flexible energy system. Gas pipelines can play a key role in renewable energy storage by providing backup to fluctuate renewable power. The use of P2H means that large amounts of excess renewable energy can be converted to hydrogen stored within the gas network, providing long-term storage, and used at times of low availability of renewables replacing fossil fuels and reducing carbon emissions.

EXPERIMENTAL METHODS

The results from the computing analysis of the gas network system incorporating green hydrogen show that green hydrogen can be injected into the gas network without significant changes to its operation, as "pressure drop" and "flow rate" will not encounter big changes [2]. Also, by injecting green hydrogen, generated from excess renewable power, there is a reduction in flow rate from the natural gas supplier of up to 2%. This is approximately daily 200,000 cubic meters of natural gas reduction and consequently a decrease of CO_2 about 432 tonnes during the specific day. There are limitations in accepting hydrogen levels by different gas-based fuel devices. Concerning operating limits, such as the Wobbe index, as well as material compatibility, and safe permissible hydrogen concentration, the permissible upper hydrogen limit have been considered in practical standard projects. The gas distribution pipelines could convey up to 50% (even 100%) hydrogen concentration depending on the type of pipeline components and the designated standards; however, because of the end-users devices, the allowable hydrogen concentration is likely to be at a maximum blend of 20% in distribution networks. Figure (1) shows the current limits of hydrogen fraction in pipelines, considering the Wobbie index and calorific value limits. According to this plot, provided by European standards, The Red area relates to Common Business Practice (CBP) which is pointing to the gas quality criteria specification, used in Europe for Natural Gas. The hydrogen content should not exceed 15–20%. Since above 20%, there are technical concerns, due to safety perspective, metering and energy conversion.

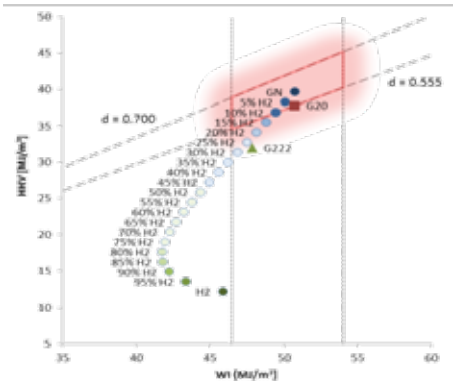

Figure 1. Admissible H2 considering the blends Wobbe index and heat value [5]

In the existing transmission gas system, the Wobbe index and the calorific value should not exceed the limits. As a consequence, natural gas may not meet the quality and safety requirements provided in the relevant standards. The current European standards which consider the gas quality of hydrogen blends are EN 437 for Test gases, Test pressures, and Appliance categories. This study is a collaboration between UCD Energy Institute and Gas Networks Ireland (GNI), Hydrogen Innovation Centre to ensure the safety and operability when blending hydrogen in the gas network. This looks at the feasibility of different volumes of green hydrogen being added to the gas network and the impact this will have on the operation of domestic appliances. Two main steps have been implemented by UCD and GNI for investigating the potential of gas networks for storing and transporting hydrogen. As a first step, the research

project started off by using modelling approaches to investigate how hydrogen impact the operation of the gas system when there are large variations of gas quality incorporating green hydrogen. The project will involve testing hydrogen blends in domestic appliances to make sure the designed computer models are valid and reliable in the real world. This will also test to ensure that the hydrogen is safe to be used by different appliances including (boiler, cooker, and heaters) also to determine how much does the addition of hydrogen impact the operation of gas pipelines in a distribution network.

CONCLUSIONS

Concerning operating limits, such as the Wobbe index, as well as material compatibility, and safe permissible hydrogen concentration, the permissible upper hydrogen limit has been considered in this practical project. The gas distribution pipelines could convey up to 50% (even 100%) hydrogen concentration depending on the type of pipeline components and the designated standards; however, because of the end-users devices, the allowable hydrogen concentration is likely to be at a maximum blend of 20% in distribution networks. The outcome of this research helps to inform the use and operation of gas networks as they move to decarbonise the energy systems to ensure that the hydrogen concentration meet the end-users limits and it can be a safe, secure and clean alternative fuel in the residential segment. Also, to help the National Standards Authority of Ireland (NSAI) which is following all the latest hydrogen standards developments to standardise the use of hydrogen blends.

ABSTRACT

The enforcement of regulation on hydrogen fuel quality is a need supported by car manufacturer, policy makers and end users. Several laboratories in Europe and worldwide are becoming able to measure hydrogen fuel quality according to ISO 14687. However, it is currently difficult to evaluate the quality of these laboratories. Lack of gas calibrants, reference material and inter-laboratory comparison is a barrier for European commercial laboratory to prove their competences and obtain accreditation ISO 17025. National Physical Laboratory (NPL) has ISO 17025 accreditation and developed reference materials for hydrogen fuel quality. Based on experience in the previous proficiency testing on hydrogen fuel quality, NPL propose a new proficiency testing scheme and guidance on common issues. NPL will present new results on stability of contaminant in sampling container and advice for hydrogen fuel sampling. The presentation will provide advanced results and good practices to ensure reliability and accuracy of hydrogen quality analytical laboratory.

INTRODUCTION

Deployment of FCEVs is a growing reality in Europe (i.e. 1600 Hyundai trucks in Switzerland by 2025 [1] or H2ME deploying 1400 FCEVs by 2022 [2]) with FCEVs production ramping up worldwide (i.e. Toyota increase from 3000 to 30000 FCEVs equivalent by 2020 [3] or Hyundai increase to 700000 FCEVs by 2030 [4]). At the same time, the number of refuelling stations is exponentially increasing with more than 152 stations currently in Europe. The enforcement of regulation on hydrogen fuel quality (European Directive 2014/94/EU [5]) is becoming a societal need supported by car manufacturer, policy makers and end users. Hydrogen fuel quality control is critical to meet the international regulations and recommendations and ensure the longevity of the vehicles (impacted by hydrogen fuel contaminants). Therefore, measurements of hydrogen fuel quality according to international standards (ISO 14687 [6], EN 17124 [7]) is required to demonstrate the actual fuel quality at the nozzle of the hydrogen refuelling stations. In order to support this need, European laboratories are developing the capability to measure the contaminants specified in ISO 14687 [6] and EN 17124 [7]. Several laboratories in Europe (as part of European project MetroHyVe, HYDRAITE or commercial laboratories) are becoming able to measure hydrogen fuel quality according to ISO 14687 [6]. The new challenges linked to the increase of analytical laboratories potentially capable of performing the analysis according to ISO 14687 [6] is to ensure that the results are accurate and agree between laboratories. There is a new requirement of cross check between laboratories or quality control check to ensure that the quality of the results is satisfying. Metrological tool (reference materials, proficiency testing) and accreditation requirements are the best strategy to promote better measurement agreement. The first inter-laboratory comparison led by EURAMET showed that several NMIs and analytical laboratories have good agreement on measurement of CO and H_2S in hydrogen [8]. However, this study was performed on gas standard not on real hydrogen fuel sample and the amount fraction level for H_2S was 250 time higher than ISO 14687 threshold [6]. Recent bilateral comparison organised by European projects (HyCoRa and HYDRAITE) showed discrepancies between laboratories results for hydrogen fuel quality especially for water and hydrocarbons [9]. Recently, MetroHyVe project organised an inter-laboratory comparison for 4 contaminants out of the 13 regulated in ISO 14687 [6]. Ensuring equivalence between analytical laboratories worldwide require that the metrological tools are available and recognised: reference materials, calibrants, proficiency testing schemes, accreditation. Lack of gas calibrants with sufficient uncertainty, reference material and inter-laboratory comparison is a barrier for European commercial laboratory to prove their agreement to ISO 21087 which is mandatory according to ISO 14687. The National Physical Laboratory (NPL) has successfully developed analytical methods and obtained ISO 17025 testing accreditation to measure accurately hydrogen contaminants according to ISO 14687 [6] at low amount fractions (i.e. 4 nmol/mol for total Sulphur, 100 nmol/mol for ammonia). Moreover, NPL has engaged in the development of new reference materials for most of the hydrogen fuel contaminants. The presentation will provide details information on contaminants reference materials in hydrogen and stability. Based on these developments and on knowledge on proficiency testing, NPL will present new proficiency testing scheme guidance for hydrogen fuel quality. Finally, an overview on different new sampling system developed and deployed

in the recent years to tackle sampling from production site, fuel cell vehicles or heavy duty will be provided with emphasis around the methodology. The presentation will be structured on four points: NPL accreditation scope for hydrogen fuel analysis, new hydrogen fuel reference materials, proficiency test and new sampling.

NPL ACCREDITATION SCOPE FOR HYDROGEN FUEL ANALYSIS

NPL achieved to validate method for most contaminant in hydrogen required in ISO 14687. Following method validation and quality control implementation, NPL obtained accreditation scope ISO 17025 and will extend it to complete ISO 14687 scope in 2020. NPL will present the different steps involved in method validation, the quality control tools implemented, and the final scope obtained (Table 1). Moreover, a perspective towards new analytical methods developed recently around picomol/mol of total sulphur and oil amount fraction will be mentioned with the first achievements from NPL.

Table 1. NPL hydrogen fuel quality analytical laboratory with ISO 17025 scope on December 2019.

Gas analysis	ISO 14687 EN 17124 [µmol/mol]	Analytical Method	Detection Limit [µmol/mol]	ISO 17025 testing	Required amount of gas [L]
Water	5	Quartz crystal microbalance CRDS	0.2 0.030	Yes No	30 30 - 60
Total Hydrocarbons	2	GC-Methaniser-FID	0.05	Yes	2
Methane	100	GC-Methaniser-FID	0.05	Yes	2
Oxygen	5	GC-PDHID	0.3	Yes	2
Helium	300	GC-TCD	10	Yes	2
Argon Nitrogen	300	GC-PDHID	0.3 1	Yes Yes	2 2

Ammonia	0.1	FTIR SIFT-MS	0.05 0.02	No No	30 2
Key halogenated compounds according to ASTM D7892-15	0.05	TD-GC-MS	0.016	No	1.5

NEW HYDROGEN FUEL REFERENCE MATERIALS

NPL developed new sets of multi contaminants in hydrogen gas mixture. The reference mixtures were prepared gravimetrically from the pure components in accordance with ISO 6142-1 [10] in different cylinders (aluminium, aluminium with passivation). Mixtures containing 7 to 12 contaminants have been prepared and studied over a period of several months to one year (example of composition presented in Table 2).

Table 2. Example of NPL reference materials for seven contaminants in hydrogen

Component	Amount fraction / [µmol/mol]
Helium	300
Argon	300
Nitrogen	300
Methane	100
Carbon dioxide	2
Ethane	1
Carbon monoxide	0.2
Hydrogen	Balance gas

NPL investigated reactive species and achieved to produce stable reference materials with low nmol/mol of reactive species including sulphur compounds (i.e. 15 nmol/mol of dimethyl sulphide in hydrogen for several months). NPL will present the new reference materials for hydrogen fuel with length life and uncertainty.

PROFICIENCY TESTING SCHEME

Based on NPL involvement in all the hydrogen fuel inter-laboratory comparisons, a review of the different good and bad practices will be presented involving the reference materials used (cylinder type, composition), the length of the proficiency testing (i.e. 3 months to 2 years), the scheme (shared cylinder versus batch). Following the state-of-the-art

review, NPL will present a new scheme trying to mitigate all the past issue encounter and allowing simpler proficiency testing using the new reference materials recently developed.

NEW SAMPLING SYSTEM

Based on the evolution of hydrogen economy, NPL has developed new sampling system to achieve sampling of hydrogen gas from various production facility, fuel cell electrical vehicles or heavy-duty application. The systems developed have been applied in real situation and hydrogen gas quality according to ISO 14687 was achieved. The presentation will highlight the different type of sampling system and the key points to achieve reliable sampling. The perspectives around these new sampling capabilities will be presented alongside the sector evolution and the need for standardisation.

CONCLUSIONS

The National Physical Laboratory has successfully obtained ISO17025 testing accreditation. New reference materials for a large part of the hydrogen fuel contaminants is available with sufficient length life. Therefore, it will allow to provide new proficiency testing scheme to assess analytical laboratory performance. Adherence to this new proficiency testing scheme will support higher degree of equivalence between laboratories and more reliable results of analysis on hydrogen quality. Finally, the complexity of hydrogen fuel sampling around new system and application will be highlighted and perspectives to support these new sectors will enhanced new research needs on material passivation, intercomparison and contaminants behaviour study. The results presented by NPL will highlight new critical issues to ensure adherence to regulation and international standard (ISO 14687) which seems highly challenging today.

ABSTRACT

Hydrogen fuel cells are an alternative power supply for electric drive trains and could represent 32 % of fuel demand by 2050. To deploy fuel cell electrical vehicles, there is current regulatory barriers (ISO 14687, OIML recommendations) that requires accurate measurements. The European funded project MetroHyVe has provided solutions and improvements in the four measurements challenges (flow metering, quality control, quality assurance and sampling). New challenges arised due to increase of hydrogen economy, therefore a new European project MetroHyVe 2 started in 2020 and its objectives will provide perspectives for the hydrogen economy to solve all regulatory barriers (ISO 14687, ISO 19880-8, ISO 19880-1, ISO 21087, OIML R139-1) and new measurement challenges (flow metering, quality control, sampling and fuel cell stack testing). The presentation will provide a comprehensive overview of the project achievements. The achievements around primary standard for flow metering (light and heavy duty), worldwide inter-laboratory comparison for hydrogen fuel quality, hydrogen sampling inter-comparison and fuel cell stack testing recommendations will be highlighted.

Keywords: Hydrogen fuel quality, ISO 14687, flow metering, metrology, regulations

INTRODUCTION

Climate change, air quality and reliance on imported fuels from non-renewable sources require immediate deployment of alternatives such as hydrogen to meet the 2050 Europe carbon neutral targets (net-zero emission from transport) [1]. Hydrogen fuel cells are an alternative power supply for electric drive trains and could represent 32 % of fuel demand by 2050 [2]. According to 78% of automotive executives polled, FCEVs are “the real breakthrough for e-mobility” [3]. To achieve mass implementation of hydrogen in transport, there is current regulatory barriers. European Directive 2014/94/EU [4] and OIML recommendations [5] must be met by all European hydrogen refuelling stations (HRS) and therefore requires accurate measurement and metrology support. European project MetroHyVe was the first metrological project funded by European metrology program for innovation and research (EMPIR) with focus on solving measurement challenges for fuel cell electrical vehicles. These measurement challenges are linked to the regulatory barriers and international standards (hydrogen quality: ISO 14687, hydrogen quality control: ISO 19880-8, flow metering: OIML R139-1, analytical methods: ISO 21087) ([5; 6; 7; 8; 9]. At the end of the project in 2020, it was evident that new measurement challenges arise in relation with the rapid growth of the hydrogen economy. Therefore, a new European project MetroHyVe 2 was funded by EMPIR around four measurement challenges:

- Flow metering: to develop and harmonise a metrological framework for testing hydrogen meters used to measure the mass of hydrogen dispensed from HRS using secondary standards for light-duty vehicles and primary or secondary standards for heavy duty FCEV).
- Hydrogen quality control (development quality control tool for analytical laboratory (reference materials and inter-laboratory comparison for all contaminants regulated in ISO 14687 and development of metrological guidelines for sensor and analyser at HRS over long period).
- Sampling (harmonization of hydrogen sampling methods at HRSs in Europe and worldwide with ASTM and Japan).
- Impact of contaminant on Fuel cell stack (reproducibility study with FC stack and inter-comparison evaluation, which will eventually result in a standardisation of automotive FC stack testing).

The presentation will highlight the achievement in the four measurement challenges: flow metering, quality control, sampling and Impact of contaminant on Fuel cell stack.

FLOW METERING

In Europe, the flow metering primary standards got developed as part of MetroHyVe and MetroHyVe 2 project. At least four primary standards are operational currently in Europe and two under approval by notified bodies. These mobile facilities are capable of calibrating or testing flow meters in the HRS at the operating conditions during

refueling (nominal working pressure of 700 bar) for light-duty vehicles [10]. The current primary standards are compliant for fuel delivery to light-duty vehicles according to the Society of Automotive Engineers (SAE) J2601 protocol but an international field comparison for clear acceptance by the HRS operators and notified bodies is missing. The MetroHyVe 2 project partners are currently undertaking the first key comparison of flow metering primary standards at EMPA HRS in Switzerland. The presentation will provide insight on the different primary standards in Europe and the status of the inter-comparison.

The implementation of heavy-duty vehicles such as buses and trucks into the hydrogen infrastructure requires primary standards that are capable of reaching higher flow rates and therefore require a dedicated standard, which is currently not available. The project partners are progressing with the development of two first primary standards for heavy-duty vehicle (35 and 70 MPa) with completion expected in summer 2022. The presentation will highlight the status of the two primary standards and will present the results of the uncertainty budget for these heavy-duty primary standards.

The project will also go beyond the state of the art by developing and demonstrating the traceability chain from primary standards to secondary standards for regular verification of small and light-duty vehicles as well as for heavy-duty vehicles. This method for field verification of HRS is using calibrated master meter and the outline of this new methodology will be presented. Finally, a summary of the finding of the project will be presented to support a revision of OIML R139-1 [**Error! Bookmark not defined.**].

HYDROGEN QUALITY CONTROL

European laboratories are developing the capability to measure the contaminants specified in ISO 14687 [6] and EN 17124 [11]. However, the current lack of gas calibrants with sufficient uncertainty, reference materials (RM) for validation and inter-laboratory comparison scheme is a barrier for European commercial laboratories to be able to prove their agreement to ISO 21087. The consortium published an open access report summarising the results of a survey on the requirements of gas calibrants for hydrogen fuel quality which highlights the industry needs. The partners have engaged in ambitious study to enhance gas calibrants stability. The study is evaluating stability of three new multi-contaminant (8 – 14 contaminants) gas mixtures in hydrogen in a large variety of gas cylinders. The stability study will last for at least 12 months and cover contaminants found in real hydrogen fuel samples and detailed in ISO 14687. The presentation will highlight and present the new interlaboratory scheme covering eight contaminants (specified in ISO 14687) in hydrogen fuel. It is the most ambitious interlaboratory comparison worldwide as it involves production of complex gas mixture in batch (14 equivalent gas mixtures), largest number of contaminants in gas cylinder (8 compounds) including reactive compounds at ISO 14687 threshold (i.e. 4 nmol/mol of sulphur compounds). Currently 13 laboratories (including commercial laboratories) from Europe, North America and Asia registered for the intercomparison that will take place in 2022. Finally, a presentation on the activity around validation of sensors in laboratory and at Hydrogen refuelling stations will highlight on the challenges for this new sensing requirement [12]. It will be based on recent study by the consortium on the performance of two sensors for water in hydrogen in laboratory condition and on the implementation of analysers at 3 HRS in Europe which is ongoing in 2022.

HYDROGEN FUEL SAMPLING

Hydrogen fuel sampling methods at HRS nozzle are currently not all validated or compared, which has raised concerns on sampling equivalence worldwide. Partners published an extensive peer-review article on sampling containers, sampling equipment and methodologies used for hydrogen fuel sampling [13]. The presentation will provide an overview on hydrogen fuel sampling system and methodology. To determine the degree of equivalence between hydrogen sampling method, the partners organised bilateral sampling intercomparison. The partners achieved bilateral sampling comparison between Europe and US approach (in collaboration with ASTM). Two joint samplings at HRS in USA were performed by US representative and project partner in 2021. The results of analyses will be presented alongside the status of the sampling inter-comparison in Europe and Asia.

FUEL CELL STACK TESTING

Harmonisation of automotive FC stack testing is needed for the assessment of their performance and durability under operating conditions (including reproducibility issues) and hence of their technological progress. Several European project (HyCoRA, HYDRAITE) has studied contaminant in fuel cell stack recirculation loop [14], however the protocol has not been standardised. The project objective is providing the first guideline for FC stack testing with a recirculation loop, highlighting the critical parameters for their performance, as well as harmonising the test protocol.

Based on an extensive literature review and state-of-the-art systems, the partners will be performed measurements on 4 different stacks. The measurements, comparison and evaluation are currently ongoing. The importance of reactive species behaviour in recirculation loop (temperature, humidity) are critical for the representativity of the results. Therefore, a study was dedicated on clean-up protocol of fuel cell pipes after exposure to contaminant (inert,

hydrocarbons, reactive species) in hydrogen. Further study on adsorption/desorption of reactive compounds (i.e. ammonia) will follow in hydrogen fuel cell system in correlation with online measurement (i.e. FTIR) at partner laboratories. The presentation will highlight the first results and the current progress of the studies.

CONCLUSIONS AND PERSPECTIVE

MetroHyVe 2 provided key studies for hydrogen fuel quality, fuel cell stack testing hydrogen flow metering at HRS and support to enforce regulation and international standards. Its impact is strong in the hydrogen community and support the quick expansion of hydrogen economy in Europe. The project is progressing significantly the measurement for hydrogen for transport however new needs and new activities are planned at European level and the link between MetroHyVe 2 project, the initiative of Clean Hydrogen partnership, the standardisation committees and more recent project will be highlights as perspective of this work.

ACKNOWLEDGEMENT

The Joint Research Project «Metrology for hydrogen vehicles 2» is supported the European Metrology Programme for Innovation and Research. The EMPIR initiative is co-funded by the European Union's Horizon 2020 research and innovation programme and the EMPIR Participating States.

ABSTRACT

Proposals on the inclusion of hydrogen as an energy vector into the large-scale energy socio-technical system has gained considerable momentum along with the effects of the climate crisis and the COVID-19 pandemic. This study examines the conflict between various dimensions of decarbonization with hydrogen agenda within the conceptual framework of international environmental law and policies. Firstly, we carry out a general due diligence of the technical, economic, and legal aspects of the hydrogen economy particularly in Europe. Subsequently, via textual analyses of European Union's strategic documents, the incompatibility of the hydrogen risk chain with the hydrogen value chain is revealed. Finally, as one remedy to this incompatibility; the precautionary principle, its relation to science, technology and society studies, and its possible policy applications in the context of hydrogen technologies are discussed.

Keywords: Hydrogen, Decarbonization, Risk, Precautionary Principle, Environmental Law and Policy.

INTRODUCTION

The COVID-19 pandemic triggered the already existing volatility in the world's energo-political regimes to the point that the processes of sociotechnical change related to energy systems are more relevant than ever. Hydrogen is receiving unprecedented interest and investments as the post-fossil fuel world anticipates CO2-neutral chemical conversion of energy. This paper examines the conflict between various dimensions of decarbonization with hydrogen agenda within the conceptual framework of precautionary principle (PP).

EU is a pioneer in the promotion of a "hydrogen economy". The European Commission considers clean hydrogen as "a vital missing piece of the puzzle" to decarbonize heavy industries such as steel and help the EU achieve its 2050 climate neutrality goals. The 2020 EU Hydrogen Strategy [1]-flags up to €470 billion of investment. Hydrogen lobby declared €58.6 million expenditure in 2020 trying to influence Brussels policymaking [2]. On the other side of the coin, from Hindenburg to Fukushima, accidents involving hydrogen are fires and/or explosions with serious consequences for humans and the environment. Hydrogen value chain is more dynamic than ever before. In order to benefit from hydrogen's potential to reduce global and trans-national energy disputes and to solve environmental pollution and health problems; it should be used by minimizing the risk potential caused by its physical and chemical properties.

RESEARCH QUESTIONS

Research questions include: How can precautionary theory serve to explore the delicate balance between desires for a rapid advent of hydrogen energy technologies whilst keeping the highest safety level for the users? How to create value for policy-level research pursuing ecological complexity while analyzing the immature, complex, and differing nature of legal processes necessary for the deployment of hydrogen technologies? How to open hydrogen risk management to qualitative concerns? How to marry innovation and safety in terms of gas quality given that there is no present consensus and a future one is quite difficult to establish?

The answers to these questions are significant as hydrogen can play a crucial role in the transition to a new global sustainable energy regime. The decarbonization potential of hydrogen concerns almost all the economic spheres from industry, transport, services to household activities. In this context, PP offers trans-disciplinary expertise for safe and just energy transitions [3]. Implementation of precautionary theory requires continuous and holistic audit, where information and knowledge are always prone to revision and change [3]. PP can also encourage more open discussion of the value judgements underpinning methods of risk assessment and cost-benefit analysis. This makes policy-making more reasonable, scientific, and accountable.

The objectives of the research are examining the relationships between technical, economic, and legal aspects of «decarbonization with hydrogen» agenda; delving into the risk aspects of the hydrogen infrastructure for sound policy making and regulation as an integrated vision is in its infancy in the EU; contributing to scientific hydrogen policies

by offering extra transparency; suggesting hydrogen policies that enable more deliberative, participatory, democratic decision-making processes.

This study is novel as it tries to find ways for precaution and innovation to coexist. It is novel domain-wise regarding the intersection of energy studies with precautionary theory. Until now, hydrogen has not been the object of such study. It is also novel as one of the major findings reveal hydrogen risk chain – hydrogen value chain incompatibility; an issue yet "to be treated by the relevant literature. Finally, concrete policy recommendations are made in line with abstract principles as another novel feature of the study.

LITERATURE REVIEW

EU laws, official and strategic EU documents, EU directives, EU regulations, EU project reports consist of the first part of literature review. The second part of the literature includes readings of precautionary theory, its weak and strong versions from authors such as Sunstein, Morris, Marchant & Mossman, Fisher, Grant & Quiggin, Persson, Garnett & Parsons. The legal readings of PP are done in legally binding international agreements and treaties, case law, legal doctrine, customary international law and jurisprudence at the international level and state practice at the national level.

As one very successful example of PP, we focus on the Montreal Protocol in detail. It is the first Multilateral Environmental Agreement to set targets and timelines to phase out chemicals harmful to the atmosphere. It is designed in a way that protected the interests of producers and importers, preventing high price inflation or overproduction during the phase out period of the targeted gases [4]. Examination of this Protocol contributes to understanding the delicate balance between innovation and regulation.

METHODOLOGY

We used conceptual, analytical, and descriptive legal qualitative method. The research is conceptual as it doesn't involve conducting any practical experiments. It is related to abstract concepts or ideas. It is analytical as it involves critical thinking skills and the evaluation of facts and information relative to the research being conducted. It is descriptive, describing the characteristics of the phenomenon that is being studied. We also used discourse analysis on the relevant EU documents, conducting specified sets of research on precaution, safety, environmental principles, and energy transition. Legal discourse analysis enabled us to uncover/look at the social context and the political and cultural dynamics behind legislative processes or the policy implementation.

RESULTS

We found out that lack of consensus on hydrogen safety results in non-presence of references to safety. Use of discourse analysis of the latest official documents of EU revealed their perception of law as a "barrier", the absence of "safety" issues therein and loopholes allowing the gas industry to continue burning fossil fuels.

The existing framework for hydrogen in EU is ten years old and not clear enough to build up support schemes for hydrogen. Therefore, in terms of regulatory framework, the scenery is patchy and blurry. It was highly anticipated that the necessary regulations that will clarify the blurriness and reorganize the patchiness will come up with the new Hydrogen and Decarbonised Gas Markets Package [5,6]. This package was delayed for two years now due to the challenges of standardization and of patchwork features of the regulatory framework. The relevant Proposals published on December 15th, 2021, are now on scrutiny process at the European Parliament and European Council. These Proposals do not offer an exhaustive take on hydrogen in Europe. Rather, they add new pieces to a broad set of legislation puzzle including but not limited to the Renewable Energy Directive II, Energy Efficiency Directive (EED) and Emissions Trading Scheme (EU ETS) the proposal of the Carbon Border Adjustment Mechanism, the revised Climate, Energy and Environmental State Aid Guidelines, etc. This means that the regulatory patchwork problem is not solved, a multitude of legal acts will govern hydrogen.

In terms of standards for gas quality, currently Member States have discretion to set the hydrogen limit at the national level, including for gas interconnection points. Such a standard is difficult or perhaps impossible to establish given the diversity of conditions concerning the use of hydrogen, the resistance uncertainty of the pipelines to embrittlement, etc. The Proposals create an obligation for transmissions system operators to accept cross-border blended streams with up to 5% hydrogen content from 1 October 2025. There might be serious repercussions considering the variety of energy systems in different Member States, with different storage facilities and pipelines which cannot tolerate that amount of hydrogen.

DISCUSSION

a. Overall finding: Hydrogen risk chain – hydrogen value chain incompatibility

Hydrogen Value Chain (HVC) from generation to the end uses is well-appreciated. Hydrogen Risk Chain (HRC) appears not to receive the same attention. HVC goes hand in hand with HRC. Leakage, fire and explosion risks are present in all segments of HVC.

b. Policy and legal considerations for EU

We determined some preliminary precautionary policy action in light of the results of the study. They include,

- In terms of standards for gas quality, one solution is PP in its strong version: Do not store or transport hydrogen in its most dangerous gaseous form because the risk is not in the energy conversion of hydrogen by combustion or by fuel cells but in its storage and transport. Standards may then concern:

  1- In situ on demand generation (regulation: zero or minimal storage)
  2- Transport of hydrogen in a different form than gaseous: liquid, ammoniac, adsorbed in solids... (regulation: impose the different transport modes depending on distance, milieu, etc.)

- Incentivizing uses and users with already existing know-how to develop preventive measures
- Standardization for gas quality, but nuanced policies for different uses, users, countries, and regions
- Avoiding EU-level regulatory patchworking
- Accelerating ongoing EU safety assessment processes
- Developing regulatory sandboxes with varying precautionary levels
- Lower precautionary levels for industrial uses and dedicated pipelines
- Higher precautionary levels for general public end-users

c. Innovation Principle & Precautionary Principle as non-competing elements

Precautionary principle gives us room to genuinely shape and design our energy futures. It enables clean energy opportunities, provides “legitimacy” -so as to create an agency framework that is accepted to serve the common good. PP means policy that takes regulation back into real action. Regulation not in a strict sense, but a comprehensive one, one that uses hard and soft and mixed tools, directed at management of transitions via sound policy options, involving public participation in policy processes. We argue that innovation principle and PP are complementary, non-competing elements and the right implementation of PP can foster sustainable innovations. They can and should co-exist, to find innovative, safe and sustainable solutions to key societal challenges [7].

CONCLUSIONS

Considering the hydrogen risk chain, we introduced the concepts of precautionary theory developed to design the main ingredients of environmental laws. We also offered some preliminary considerations for the application of the precautionary principle to the safe development of hydrogen technologies. This study evokes significant research topics such as developing a general precautionary framework applicable to emerging technologies, ex-ante and ex-post impact analysis of precautionary applications, searching for various ways to implement PP in environmental cases, bibliometric studies on precaution, safety and energy transitions.

HYDROGEN ROADMAP ASSESMENT FOR COLOMBIA UNDER AN INTERNATIONALLY COMPARATIVE FRAMEWORK

[1]Paula Riveros-Melo, [1]John Sanchez C., [1]Martha Cobo-Angel,[1*]Cesar Barraza-Botet
[1]Universidad de La Sabana, School of Engineering, Energy, Materials and Environment Laboratory, Km. 7 Autopista Norte de Bogotá, Chía, Cundinamarca, Colombia

ABSTRACT

Hydrogen roadmaps and national strategies have been used to evaluate scenarios and define pathways to include hydrogen as an energy vector in different countries. Aiming to become one of the early adopters of hydrogen in Latin America, Colombia has recently issued its hydrogen roadmap that sets goals for the near and long term. The aim of this study is to develop an assessment matrix to evaluate the hydrogen roadmaps of several countries and to propose a framework to compare them with Colombia's. To design the matrix, the key elements proposed by the International Energy Agency (IEA) were considered to evaluate the selected roadmaps. As an initial result, the analysis showed that the Colombian hydrogen roadmap contains several of the main aspects that a roadmap well-established should have. However, it should be improved by including more detailed information related to the use of the natural resources, setting milestones for the proposed goals, and designing policies aligned to the country's commitments to the Paris Agreement. As a result, the authors recommend the roadmap to be complemented by an actionable National Hydrogen Strategy containing the aspects identified in this work.

Keywords: Roadmap; Hydrogen, Policy, Comparative Assessment, National Strategy.

INTRODUCTION

Roadmaps are policy instruments used to establish actions and priorities to achieve expected outcomes and goals [1]. Such instrument is widely used to create momentum for the adoption of new technologies, and currently used to outline long-term transition pathways to net zero carbon emissions. Countries such as Australia, Republic of Korea, Japan, Russia and Colombia had recently published their hydrogen roadmaps to identify prospective technologies needed for the large-scale deployment of hydrogen as a novel clean energy vector [2].

In this study, we developed an assessment matrix to evaluate multiple key aspects that a comprehensive roadmap should have, based on the guide proposed by the IEA [1]. To our knowledge, there is not a comprehensive comparative analysis of multiple country's hydrogen roadmaps in the literature. Hence, as a first approach, this abstract presents the assessment matrix applied to the Colombian Hydrogen Roadmap [3]. By applying the same comparative methodology to the hydrogen roadmaps of the countries mentioned above, we will draw conclusion on how to improve Colombia's policies for hydrogen.

MATERIALS AND METHODS

To analyze national hydrogen roadmaps, we proposed a comparative methodology to assess technical, policy, legal, market, financial, environmental, and institutional aspects of the transition toward the hydrogen economy. The selected aspects were based on the guide for the development and implementation of roadmaps proposed by the IEA [1]. The methodology was initially applied to Colombia's hydrogen roadmap [3] and the analysis is presented in **Error! Reference source not found.**.

RESULTS AND DISCUSSION

Error! Reference source not found. shows the analysis of the Colombian roadmap following the key items proposed by the IEA [1]. According to **Error! Reference source not found.**, the main opportunities to reach the goals of the Colombian roadmap require actionable pathways to (i) identify available energy sources; (ii) establish economic policy commitments in both public and private sector, as well as the specific way to use those resources; (ii) define milestones for each of the goals; (iv) carry out technology assessments based on the current state of the art and the prospective technologies; (v) define indicators for each goal and milestone; (vi) identify and engage stakeholders in sectors with high adoption potential of production and end-use technologies to reduce GHG emissions. The assessment also shows that the lack of meaningful stakeholder participatory activities during the development of the roadmap may have affected the inclusion of detailed information. Hence, it is necessary to define methodological approaches for a stakeholder participatory strategy as a mean to fill these information gaps.

Table 1. Criteria matrix to compare the main subjects in roadmaps following the IEA guidelines [1].

Criteria	Assessment
Are there quantitative goals, milestones, gaps, and barriers defined to establish concrete actions?	The document presents quantitative goals for the production and demand of green and blue hydrogen. From a sustainability perspective, investment, job creation, and emission mitigation goals are established as well. However, no milestones associated with the goals were proposed. Regarding progress indicators, only 5 out of 6 have associated goals; and only 5 out of 9 goals have associated indicators.
Are the technologies to be used throughout the value chain and their development indicators defined?	Multiple technologies are mentioned in the roadmap, but none of them are prioritized for R&D or investment support. There is no technical or detailed information on main and enabling technologies applicable to different sectors. After assessing IEA's criteria, [1] the following aspects remain unanswered: Technology development status • Technology performance (e.g., conversion efficiencies) • Technology costs • Environmental impact (air, water, and land impacts) • Technology potential (saturation levels/other limitations) • Links to other technology areas The answer to all these technology aspects may require the development of detailed technology assessment studies and research agendas.
Are there defined policies that affect the development and establishment of hydrogen in the country?	The roadmap proposes policies to promote the use of hydrogen in Colombia in the residential, industrial, tertiary, land, maritime and air transport sectors, among others. However, the document does not establish quantitative goals nor describes a clear methodology to fulfill the purpose of the policy with a chronological priority of implementation, which is fundamental in policy measures associated with the objective [1].
Is there a detailed legal framework and is it enough?	The roadmap contains and describes the current and pertinent legislation for the implementation and development of the hydrogen economy in the country. In addition, it mentions the modifications and creation of necessary new legislation.
Are the hydrogen end-use sectors and their share of participation defined?	• Supply: 31.6 kt H_2 by 2040, and 37kt H_2 by 2050. • Industry demand: 112.8 kt H_2 by 2030, 387.1 kt H_2 by 2040, and 629 kt H_2 by 2050. • Transport demand: 7.2 kt H_2 by 2030, and 1184 kt H_2 by 2050. • Number of vehicles: 1500-2000 LDV, and 1000-1500 HDV by 2050. • There is not an indicator associated to green hydrogen demand, but the roadmap proposes a goal of a consumption of 40% of low emission hydrogen (green and blue) in the industry by 2050.
Is the installed capacity for hydrogen production projected in the national energy matrix?	Although the document presents these quantitative goals, it does not show any specific details on the project's locations, the sources that will be used, nor technical details related to the install capacity, size of the plants or specific milestones that should be accomplished. Related with these criteria the roadmap stablishes the following goals: • Electrolysis installed capacity: 1 - 3 GW by 2030 • Production volume: 50 kt H_2 by 2030 • Number of hydrogens fueling stations: 50 a 100 by 2030
Are the natural resources available for the generation of hydrogen established?	In terms of energy generation, the document does not propose the sources that will be designated to produce either green or blue hydrogen. One of the main opportunities to improve the roadmap is to identify and assign the energy sources and their contribution to hydrogen production.
Are the economic resources that will be used for the development and establishment of hydrogen in the country established?	An investment goal of the private sector of 2.5 to 5.5 billion USD is proposed, but there is not any information related to the sectors that will fund those investments or how they will be used. On the other hand, the government does not commit any economic resources. Related with these criteria, the roadmap stablishes the following goals: • Investment goal: 2.5 to 5.5 billion USD, this goal does not have a specific indicator. • Jobs creation: 7000 to 15000, this goal does not have a specific indicator.
Are hydrogen production cost (LCOH) targets set?	• Levelized cost of hydrogen (LCOH) goal: 1.7 USD /kg H_2 by 2030, this goal does not have a specific indicator. • Green hydrogen: LCOH of 1.5 USD/kg H_2 by 2050. • Blue hydrogen: LCOH of 2.4 USD/kg H_2 by 2050. • Grey hydrogen (Natural gas): LCOH of 2.9 USD/kg H_2 by 2050. • Grey hydrogen (Coal): LCOH of 4.4 USD/kg H_2 by 2050.

Criteria	Assessment
Are CO2 emission reduction targets defined?	• Greenhouse gases emission reduction goal: 2.5 to 3 Mt CO_{2eq} by 2050, this goal does not have a specific indicator. The document does not provide the information on how the GHG reductions was calculated or how it will be achieved.
Is it a governance model stablish and are the responsibilities and the members described?	The roadmap establishes a clear governance model linking the public and private institutions that will be a part of a steering committee and describes each member's responsibilities.

Since a roadmap should be credible, adaptable, and desirable [4], it should be tailored to each country's reality. Colombia is a country with a clean electricity mix—70% of the electricity is generated from hydropower [5]—as well as high potential for renewable energy, which represents a high potential source for low-carbon hydrogen production [3]. On the other hand, Colombian economy highly depends on fossil fuel—mainly coal and oil—since they represent over one third of exports [6]. Finally, recent mitigation commitments to the Paris Agreement in Colombia's NDC set a 51% GHG reduction goal by 2030 [7]. In the opinion of the authors, it is not clear how these key factors are accounted for in the hydrogen roadmap.

Even though a roadmap is a valuable instrument, is not enough to define the transition pathway to a low-carbon hydrogen economy. The roadmap is essential to set the aspirational goals, but it is also required to define the policies to achieve them [8]. For Colombia, a National Hydrogen Strategy should provide the set of policies aligned with the country's reality and environmental commitments to be implemented in the near, medium, and long terms.

CONCLUSIONS

A roadmap should be adaptable, and it would be susceptible to updates and improvements. The Colombian roadmap is an important framework to start with because it considers key elements proposed by the International Energy Agency. However, it is susceptible of improvements in the several aspects—i.e., technology assessments, milestones, and policies, which could be strengthen by the participation of relevant stakeholders. In this regard, the development of an actionable National Hydrogen Strategy that includes the missing aspects should define the pathways for the country to reap the benefits of deploying the hydrogen economy.

CREATING A GLOBAL HYDROGEN ECONOMY: REVIEW OF INTERNATIONAL STRATEGIES, TARGETS, AND POLICIES WITH A FOCUS ON JAPAN, GERMANY, SOUTH KOREA AND CALIFORNIA

[1*] *Vishnu Vijayakumar, Lewis Fulton, Mahdi Shams, Daniel Sperling*
[1] Institute of Transportation Studies, University of California, Davis, California, US

*Corresponding author e-mail: vvijayakumar@ucdavis.edu

ABSTRACT

Motivated by increasing emphasis on decarbonization, hydrogen is enjoying unprecedented political and business momentum. This paper reviews the status of hydrogen strategies and progress in major global economies investing in hydrogen, and then focus on four jurisdictions (Japan, Germany, S. Korea and California) that have been among the most aggressive, though in different ways. Japan, Germany and S. Korea are more focused on developing a sustainable hydrogen supply chain. In contrast, California has been more focused on spurring hydrogen demand, especially in the transportation sector. Japan's strategy involves forging partnerships to import "blue" hydrogen while Germany has focused on "green" hydrogen production, along with plans to leverage its extensive natural gas pipelines for hydrogen distribution. Japan anticipates the power sector to be the largest consumer of hydrogen, while others expect the transportation and industry sectors to be the prime movers of future hydrogen demand. Japan, S. Korea and Germany will likely import a substantial portion of their future hydrogen supplies, while California has the potential for low-cost hydrogen production but establishing the distributional infrastructure continues to be a challenge. In all four jurisdictions, investments are still small and there exists huge opportunities for cooperation to develop a self-sustaining global hydrogen market.

Keywords: GHG Emissions, Sector Coupling, Blue and Green Hydrogen, Hydrogen Economy

INTRODUCTION

A concerted and coordinated effort to keep global warming well below 2°C, has become an urgent need. Achieving this target would mean an 85% reduction in global greenhouse gas (GHG) emissions by 2050 [1][2]. Decarbonization would be required across sectors such as transportation, buildings, and industry. Hydrogen is a potentially important option for decarbonization plans given its versatility to be used across different sectors. Hydrogen's versatility suggests that significant increases in hydrogen use, with accompanying economies of scale and cost reductions, will aid countries in achieving their carbon targets and eventually building a carbon-neutral energy system. But building up this hydrogen system is challenging and infrastructure intensive. Strong early investments, with a clear vision of where the hydrogen system buildout is going, are needed. While many countries have latched onto this opportunity to incorporate hydrogen in their long-term energy and transportation plan, they are not all approaching this in the same manner, and no country so far has put all the pieces together.

We begin the paper by reviewing policy activities, targets, and strategies in 8 of the world's most active economies, then focus on the "big four": Japan, Germany, South Korea and California. These four are among the world's largest economies, with a combined gross domestic product (GDP) greater than $15 trillion[3][4]. The sheer magnitude of these economies will be an enabling factor to undertake large scale capital investments necessary for the initial commercialization and adoption of hydrogen into the energy portfolio. Notwithstanding differing emphases and patterns, these four economies share common policy drivers for hydrogen development and deployment: achieving strong climate mitigation goals, energy supply diversification, energy storage for renewables-based grid, and attaining technology leadership. Differences in their policy emphases has led to varying levels of hydrogen adoption across these economies, in different sectors, with different levels of progress. The present study analyzes the policy framework of these four jurisdictions, considering the following aspects.

1. Carbon mitigation targets and the role of hydrogen envisaged by each jurisdiction.
2. Hydrogen in transportation: fuel-cell vehicles and hydrogen refueling infrastructure.
3. Differing policy emphasis on blue and green hydrogen along with supply chain development plans
4. Hydrogen demand projections and underlying policy drivers.

The study looks to draw policy parallels and contrasts, analyze the potential impacts, and provide plausible recommendations for the four jurisdictions to better align their decarbonization strategies using hydrogen. Since the

policies around hydrogen are still evolving, this work will keep pace with the latest announcements and suitable modifications in the analysis framework will be incorporated as and when necessary.

MATERIALS AND ANALYSIS

Worldwide, many countries are aggressively pursuing hydrogen policies and system developments. We start with a review of recent policy status and activities globally as of 2021. We then drill down to the four jurisdictions of interest. This study will draw from existing literature, announced policy targets and apply our own projections/extrapolations to draw plausible comparisons of these four jurisdictions. The ensuing analysis will try and compare carbon mitigation trends/targets extending until 2030(shown below), fuel cell vehicle and infrastructure deployment trends, hydrogen supply chain cost projections (production, distribution), hydrogen demand projections (sector wise) with detailed discussions of the possible impact of policies in each of the above.

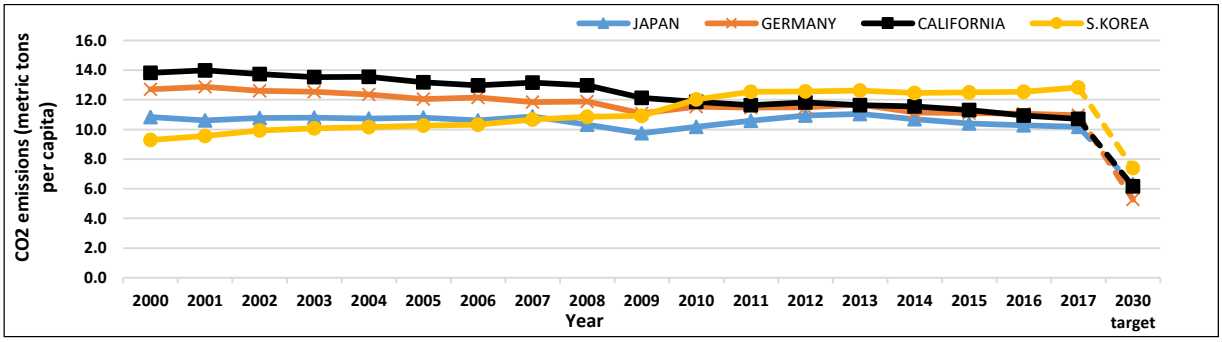

Figure 1 Per-capita GHG emissions from 2000 to 2017 and targets derived until 2030[5][6][7][8]

A big picture overview of the major policy/strategy developments of the four jurisdictions of interest are

Japan

Japan became one of the first countries to roll out a comprehensive hydrogen strategy in 2017, and it has since set out specific plans to become a “hydrogen society.” The strategy notably seeks to achieve cost parity with competing fuels, such as liquefied natural gas for power generation. In March 2019, the government released its third Strategic Roadmap for Hydrogen and Fuel Cells. Japan considers its domestic uptake of hydrogen as a viable way to increase its energy self-sufficiency; decarbonize its economy; increase industrial competitiveness; and position Japan as a fuel cell technology exporter. Japan is enroute to establishing a global supply chain for importing low-cost hydrogen mostly produced using fossil fuels and utilizing carbon, capture and storage (CCS) technology which is currently more economically competitive than renewable hydrogen. Japan is interested in importing green hydrogen if the price is competitive, and at least one Japanese company has signed an investment deal for green hydrogen projects in New Zealand[9].

Germany

In June 2020, Germany rolled out a national hydrogen strategy that eyes a 200-fold increase in electrolyzer capacity—of up to 5 GW by 2030. An additional 5 GW of capacity may be added by 2035 and no later than 2040. According to the IEA Future of Hydrogen report, as of 2030 German hydrogen demand is expected to increase significantly; about 340 TWh between 2015 and 2030, with industry (+164 TWh) and mobility (+70 TWh) being the main growth contributors. Germany has been focusing on establishing a strong supply chain, backed by import agreements as well as by bumping up the production capacity of green hydrogen domestically. The technology development for hydrogen systems have been historically funded and supported by the National Organization for Hydrogen and Fuel-cell Technology (NOW).

South Korea

In January 2019, Korea announced its Hydrogen Economy Roadmap. The roadmap outlines the goal of producing 6.2 million fuel-cell electric vehicles and rolling out at least 1,200 refueling stations by 2040. Additionally, the plan aims to roll out at least 35 hydrogen buses in 2019, ramping this number up to 2,000 by 2022 and 41,000 by 2040. Korea aims to become the world’s largest producer of hydrogen-powered vehicles and fuel cells by 2030, and to eventually also develop hydrogen ships, trains, and machinery. Of the total 6.2 million vehicles to be produced by 2040, 3.3 million would be exported. To achieve these targets, the government provides a subsidy of about 50% of the purchase price of a hydrogen passenger vehicle and subsidizes up to 50% of the installation cost of refueling stations. In 2018, demand for hydrogen was 130,000 tons and is estimated to increase to 470,000 tons by 2022, 1.94 million tons in 2030, and 5.26 Mt in 2040. Korea has a limited domestic capacity for eco-friendly hydrogen production, and it plans to establish overseas bases for hydrogen production. By 2040, South Korea aims to meet 70% of domestic demand through hydrogen from electrolysis and overseas production and 30% by reformed hydrogen.

California (US)

In June 2021, the US Department of Energy (DOE) launched the first “Hydrogen Energy Earth shot”, seeking to reduce the cost of producing green hydrogen by 80% to $1 per kilogram in one decade. This is the latest of the many initiatives taken by the US government to kick start the hydrogen economy. This is a combination of an R&D and deployment

initiative but without specific implementation policies. California has been leading the US efforts to deploy hydrogen with transportation-focused policies that have resulted in among the most fuel-cell vehicles in the world through 2020, only recently overtaken by S. Korea. California has over 90% of both the fuel-cell vehicles and hydrogen refueling stations in the country. Policies like the ZEV mandate, Low Carbon Fuel Standard (LCFS) and the recently announced Advanced clean truck rule have all encouraged uptake of hydrogen in the transport sector. However, the currently high retail costs of hydrogen (over $15/kg in many cases) have been a major impediment to the growth of fuel-cell vehicle sales.

RESULTS AND DISCUSSION

Figure 2 attempts to summarize the relative level of effort or success in different areas of the hydrogen market, and the emphasis and priority that each jurisdiction places on a range of strategies. The figure uses a simple low, medium, and high classification for each indicator listed, pertaining to the development of the hydrogen economy, based on current status and future targets. These ratings are not all encompassing and conclusive (owing to the dynamic nature of the hydrogen market) but provide some sense on progress and how the jurisdictions are similar and different from each other.

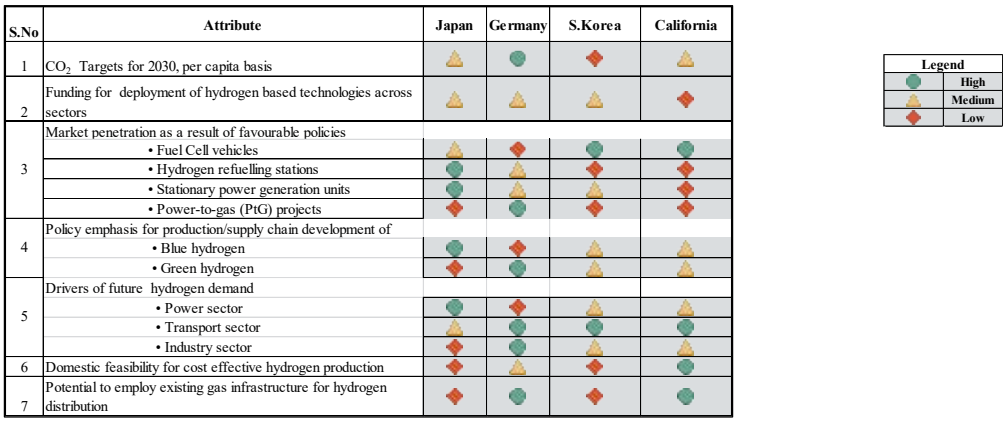

Figure 2 Summary of the relative areas of emphasis and progress for the four jurisdictions

CONCLUSIONS

Hydrogen is being increasingly promoted as a feasible decarbonizing tool by major economies. The current study investigated the policies and strategies of four prominent hydrogen economies: Japan, Germany, S. Korea and California.

- Japan's efforts have focused more on stationary demand side applications such as fuel-cell based off-grid power generation, whereas Germany has been the most proactive on developing hydrogen supply, mostly through the green hydrogen (electrolysis) route. California's hydrogen strategy has centered primarily around the demand side, specifically the transportation sector, by promoting fuel-cell vehicle sales. South Korea is bullish to become a global leader in the production and deployment of fuel cell electric vehicles and large-scale stationary fuel cells for power generation and has the third-largest public investment in hydrogen after Germany and Japan.
- Japan's major challenge will be to develop a self-reliant domestic hydrogen supply chain. Germany will need to incentivize a larger adoption of fuel-cell vehicles on road and look to diversify its low carbon hydrogen import basket. California should aim to increase the role of hydrogen in other sectors (apart from transportation), by incentivizing fuel-cell based power generation units, permitting blending of hydrogen into existing natural gas pipelines, and modifying the LCFS program to become more receptive towards hydrogen. South Korea has not yet focussed on the use of hydrogen in hard-to-decarbonize sectors (such as steelmaking and shipbuilding) which will be critical given its ambitious GHG reduction goals.

All four countries need to develop full hydrogen systems including supply, demand, and the infrastructure to move and store hydrogen in a cost-effective manner. This overall scaleup will be quite challenging, but the time to build it appears to have arrived.

ABSTRACT

Hydrogen is a versatile energy carrier and storage medium that may be employed in a variety of applications. It may be produced using different processes, each one generating a peculiar hydrogen identified by a color. In this work, process simulation is used to obtain material and energy balances for each process investigated, as well as for the evaluation of capital and maintenance costs. Process simulation outcomes are then used for to estimate three key performance indicators focusing on sustainability issues: the energy return of energy invested, the levelized cost of hydrogen and the life cycle assessment. We compared several hydrogen generation processes, each denoted by a unique color code: (i) green hydrogen, produced by electrolysis of water using electricity from renewable sources, (ii) yellow hydrogen, produced by electrolysis using grid electricity, (iii) grey hydrogen, produced from natural gas using steam reforming and (iv) blue hydrogen, like grey one, but with carbon capture and sequestration (CCS). From the results obtained it is possible to conclude that the most sustainable hydrogen production methods is the so-called green hydrogen, produced by water electrolysis.

Keywords: Hydrogen Production, EROEI, LCOH, LCA

INTRODUCTION

Human energy use has increased rapidly over the last few decades, putting growing strain on the energy industry. Per capita, primary energy use differs among countries and regions, and the global average has significantly increased from 2000 to 2019, of about 42%, passing from 122073 to 173340 TWh. Recent reports of IPCC [1] and EIA [2] indicates that a strong reduction in the usage of fossil fuels must be achieved in order to meet the 2030 greenhouse gases emission targets. Since energy production form renewable sources are not dispatchable due to their fluctuating nature, great attention is given to energy storage and energy carrier systems. Hydrogen is one of the most suitable energy carriers for several applications, mainly in heavy transportation and logistic.

Decisions in the energy sectors should be based on indicators able to summarise different aspects of the sector under study. There are several indicators available in the literature that are commonly employed by decision-makers. One of them is the Energy Return on Energy Invested (EROEI) [3], that relates the amount of net energy stored in the hydrogen produced to the total invested energy. It has recently been proposed as a benchmark tool by the international energy agency (IEA) in the guideline methodology for the net energy analysis [4].

Another key performance indicator, specific for hydrogen, is the Levelized Cost of Hydrogen (LCOH), which considers the cost of hydrogen production process and is calculated as the ratio between the net discounted costs over the amount of produced hydrogen [5]. Inputs to LCOH include cost of capital, investment costs and plant lifetime.

These two indicators focus on hydrogen productions in terms of energy consumption and economic analysis, however, they are insufficient for determining the overall environmental effect of the activities under consideration. We carried out a complete Life Cycle Assessment (LCA) study to achieve this goal.

This paper aims at providing reliable data for different hydrogen production processes in an early process design stage. In this paper we demonstrate how to use process simulation for the estimation of the performance indicators described above for hydrogen production processes. Specifically, we compare different methods of production of hydrogen each one defined by the appropriate color code: (i) green hydrogen, produced by electrolysis of water using electricity from renewable source, (ii) yellow hydrogen, produced by electrolysis using grid electricity, (iii) grey hydrogen, produced from natural gas using steam reforming, and (iv) blue hydrogen, like grey one, but with carbon capture and sequestration (CCS).

The paper considers as case study the production of hydrogen necessary for a medium size cruise ship to navigate for 8 hours full electric in the Adriatic Sea with an energy requirement of about 320 MWh. Considering an energy

content of hydrogen of 140 MJ/kg, and an efficiency of fuel cells of 60%, the quantity of hydrogen to be produced for a one-way trip is 13000 kg. The production of hydrogen will be set to consider 10 trips per day.

MATERIALS AND METHODS

Process simulation is used to perform material and energy balances, physical property estimations, design/rating calculations, process optimization, heat integration and economic analysis evaluation for a given hydrogen production process. The simulation starts with the definition of the problem and its objective. The process model consisting of process flow configuration and accompanying equations is then developed. Since in process simulators, constants and equations are already built-in to the system, it is only necessary to select the unit models, thermodynamic models and method of solution. Additional data is collected if data gaps were identified and required for the model: these may include stream data, equipment data/specification and operating data. The equations are solved and the results are then analyzed if further improvements can be made. The process is repeated until the whole process is finally optimized [6].

RESULTS AND DISCUSSION

The following processes have been simulated using Aspen plus™ 12.0: (i) water electrolysis (Figure 1), (ii) methane steam reforming (Figure 2 left) and carbon capture and storage (Figure 2 right).

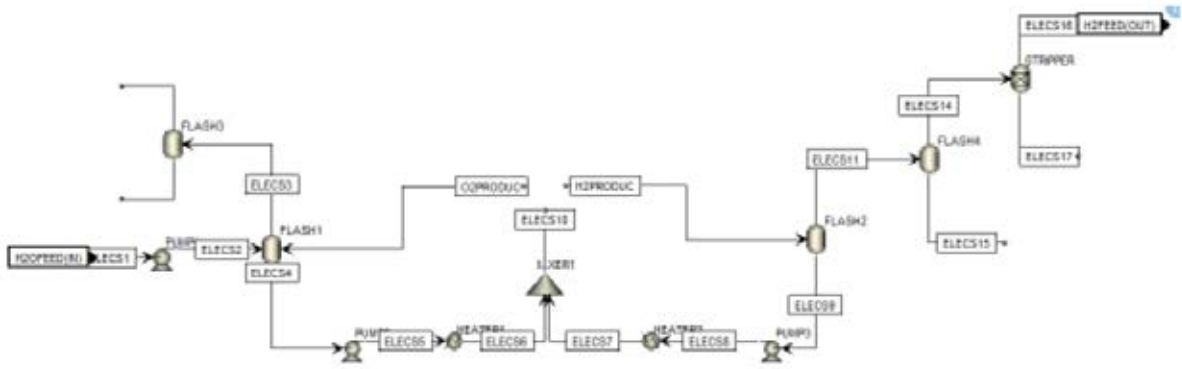

Figure 1. Water Electrolysis process flowsheet within Aspen Plus™..

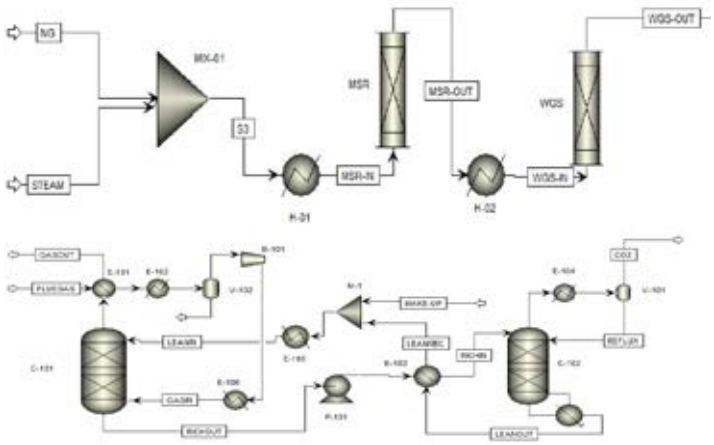

Figure 2. Methane steam reforming process flowsheet (left and MEA carbon capture process flowsheet (right) within Aspen Plus™..

Material and energy balance data coupled with cost estimation obtained by process simulation software are used to calculate the performance indicators: the detail of the data transferred from the process simulation are reported in Table 1.

The equation for the calculation of EROEI is:

$$EROEI = E_{out}/E_{in} \quad (1)$$

where E_{out} is the available energy that the process stores in the hydrogen (140 MJ/kg) and E_{in} is the total energy that is provided and consumed during the production and operations periods of the plant and is made up of three contributions: E_{cap} is the capital energy embodied in the materials and used for construction and decommissioning

of the plant; $E_{o\&m}$ is the energy needed for operating and maintaining the power plant; E_f is the energy needed for procuring and distributing the fuels, which includes also the energy used for extracting, refining and transporting the fuels from the production well to the power plant. All terms are expressed in GWh for consistency: the EROEI is thus dimensionless [7].

The LCOH is calculated as follows [7]:

$$LCOH = \frac{Total\ Costs - Electrical\ Revenue}{H_2 Annual\ production} \quad (2)$$

Table 1: Summary of data retrieved from process simulation for the estimation of EROEI, LCOH and LCA (cf = capacity factor).

		EROEI	LCOH	LCA
Installed capacity (P_{inst})	**kW_e**	x	x	x
Energy for auxiliary	**%**	x		x
Thermal energy	**%**	x		x
Net power output (P)	**kW_e**	x	x	x
Total plant cost (TPC)	**€**		x	
Share of investment costs due to operation and maintenance ($s_{o\&m}$)	**%**	x		
Fixed operation and maintenance costs (FO&MC)	**€/kW/year**		x	
Variable operation and maintenance costs (VO&MC), cf = 0.4	**€/kWh**		x	
Variable operation and maintenance costs (VO&MC) cf = 0.85	**€/kWh**		x	
Total amount of solvent	**kg**			x

The LCA procedure employs material and energy balances over the entire life cycle of the product system, taking into consideration the extraction of raw materials, manufacturing, use phase, end-of-life and the transportation between life cycle stages [8]. The results of life cycle assessments are depicted by means of several impact categories, which are able to represent the entire range of ecological burdens associated with the product system, avoiding shifting the impact among environmental compartments. The LCA procedure involves the implementation of four main phases: goal and scope; Life Cycle Inventory (LCI), Life Cycle Impact Assessment (LCIA) and interpretation.

CONCLUSIONS

Values of the key performance indicators, namely EROEI, LCOH and LCA, indicates that the best route for producing hydrogen in terms of global impact is the green hydrogen.

ABSTRACT

Local renewable hydrogen production is being promoted by European countries. In this sense, the deployment of renewable hydrogen requires evaluating whether countries or regions could achieve specific future hydrogen production and environmental targets. Within this context, this work proposes a linear optimisation model to find the most suitable production mix at the regional level in terms of costs, while respecting an exogenous environmental constraint. The model was applied to the case study of Spanish regions, analysing the potential contribution to meeting the Renewable Energy Directive II (RED II) target for the transport system in 2030. According to the results, production mixes would vary strongly depending on the region, and only one of the assessed regions would fail to meet the hydrogen demand from renewable sources. It was found that the overall national demand could be fulfilled using indigenous renewable sources, and renewable hydrogen hubs were identified with a regional scope.

Keywords: Environmental Impact, Levelised Cost, Linear Optimisation, Regional Assessment, Renewable Hydrogen

INTRODUCTION

Renewable hydrogen is foreseen as a key actor in decarbonising the economy across crucial sectors (in particular, energy, transport and industry). The EU Hydrogen Strategy structures the efforts that should be made to boost renewable hydrogen, setting a halfway target of 10 million tonnes of renewable hydrogen produced by 2030 [1]. This strategy emphasises the need for a decentralised hydrogen production mix to guarantee a good coupling with renewable energy systems and reduced transport distances. According to the expected economic and environmental benefits of this approach and the unequal distribution of renewable resources, territories will have to adopt different strategies in the near future. This new geopolitical scene can be observed in the hydrogen roadmaps of some European countries such as Germany and Spain, which start to contrast national hydrogen demands with potential indigenous resources for renewable hydrogen production [2].

Kakoulaki et al. [3] addressed the regional assessment of renewable hydrogen production for Europe considering the substitution of the current hydrogen demand. They identified potential hydrogen clusters and importers assuming that regional “grey hydrogen” is converted into “green hydrogen”. Other studies –focused on the quantification of renewable energy sources (RES)– estimate the potential hydrogen production from solar and wind energy by means of geographical information systems [4]. On the other hand, some studies place the focus on developing plans for hydrogen deployment [5]. These are generally based on linear programming optimisation models that minimise a cost-based objective function, considering an environmental constraint. Some of these works present models for regionalised hydrogen production networks [6,7]. However, none of them contrasts RES technical potential with current hydrogen roadmaps and projected hydrogen demands to answer questions on, e.g., the limits for renewable hydrogen production within a given territory and the hydrogen-related opportunities or gaps of a given region.

Within this context, this work aims to develop a model to estimate the potential of territories to generate renewable hydrogen. The objective of the study is twofold: (i) to establish regional production capacity of renewable hydrogen, and (ii) to quantify the required hydrogen and energy flows on a regional scale. The proposed methodology was applied to the case study of Spain, exploring the capacity of the Spanish regions to meet the RED II targets for the country as regards the final energy consumption of the transport sector.

MATERIALS AND METHODS

The methodology presented in this work requires three types of data: (i) RES technical potential at the regional level, (ii) techno-economic and environmental data of the hydrogen production technologies of interest, and (iii) hydrogen demand projections. The latter is implemented exogenously in the model, allowing the use of this methodology to evaluate different roadmaps and targets. Data regarding RES technical potentials were retrieved from ENergy Systems Potential Renewable Energy SOurces (ENSPRESO) [8] for solar, wind and biomass energy. This database presents normalised values for the period 2010-2050, defining the RES technical potential as the available technically-viable renewable resources regardless of whether they are already being exploited. The database has a maximum resolution

that corresponds to the Nomenclature of Territorial Units for Statistics no. 2 (NUTS 2), which was the one adopted in the proposed model. In addition to this dataset, the projected energy demand of other economic sectors (i.e., other than the one under study) can be included so as to quantify the available energy for hydrogen production. Furthermore, besides these RES (solar, wind, biomass), other renewable resources could be included (e.g., organic waste) if they are deemed relevant to the studied territory. For instance, domestic organic waste was considered in the case study shown in this work.

Techno-economic data on hydrogen technologies may be obtained from different sources (e.g., literature, industry) regarding parameters such as capital expenditure (CAPEX), operation and maintenance costs (OPEX), energy and feedstock consumption, and working hours. Since the model employs the levelised cost of hydrogen (LCOH) as the economic variable, LCOH values could also be directly fed to the model. Besides, environmental life-cycle impacts were included to evaluate specific targets (e.g., hydrogen carbon footprint reduction). In this regard, the calculation and implementation of harmonised life-cycle environmental indicators is recommended since they prevent inconsistent methodological choices in comparative studies. In particular, the proposed model employs the harmonised carbon footprints of hydrogen options calculated through the web-based software GreenH$_2$armony® [9]. Techno-economic and environmental values were then evolved and recalculated to 2030, respectively.

For each NUTS 2 region, the proposed model minimises the annual LCOH, which involves a set of n renewable hydrogen production technologies (k) with specific shares (x_k). The minimum cost is found while respecting some environmental constraints or targets as expressed in Eq. (1) and Eq. (2). In this case, the environmental constraint refers to a minimum relative carbon footprint reduction of 60% with respect to the global warming impact of conventional steam methane reforming in 2020 (GW_{SMR}). This reduction target was set to guarantee that the produced hydrogen is renewable according to the definition given by CertifHy [10]. It should be noted that the hydrogen demand (D) for each year (t) refers to the marginal value, meaning that only the annual increased demand is to be additionally produced. The model includes an iterative parameter γ that represents the fraction of the demand which can be fulfilled by indigenous resources. A γ value below 1 means that the region under assessment is not able to meet the corresponding hydrogen demand under the technical and environmental constraints implemented in the model. Further constraints were included in the model to contrast resource availability (R) from each RES (i) and regional hydrogen demand at each year as expressed in Eq. (3). Besides, a maximum share of 75% was imposed per year to production technologies based on the same renewable resource as expressed in Eq. (4), where x_j is the share of each technology based on the RES i and r stands for the total amount of technologies employing the RES i.

$$f(x)_t = (D \cdot \gamma \cdot \sum_{k=1}^{n} LCOH_k \cdot x_k)_t \quad (1)$$

$$\sum_{k=1}^{n} (GW_k \cdot x_k)_t \leq 0.6 \cdot GW_{SMR} \quad (2)$$

$$(D_i \cdot \gamma)_t \leq R_{i,t} \quad (3)$$

$$\sum_{j=1}^{r} x_{j,i,t} \leq 0.75 \quad (4)$$

The case study proposed was built upon current data for the final energy consumption of the transport sector in Spain [11]. Road transportation accounted for 77% of this final energy consumption, so the renewability target of the subsector was set to 10.7% of the final energy consumption of the transport sector. This assumption implies that other transport subsectors would also contribute to achieving the 14% sectoral target set by the RED II [12]. The hydrogen demand was regionalised considering that the necessary fossil-fuelled vehicles, both light-duty vehicles (LDV) and heavy-duty vehicles (HDV), are converted into hydrogen-fuelled vehicles. To this end, the 2019 distribution of fossil-fuelled vehicles by region was considered [13].

RESULTS AND DISCUSSION

The results include the regional hydrogen production mix evolution in Spain until 2030, identifying the export capacity or import needs of each region. The export capacity of each region was expressed relative to its accumulated hydrogen demand by 2030 (negative values meaning import needs). For reporting purposes, this score was then normalised to the highest value, resulting in the final indicator shown in Fig. 1. This indicator gives a clear picture of the capacity of a given region to satisfy its potential future hydrogen demand, as well as of the overall capacity of the analysed territories to fulfil the hydrogen demand by trade among regions.

For the case study of Spain (without Canary Islands, Ceuta, and Melilla), it was found that all of the regions under study, except for the Basque Country, could satisfy the projected regional hydrogen demand until 2030, while respecting the technical and environmental constraints implemented in the model. The unmet demand for hydrogen in the Basque Country could be fully satisfied by hydrogen produced in neighbouring regions. Finally, it should be noted that this picture would change if other hydrogen demand scenarios were fed to the model.

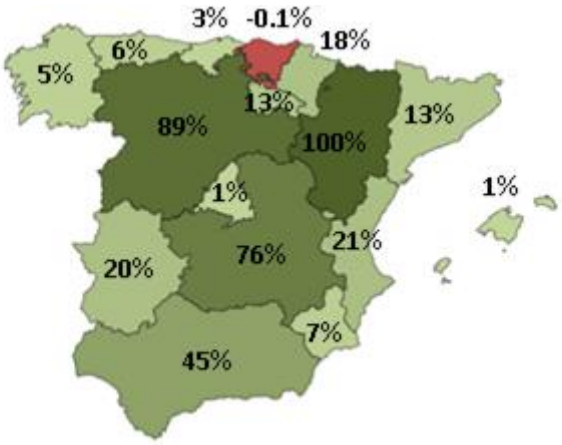

Fig.1. Resultant renewable hydrogen export capacity of Spanish regions (normalised to the highest score)

CONCLUSIONS

The proposed model serves to explore renewable hydrogen production capacity on a regional level, identifying potential hydrogen hubs and evaluating the feasibility of achieving hydrogen targets in terms of demand, cost, and environmental targets. According to the results, Spain would be able to achieve RED II targets by introducing renewable hydrogen in the road transport system. A significant export capacity was found for all of the regions under study except for the Basque Country, whose hydrogen demand could be fulfilled by neighbouring regions. The proposed approach could be implemented to explore other European countries and their potential relationships regarding renewable hydrogen trade.

ABSTRACT

Latin America is starting its transition towards sustainable energy alternatives. In particular, given its abundant natural resources and fossil fuel reserves, hydrogen (H_2) could play a leading role in Colombia. This contribution presents an analysis of the potential of blue H_2 in Colombia, considering it a possible promoter for the H_2 economy. The study focuses on the natural resources available to produce blue H_2 in the context of the recently launched H_2 Road Map and Energy Plan to 2050. Results indicate that the production of low-emission blue H_2 in Colombia, mainly from coal, besides allowing a more sustainable use of non-renewable resources would open the way to green H_2, and could supply up to 10% of global demand of blue H_2 by 2050. However, implementation of a clear public policy and a more detailed roadmap for the inclusion of blue H_2 in the energy matrix is required for the establishment of a H_2 economy in the country.

Keywords: Carbon Footprint, Blue Hydrogen, Coal, Gasification, Natural Gas.

INTRODUCTION

Energy demand keeps increasing due to economic growth, increasing population, and higher life-standards. Ensuring access to affordable, reliable, sustainable, and modern energy for all is indeed one of the 17 UN's sustainable development goals. However, the energy sector is an immense contributor to Greenhouse Gas (GHG) emissions, and the recent Intergovernmental Panel on Climate Change (IPCC) report has highlighted the urge for decarbonisation. For this, Latin American countries such as Chile, Uruguay, Brazil and Colombia are developing strategies to promote energy transition in the region.

While most of the attention has turned to solar and wind energy, the need to store electricity and integrate the locally available energy resources are smoothing the way for H_2 as an energy vector in Latin America. H_2 is a sought-after energy carrier because of its zero direct GHG emissions. Since pure H_2 is not found in nature, though, energy is required for its production, which usually results in indirect GHG emissions. Thus, the quest for clean energy has led to low-emission H_2 (< 5 gCO_2-eq/gH_2), either via water electrolysis using renewable energy sources (solar, wind, hydraulic and biomass), known as green H_2, or via fossil fuels (natural gas, coal, and oil) with carbon capture, utilization and/or storage (CCUS), known as blue H_2.

Currently, up to 98% H_2 produced worldwide comes from natural gas, oil, and coal, without CCUS (i.e., gray H_2) [1]. In this context, less than 2% of Latin American renewable energy projects involve green H_2 production, and at least a decade might be needed to see large-scale green H_2 production in the region. However, recent environmental policies and regulations call for low-emission H_2. This scenario has led to propose blue H_2 as a transitory solution to supply the low-emission H_2 demand in the region considering that the large fossil fuel industry infrastructure could favor the implementation of necessary CCUS technologies, while continuing to take advantage of the local natural resources, and reducing the impact of energy transition on employment in some countries. This could apply to Colombia, which has significant reserves of non-renewable resources and a strong economic dependence on the oil and coal industries.

This work presents an analysis of the potential for blue H_2 production in Colombia, examining mainly technical aspects.

METHODOLOGY

Calculations for potential blue H_2 production were based on fossil fuel reserves and annual production reported by Colombian official agencies [2]–[4]. The amount of coal available for H_2 production was calculated from the projected decrease in worldwide demand under conservative (Stated Policies), medium (Alleged Pledges), and optimistic (Net Zero Emissions) scenarios [5]. Given that most Colombian coal is exported, the underlying assumption was that coal not marketed due to the aforementioned decrease could be used in Colombia for H_2 production. A factor of 0.156 kg_{H2}/kg_{coal} was used, which includes gasification, water-gas shift, CO_2 absorption, and

pressure swing adsorption steps [6]. Demand and market projections were obtained from technical reports and international energy outlooks, Colombia's Energy Plan 2020-2050, and Colombia's National H_2 Road Map [5], [7], [8].

RESULTS AND DISCUSSION

Oil, natural gas, and coal industries represent about 35% of Colombian exports, generating more than 70,000 direct jobs. These non-renewable resources can be used to produce blue H_2 and energy through well-known processes. Figure 1 shows a general scheme of the conventional use of these resources and the potential technologies to produce H_2 instead. The standardized technologies for H_2 production differ only on the syngas production stage, and then follow a single path to H_2, while the emerging membrane reforming couples production and purification steps. Colombian fossil fuel reserves are included in the figure as a starting point for the potential transformations. Law 2099 of 2021 grants fiscal benefits for the production of green and blue H_2, aiming at a low-emission H_2 production of up to 120 kt/year by 2050 and making H_2 production pathways attractive for the fossil fuel industry [8]. In the following sections, the potential of each non-renewable resource available in Colombia to produce blue H_2 is reviewed.

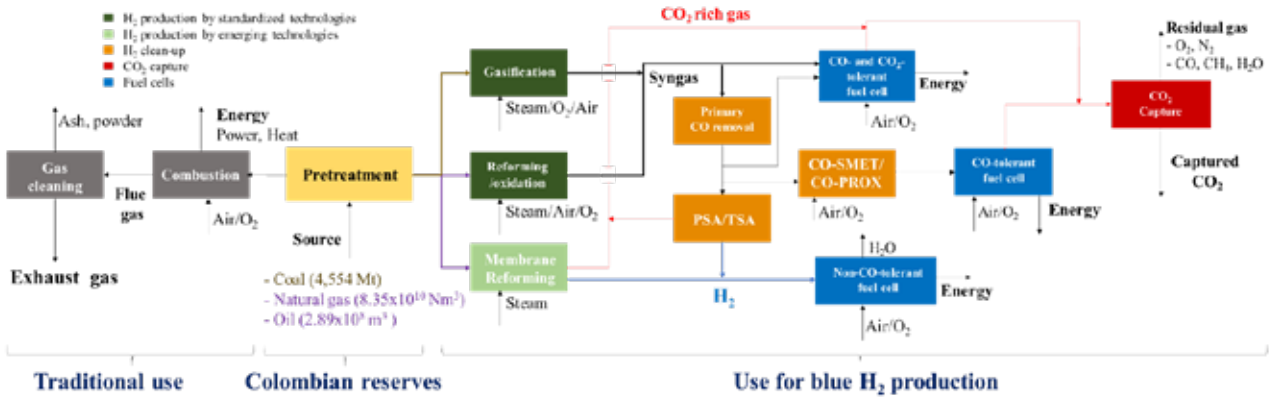

Figure 1. Conventional use (left) and H_2 production pathways (right) from fossil fuels. Simplified process diagram.

Blue H_2 from natural gas

H_2 from natural gas can be produced through the well-established Steam Methane Reforming (SMR), Autothermal Reforming (ATR) and Partial Oxidation (POX) processes, or the emerging Membrane Reforming (MR) process, as seen in Figure 1. SMR, ATR and POX all produce syngas (CO + H_2), which then passes through the H_2 clean-up stages shown in Figure 1, while MR directly produces high-purity H_2. H_2 in Colombia is produced through SMR without CCUS, solely for refinery consumption [8]. Nonetheless, the national H_2 strategy calls for 50 kt/year blue H_2 by 2030, either by replacement or retrofitting of current grey H_2 processes, and expects blue H_2 to be more competitive than grey H_2 by 2035 [8]. However, proven natural gas reserves in Colombia shown in Figure 1 translate into 7.7 years of self-sufficiency at the current annual consumption (1.09 x 10^{10} Nm^3) [4]. Thence, large-scale blue H_2 production from natural gas in Colombia would be a temporary option, unless reserves increase in the near future or gas imports are considered for H_2 production. Furthermore, H_2 from natural gas (e.g., for heating, Figure 1) may not be competitive with the direct use of natural gas.

H_2 from coal

H_2 from coal is produced through gasification processes, which produce syngas that then follows the H_2 clean-up pathway, Figure 1. Colombia is currently the lead coal producer in Latin America, and the third coke producer and fourth thermal coal producer worldwide [3]. Considering its proven coal reserves (Figure 1) and an annual production rate of 84.5 Mt [2], the country has coal for 54 years, whereas considering its estimated reserves (16,569 Mt in 2019) increases coal availability to 194 years, making it attractive as a H_2 feedstock. Most of this coal is exported, thus becoming the main mining export and a major contributor to the country's economy [2]. However, global warming and environmental agreements demand urgent decarbonisation of energy systems and production processes, envisioning a decrease in global coal consumption that could significantly affect the economy if sustainable alternatives are not considered. Table 1 shows Colombia's H_2 production potential if the coal not marketed internationally due to the projected decrease in worldwide consumption were to be used as feedstock. Results show that this production, even under conservative scenarios, could cover and exceed the projected internal demand as stated in Colombia's National H_2 Road Map [8]. With such surplus, Colombia could supply up to 10% of the global demand of blue H_2 by 2050 under an optimistic scenario. Thus, blue H_2 production from coal

could be a possibility for the mining sector to use such important reserves in a more sustainable way, while continuing to support the country's economy.

Table 1. Potential of H_2 production from coal not marketed due to expected decrease in worldwide consumption

Annual production Colombia (kt/year)	Decrease in world demand to 2050 (%)	Scenario	Available amount in 2050 (kt)	Potential H_2 (kt/year)	Ratio to projected demand Col. 2050
84500	25	STEPS [5]	21,125	3,296	1.78
	50	APS [5]	42,250	6,591	3.56
	90	NZE [5]	76,050	11,864	6.41

STEPS: Stated Policies Scenario; APS: Alleged Pledges Scenario; NZE: Net Zero Emissions.

H_2 from other fossil fuels

H_2 can be produced through reforming processes of light hydrocarbons or through partial oxidation of heavy hydrocarbons, Figure 1, but the use of fossil fuels different from coal and natural gas for H_2 production is yet only of interest in places with low availability of these resources or for the utilization of refinery residues. Still, the decarbonisation goals require a decline in the use of liquid fossil fuels that could set the conditions for their becoming H_2 feedstock and continuing to provide energy in a more sustainable way. However, Colombia's oil reserves (Fig. 1) yield 6.3 years of self-sufficiency at the current production rates (1.26×10^5 m^3/day) [4]. This short-term availability renders oil and its derivatives an unfeasible source for H_2 production unless, as in the case of natural gas, reserves increase in the near future and this matches a major decrease in fossil fuels direct use.

CONCLUSIONS

Energy transition to achieve decarbonisation has put H_2 in the spotlight as low-emissions energy carrier. Colombia, a growing economy with great dependence on fossil fuels, needs to find alternatives to use its resources in a sustainable way, and thus blue H_2 appears as an option to move towards a decarbonized economy. While blue H_2 production from oil is yet unfeasible, and from natural gas seems to be a temporary option and limited to the refinery sector, the abundance of coal makes it an attractive resource for H_2 production. Results of this work indicate that H_2 produced from not-marketed coal could cover and exceed the projected national demand, namely, the surplus could be exported and thus replace coal's current role to some extent. Introduction of blue H_2 to the energy matrix could promote H_2 use in the short to medium term and open the road to extended green H_2 uses.

COLOMBIA'S GREEN HYDROGEN: SOLAR AND WIND POWER CAPACITY SCENARIOS

*David Rodríguez-Fontalvo, Nelly M. Cantillo, Néstor Sánchez, Martha Cobo**

ABSTRACT

Producing green hydrogen (H_2) with solar and wind energy as main sources is one of the main objectives in Colombia's national strategy for decarbonizing the national energy mix. This contribution studies the role of solar and wind H_2 projects in the Colombian energy mix to meet the H_2 demand for 2030, 2040 and 2050 established on the national H_2 strategy for different scenarios. For creating each scenario, different parameters such as installed capacity of each technology, the resource-to-H_2 efficiency and distribution of the electricity produced to generate H_2 (D_{H2}) were varied. Particularly in Scenario 3, which assumed a D_{H2} of 16.7 %, the solar and wind capacities will need to be 204,749 MW and 88,970 MW, respectively. This scenario was identified as a route to achieve the yearly goal proposed in Colombia's national strategy. This work exposes the implications that H_2 demand exerts on electricity supply and project installations from renewable sources, and is an approach to the green H_2 requirements within the Colombian context. Furthermore, this analysis can guide the required strategies and incentives to successfully integrate green H_2.

Keywords: Green Hydrogen, Installed Capacity, Onshore Wind Parks, Offshore Wind Parks, Photovoltaics.

INTRODUCTION

In 2020, Colombia's Government announced the goal for 2030 of cutting its greenhouse gas emissions to a maximum of 169.44 Mton CO_{eq} (which corresponds to a 51% reduction from a baseline projected scenario), as an updated strategy of the National Determined Contribution to meet Paris Agreements [1]. For doing so, the Ministry of Mines and Energy launched a national strategy. This strategy positions H_2 as the fuel for the transition in the energy mix that will allow to meet the emission goal [2]. This H_2 is specified to come from oil and coal industry including carbon capture technologies (blue H_2), and renewables energies such as hydric, solar, wind and biomass power (green H_2). Colombia's green H_2 demand is esteemed to be 1,850 ktn for 2050, and its main sources will be solar and wind driven electrolysis [2].

Nowadays, Colombia's solar and wind share in electricity production installed capacity is just of about 0.76 % and 0.10 % [3], respectively, and its green H_2 production rate is non-existent. In the years to come, it is expected to observe a growth in the installed capacity of each by electrolysis, and its efficiencies oscillate between 51-58 kWh/kg H_2. Yet, after electricity is produced, it cannot be assumed that it will all be employed to produce H_2. A parameter for its distribution to H_2 was established in this work, so it serves as a start-up to create policies that regulate the use of green energy to produce H_2. This work assesses different scenarios of solar and wind H_2 insertion to the Colombian energy mix by means of the year-to-year demand compliance according to the goals established on the national H_2 strategy.

METHODOLOGY

To comply with the H_2 demand specified in Colombia's national kind of renewable technology, and so the possibility of producing H_2 from the generated electricity. As a fact, according to the Mining and Energy Planning Unit (UPME) report of electricity generation projects, 220 of solar and 26 wind projects have been submitted to study and start operations between 2021 and 2026, with a total 11,210 MW and 4,871 MW installed capacity, for each technology [4]. Moreover, the few installed projects in Colombia report a capacity factor of 15% for utility photovoltaics [5] and 39% for the only wind park of the country [6]. Therefore, four different scenarios of solar and wind technologies insertion were assessed. For every scenario, UPME database was used to establish the potential installed capacity of both solar and wind technologies for the 2021-2026 period. After this period, each scenario comprehends a different calculation procedure. In each scenario, data from Table 1 was used for demand compliance reference and energy conversion efficiency. Eq. (1) was used to calculate H_2 production to meet demand.

Table 1. H_2 demand and supply prospective according to Colombia's national strategy

Year	H_2 demand (kton/yr)	CF_{Solar} (%)	CF_{Wind} (%)	PEMEC (MWh/ton_{H2})
2030	177	15	39	56.4
2040	790			53.2
2050	1,850			51.6

$$HpY = \frac{IC_R\,[MW] * h_{yr}\,[h] * CF\,[\%] * D_{H2}[\%]}{1000} \quad (1)$$

where HpY is the H_2 produced in a year, IC_R is the installed capacity by resource, h_{yr} the hours in a year, CF is the capacity factor to H_2 efficiency and D_{H2} the electricity distribution to produce H_2.

Scenario 1: Utility Photovoltaic and Onshore Wind parks.
For this scenario, an average growth of 1,868 MW and 812 MW of solar and wind energy projects were assumed to be installed year to year until 2050. This value corresponds to the average of year-to-year growth in installed capacity of the 2021-2026 period data from UPME database [4]. In this scenario, the response variable corresponds to D_{H2}, which, in addition, was constrained to be equal for every technology in the same year for each scenario.
Scenario 2: Urban and Utility Photovoltaics, and Onshore and Offshore Wind parks
For this scenario, installed capacity growth averages for utility scale photovoltaic farms and onshore wind farms projects remained the same as in Scenario 1. However, urban photovoltaics and offshore wind farms were included as other electricity sources. According to UPME, using 10 % of the urban roof surface of the 22 biggest cities from Colombia would represent an installed capacity of 1,886 MW [7]. Thus, it was considered a year-to-year growth in urban photovoltaics installed capacity of 65 MW for the 2022-2050 period. Alternatively, the share of offshore installations in the wind energy market was supposed to go from 6.5 % to 21 % [8] on the 2025-2030 period and maintained at 21 % from 2030 to 2050. For calculating the year-to-year growth in offshore installations, Eq. (2) was used. In this scenario the response variable was D_{H2}, which was set to be equal for every technology.

$$IC_{Offwind} = IC_{Onwind} * \frac{\%Share}{100\% - \%Share} \quad (2)$$

Scenario 3: Utility Photovoltaic and Onshore Wind parks with constant electricity distribution
This scenario consisted of fixing every year's D_{H2} to 16.7 %, which was the D_{H2}value obtained for 2030 in the first scenario. By doing so, the installed capacity year-to-year average growth became the response variable for this case, as every other variable was already defined. The ratio between utility photovoltaic and onshore wind (S:W) installed capacity was determined to be 2.3:1 in Scenario 1, therefore it was used as a parameter to maintain in this scenario, then Eq. (3) describes onshore wind installed capacity insertion as a function of solar installations:

$$IC_{Onwind} = \frac{IC_{UtilityPV}}{2.3} \quad (3)$$

Scenario 4: Urban and Utility Photovoltaics, and Onshore and Offshore Wind parks, with constant electricity distribution
This scenario consisted of fixing every year's D_{H2} to 15.6 %, which corresponds to the value obtained for D_{H2} for 2030 in the second scenario. Urban photovoltaics capacity was assumed to be the same as in Scenarios 2 and 3, the installed capacity year-to-year average growth became the response variable for this case. The 2.3 S:W ratio was maintained as parameter for Eq. (3).

RESULTS AND DISCUSSION

The summary of the data obtained for each scenario is presented in Table 2. Scenario 1 exhibits the lowest total installed capacity of all four scenarios. At 80,568 MW in 2050, the D_{H2} rises from 16.7 % in 2030 to 40.1 % in 2040 and 60.7 % in 2050. The values of installed capacity for utility PV and onshore wind parks rise to 56,170 MW and 24,399 MW each. Moreover, for solar power, the value for 2050 can be compared to Germany's 2020 PV installed capacity [9], and for wind power, the value can be contrasted to the 28,296 MW that Spain achieved in 2020 [8]. Less wind installations are needed to meet the same H_2 demand, due to onshore wind parks have higher capacity factors than PV farms.
On the other hand, the inclusion of urban photovoltaics and offshore wind parks in Scenario 2 increases the total installed capacity for 2050 to 87,471 MW, which relieves the D_{H2} to 53.5 % for the same year. Thus, Scenario 2 shows how diversification of an energy mix can lighten the burden of electricity demand for producing H_2. In this case, offshore wind parks installations reached 5,017 MW, comparable to Germany's 2020 offshore installed capacity of 7,728 MW [8], and urban photovoltaics did not represent a high participation in H_2 supply in any of the years, reason for which its implementation for H_2 production purposes may not be needed.
Alternatively, Scenario 3 presented a higher total installed capacity, reaching 293,719 MW, due to the constraint of maintaining the D_{H2} in 16.7 % through the years. In this case, utility PV and onshore wind parks reached 204,794 MW and 88,970 MW of installed capacity, respectively. The former value is comparable to China's 2020 PV installed capacity of 253,400 MW [10], while the latter can be compared to USA's 2020 total wind installations of 122,000 MW [8]. However, even if it seems plausible to achieve a goal that the biggest economies of the world achieved in 20 years, a technical assessment of Colombia's solar and wind energy potential must be done to assure this value can be attained in a country whose territorial surface is smaller than the countries previously mentioned.
Lastly, Scenario 4 presented a slight increase in total installed capacity compared to Scenario 3 (see Table 2) due to the addition of urban PV and offshore wind projects. The decrease in D_{H2} between Scenarios 4 and 3 does not

seem to be relevant for the efforts that must be done to install urban photovoltaics or offshore wind parks, at least at that level of insertion. Moreover, the feasibility of the level of insertion for offshore wind projects (20,433 MW in this case) could discard this scenario as 24,837 MW is the total installed capacity of offshore projects for the whole European Union [8].

Table 2. Annual installed capacities, H_2 supply share and electricity distribution by technology for each scenario.

Scenario	Year	Utility PV		Urban PV		Onshore Wind		Offshore Wind		Total		DH_2 (%)
		IC (MW)	H_2 supply (%)	IC (MW)	H_2 supply (%)	IC (MW)	H_2 supply (%)	IC (MW)	H_2 supply (%)	IC (MW)	H_2 supply (%)	
1	2030	18,803	47.0	0	0.0	8,159	53.0	0	0.0	26,962	100	16.7
	2040	37,486	47.0	0	0.0	16,279	53.0	0	0.0	53,765	100	40.1
	2050	56,170	47.0	0	0.0	24,399	53.0	0	0.0	80,568	100	60.7
2	2030	18,803	44.1	585	1.4	8,159	49.8	700	4.7	28,247	100	15.6
	2040	37,486	42.0	1,236	1.4	16,279	47.4	2,858	9.2	57,859	100	35.8
	2050	56,170	41.3	1,886	1.4	24,399	46.7	5,017	10.6	87,471	100	53.5
3	2030	18,803	47.0	0	0.0	8,159	53.0	0	0.0	26,962	100	16.7
	2040	90,153	47.0	0	0.0	39,167	53.0	0	0.0	129,320	100	16.7
	2050	204,749	47.0	0	0.0	88,970	53.0	0	0.0	293,719	100	16.7
4	2030	18,809	44.1	585	1.4	8,162	49.8	700	4.7	28,257	100	15.6
	2040	84,287	41.2	1,236	0.6	36,618	46.6	8,265	11.6	130,405	100	15.6
	2050	189,621	40.8	1,886	0.4	82,395	46.1	20,433	12.6	294,336	100	15.6

CONCLUSIONS

After evaluating the total installed capacity needed to meet the H_2 demand proposed in Colombia's national strategy, Scenario 3 can be analyzed as a route to achieve the yearly goal. In this case, the D_{H2} was set to 16.7 %, which implies that less than a fifth of the electricity produced by every renewable project would be used to produce H_2. Also installed capacity of solar and wind projects should reach 204,749 MW and 88,970 MW, respectively, to meet H_2 demand. This scenario seems to be feasible as countries like China and USA have already installed similar capacities of renewables into their energy mix. This study serves as a premise to know the effect that the diversification of the energy mix has on energy demand, the impact that H_2 demand has on the electrical generation from renewable sources, and in consequence, on the further investment and planning for total installed capacity of solar and wind projects that Colombia must embrace to ensure its energy mix transition.

ABSTRACT

Constant energy demand and environmental pollution have become a global concern. Central Asia Caspian countries are shifting their focus on alternative fuels, particularly hydrogen energy, while having significant fossil fuel resources. This study is a review of work and procedures done in Kazakhstan toward achieving a net zero emission future. Current studies and projects are summarized showing the condition of hydrogen production, storage and application. In this case, the organization of hydrogen supply chain and consumption, providing national funding, fruitful partnership, assessment of risks and outcomes should be taken into consideration, although it is the very first step of Kazakhstan to hydrogen energy.

Keywords: Hydrogen Energy, Central Asia Caspian Countries, Decarbonization Challenges

INTRODUCTION

Hydrogen is found as an attractive fuel not only for industrial applications but also for transportation and building sectors. The new promising energy carrier is expected to replace conventional fuel sources and provide cleaner energy supplied world. 17 governments have already released hydrogen strategies and policies, including Australia, Germany, Japan, and 20 more countries are developing new ones [1]. It is well known that Central Asia Caspian countries (CACs) have the energy structure, which is mainly based on fossil fuels. Kazakhstan has 58% of final energy consumption which is represented by 43 % of coal, 38% of gas and 18% of oil [2]. Consequently, it may cause challenges in the decarbonization pathway of the energy structure. The government of Kazakhstan has declared its goal to achieve a 15% reduction in GHG emissions in 2030. In order to achieve this extensive energy saving, the ratio is proposed to bring renewable energy in electricity generation to 6% by 2025, to 15% by 2030 and 50% by 2050 [3].

POTENTIAL OF HYDROGEN ENERGY IN KAZAKHSTAN

New Environmental Code is published, in line with international relations standards, from July 1, 2021. The Carbon neutrality Doctrine is being developed to achieve net zero carbon dioxide emission by 2060 strategies in the context of the Paris agreement and Agenda 2030 implementation. The realization of the carbon neutrality program is unattainable without innovative technologies such as carbon capture and storage (CCS) and hydrogen energy. Kazakhstan has potential of utilizing hydrogen as an energy carrier for spreading renewable energy and mitigating environmental problems as the hydrogen system can be considered as clean water source along with clean fuel source [4]. The proposed model consists of hydrogen generation by solar-powered electrolysis. However, political support is the most important factor in a sustainable hydrogen economy. A clear strategy with long-term policies, implementation of hydrogen energy standards and codes, providing hydrogen demand are key areas that should be considered to boost production, demand, and expand hydrogen energy deployment in the country.

Since 2021 Kazakhstan has started officially to talk about hydrogen. One of the largest projects which is about to be realized is a joint project of Kazakh Invest National Company JSC and the German-Swedish Svevind Energy. The full completion of the project is planned in 2026 generating electricity with a capacity of 2 million tons based on solar and wind energy (30 GW) [3]. The project will be implemented in the Mangystau region. Through development of green hydrogen production Kazakhstan may get its niche in the hydrogen market.

Secondly, the President of the Republic of Kazakhstan instructed the Ministry of Energy to interact with the Ministry of Ecology, Geology and Natural Resources, and JSC NC KazMunayGas to develop proposals for the development of hydrogen energy as part of the implementation of the Competence Center in new technologies. The company has launched a low carbon development program for the period of 2022-2031, which aims to envisage hydrogen energy as one of the additional measures for decarbonization of the company. JSC NC KazMunayGas, Atyrau Oil Refinery and Air Liquide Munai Tech Gases signed a Memorandum of understanding on the development of a mobile hydrogen refueling station in Atyrau city. It is also planned to purchase buses and cars running on hydrogen for the

transportation of plant employees [5]. JSC NC KazMunayGas has also signed a Memorandum of Understanding under the hydrogen project with Linde and ENI [6], [7].

Therefore, the company is in the stage of creating the Hydrogen Energy Competence Center at subsidiary company KMG Engineering LLP. The Hydrogen Energy Competence Center is a research hub which aims to develop environmentally friendly fuels, including hydrogen and chemical compounds from hydrogen. The development of the center will significantly expand the research and production potential of both the company and the country. It enables scientists and researchers to work together to implement projects for the production, storage, transportation and use of hydrogen and carbon capture and storage.

Several projects have an innovative role in the development of hydrogen energy in Kazakhstan. The hydrogen production projects cover different research areas. The project proposed by Nazarbayev University is aimed to synthesize titanium-carbide nanoplates of the Mxene type, which is being studied relatively recently around the world. Researchers from Kazakh National Research Technical University are studying the synthesis of energy-storage substances with the help of which it is possible to purify polluted water and at the same time obtain pure hydrogen as a fuel [8]. The topic of catalysts in the catalytic reforming of methane and synthesis gas has always remained relevant. In this regard, Institute of Fuel, Catalysis and Electrochemistry has proposed a technology for obtaining purified blue hydrogen on new inexpensive cluster catalysts without rare metals [9]. Projects on application of hydrogen are aimed at modeling low-temperature and high-temperature fuel cells at Eurasian National University named after L.N. Gumilyov [10], Kazakh-British Technical University [11], and Nazarbayev University [12].

The project on storage and transportation of hydrogen by KMG Engineering is going to be the first study, which proposes the use of Kazakhstani metals for the preparation of titanium-based alloys at a low cost for hydrogen storage. The idea of affordable transportation has been suggested using railway which is the main type of transport connecting the whole of Kazakhstan. It will allow transporting hydrogen in a safe and optimal way. In Kazakhstan, materials for hydrogen storage alloys are abundant and their prices are less expensive. For instance, Kazakhstan has 30 % of the global reserves of chrome ores, which is second globally, 25 % of manganese ores, 10 % of iron ores and is ranked tenth in the world in terms of titanium reserves [4]. Moreover, an increase to US$ 4,535.53 million in the hydrogen storage alloys market is forecasted according to market research on “Hydrogen Storage Alloys Market Forecast to 2028” [13].

However, there is a huge problem such as a lack of technologies, specialists, and experts in Kazakhstan. We believe these projects have a positive social and environmental impact by training new personnel and jobs, developing science and reducing the negative impact on the environment in Kazakhstan, where industry plays the main role of the economy.

CONCLUSION

Kazakhstan has great fossil fuel reserves that may sustain higher energy production. However, the global coalition for net zero emissions has not been avoided by Kazakhstan as the country is also significantly influenced by climate change. This study has reviewed current procedures toward the green economy. Indeed, political support is essential for demand generation, standardization and risk control for the growth of the hydrogen market in the country. Along with it, Kazakhstan is facing certain key challenges like formulation of regulating policies, standards and codes, implementation of R&D, etc. The country is at the very beginning of hydrogen energy deployment but overcoming these issues may bring a successful green economy and sustainable future.

ABSTRACT

In August 2021 the Concept for the Development of Hydrogen Energy in Russia was released with a strategic goal to make Russia one of the global leaders in hydrogen production and export. It is a major step ahead, since from the collapse of the USSR there were no hydrogen energy program in Russia. The priorities for the development are low-carbon processes of hydrogen production from the fossils with CO_2-capture and water electrolysis using nuclear power. The Concept includes 3 stages with export targets at the end of each stage are 0.2 Mt H_2 in 2024, 2-12 Mt H_2 in 2035 and 15-50 Mt in 2050 H_2 depending on the development rate of the global low-carbon economy.

Keywords: Russian Federation, State policy, Concept for the Development of Hydrogen Energy

INTRODUCTION

Hydrogen is considered as a secondary energy carrier for energy accumulation, preferably for renewable energy sources. Development of hydrogen energy in Russia (as part of the USSR) has begun in 1970s. In 1975 the Academy of Sciences has established a Working Group on Hydrogen Energy, and in 1977 a Commission of Academy of Sciences on Hydrogen Energy was established, a concept of development of hydrogen energy in the USSR was created. Leaders of the Commission were academicians M.A. Styrikovich, V.A. Legasov and E.E. Shpilrain, base organizations were Institute for High Temperatures and Kurchatov Institute.

In the early 1980s the conception of hydrogen energy in the “purest” form considered production of hydrogen at large plants by water splitting by nuclear power, transportation of hydrogen to the centers of consumption and distribution with the next use as a fuel in that applications, which use natural gas, liquid or solid fuels [1]. There were many achievements in the field of hydrogen energy and fuel cells, including development of the first hydrogen aircraft Tu-155 and hydrogen airport infrastructure. In 1988 the 7th WHEC was held in Moscow.

After the collapse of the USSR in 1990-s the work of the Commission on Hydrogen Energy was stopped. Many efforts were made to revive activities, but until recently there were no Hydrogen Energy program in Russia. Research and development efforts were mostly concentrated in institutions of the Russian Academy of Sciences and universities, and were mostly supported within programs of the Russian Ministry of Science and Higher Education and grant programs of Russian Foundation for Basic Research and lately Russian Science Foundation. Nevertheless, the critical Technology “Novel and renewable energy sources, including hydrogen energy” was recognized within the “Energy efficiency and energy saving” top priority in science and technology development directions in Russia [2].

In the recent years, the understanding of the role of hydrogen as a clean and effective energy carrier has been increased. The G20 Osaka leaders' declaration published in June 2019 has recognized opportunities offered by further development of innovative, clean and efficient technologies for energy transitions, including hydrogen [3]. The declaration gave a new start for hydrogen in Russia, the interest has reached policymakers and on August 5, 2021 the Concept for the Development of Hydrogen Energy in Russia was released [4], with the two broad goals: increasing socioeconomic development and maintaining a commanding position in global energy, thus neutralizing future risks in a decarbonizing global economy for Russia as the major hydrocarbon producer.

CURRENT STATE

Today the global energy system is in transition, and the best available science and international cooperation are needed for deployment and dissemination of zero or low carbon emission and renewable technologies. While the share of renewables (RES) increases rapidly, the variable RES have the problem of low capacity factors and there’s a desperate need for energy storage. Hydrogen could contribute for a power system flexibility, as well as to a sector coupling with transport and industry. Russian energy sector relies mostly on cheap and abundant fossil fuels, nuclear and hydro energy. Renewables (excluding large hydro) contributes less than 1% of the total power generation and cannot compete with traditional generation within the Unified Energy System.

Nevertheless, Russian Federation actively supports international efforts in climate change reverse, conserving the environment and sustainable development, and has joined the Paris agreement (signed April 22, 2016 and adopted by the Russian government decree #1228 on September 21, 2019). Moreover, renewable energy sector is important for sustainable energy development of Russia, since 65% of the country are not covered by unified grids. Electricity in that regions is supplied mostly by diesel power stations (DPS). There are ca. 900 DPS generating 2.54 billion kWh/year (2% of total generation in Russia) with generation cost in the range 0.25-2 Euro/kWh. Power supply of isolated regions is heavily subsidized from the federal and regional budgets and causes significant environmental damage. Thus, the role of renewables in future energy systems is recognized, and Russia started to follow the global trend and introduce more RES generating capacities. For example, in 2020 there were commissioned 12 renewable power plants with total capacity 978.4 MW, an only 5 fossil and nuclear power plants with total capacity 957 MW [5]. Thus, research activities in hydrogen energy for the use in Russia have the goal of further socioeconomic development and include new technologies for low-carbon hydrogen production from traditional and renewable energy sources, fuel cells, hydrogen transport, hydrogen systems for electricity accumulation and for distributed power production, especially for isolated regions.

On the other hand, Russia is one of the major hydrocarbon producers and therefore faces future risks in the global economy decarbonization. The Concept has the strategic goal to make Russia one of the global leaders in hydrogen production and export. Today, the most economically efficient means of producing hydrogen are steam methane reforming and coal gasification, which contribute 75% and 23% of the global production, and low-carbon hydrogen production by water electrolysis with the use of renewables is only expected to reach the target of 2 USD/kg H_2 in 2050. Thus, and the criteria of success would be lowering carbon dioxide emissions for all the hydrogen technologies. Within the Concept the priorities for the development are the creation of low-carbon processes of hydrogen production from the fossils (e.g. pyrolysis) with CO_2-capture and water electrolysis using nuclear power. Potential markets are Europe and Asia Pacific region. The Concept includes 3 stages with export targets at the end of each stage are 0.2 Mt H_2 in 2024, 2-12 Mt H_2 in 2035 and 15-50 Mt in 2050 H_2 depending on the development rate of the global low-carbon economy.

The Concept proposes to use regional clusters to facilitate the development of export-oriented production of hydrogen and hydrogen-based energy mixtures, as well as production of hydrogen for domestic use. Three main clusters should be created: North-Western cluster for export in EU countries and development of low-carbon technologies, Eastern cluster for export to Asia and development of hydrogen technologies for transport and power production, and Arctic cluster to fulfill needs of Arctic regions for low-carbon energy and/or production of hydrogen and energy mixtures for export. Additional Southern cluster could be created for the use of resources of natural gas and renewables with base on the developed infrastructure of the Southern Russia. In October 2021 the Ministry of Industry and Trade of the Russian Federation presented Russian Atlas of low-carbon and carbon-free hydrogen and ammonia production projects [6], which includes 33 projects in 18 regions of Russia.

Realization of the Concept is expected with the participation of all organizations, including state institutions, Academia and universities, industry and business. The Ministry of Energy will present annual reports to the Government.

ABSTRACT

Social entrepreneurship plays a crucial role in global sustainable development, enhancing the quality of life and preserving environmental, human, and social capital. However, when it relates to the energy transition, it faces numerous challenges and experiences conflicts in terms of costs, technological innovation, public policies. This study seeks to illustrate one of the new alternative energy schemes which could replace fossil fuels in the future: hydrogen. This transformation would result in significant social impacts, leading to the question, “how should it be done?” Social entrepreneurship can integrate socio-economic actors and agents and help them to devise and implement new forms of energy innovation. Therefore, a descriptive qualitative methodology was designed, that allows us to analyze the process of building entrepreneurship with a social vision and to propose a model that enables the transition from fossil economies to the hydrogen economies. Among the most significant results, stands out the importance of the support of the three primary axes of each country and the role of social entrepreneurship as a key element for the transition. The discussion contributes to the debate on the path that academia should lead, and the fundamental role of entrepreneurship based on social conscience as a driver of change.

Keywords: Hydrogen Economy, Social Entrepreneurship, Hydrogen Energy, Sustainable Development, Innovation.

INTRODUCTION

For [1] the effort to find sustainable energy sources is driven by various factors: i) political stimuli from net energy importing nations, ii) environmental concerns, and iii) diminishing hydrocarbon reserves, especially of petroleum. In this context the development of hydrogen-based energy is logical. Hydrogen does not release carbon to the atmosphere, and the required technologies already exist and are experiencing gradual cost reductions, while the costs of discovering and extracting hydrocarbons continue to increase.

The aforementioned factors support the concept of a “Hydrogen Economy”, which has been theorized since the 19th century. In the novel “The Mysterious Island” penned by author Jules Verne in 1874, the author proposes separating the constituent elements of water by means of electricity and using them as fuel. Naturally, the concept has continued to evolve since then, but the basic transformation was envisioned long ago as humanity has sought to shift its energy matrix [2]. The term “hydrogen economy” can thus be taken to include the new business structure and system of socio-economic relationships that would be engendered by a move from fossil fuels to hydrogen [3], [4]. The question therefore arises as to how these socio-economic relationships can be created in a new business structure that is not only profitable, but also promotes projects of community interest that may encompass public works, volunteer involvement, or an array of other types.

In relation to the hydrogen economy, [5] propose that social entrepreneurship is the way to take advantage of the potential of clean energy sources existing in a territory, in this case, hydrogen; furthermore, it allows to raise the economic value of renewable energies, which as a new pattern, generates jobs and promotes the reactivation of other industries of local nature, which can act as suppliers of this. However, the cost of this new hydrogen-based economy is still too high, therefore, it must be supported by a social base, which implies the joint work of the industry through the social entrepreneur -as its goal is social rather than profit [6]-, the academy, and the state. Nevertheless, when an analysis of the state of the art on the subject is made, it is clear that the research gap between the hydrogen economy and social entrepreneurship is quite wide. Research has shown that collaboration between the hydrogen economy and social entrepreneurship is an essential condition for promoting innovation and improvement processes in the energy transition of any country; however, not all collaborative work stimulates substantial improvements in this type of transition if it is not accompanied by the key roles proposed in this research. This leads to questions such as: how is this transition going to be implemented? how to be an entrepreneur in the new hydrogen economy? what do we know about the theoretical-practical relationship between social entrepreneurship and the hydrogen economy? Why is the relationship between social entrepreneurship and hydrogen economy important?

In this context, the present study proposes a transformation of fossil fuel economies to a new model that uses hydrogen as an energy vector; and suggests that this transformation can best be undertaken through synergy with

social entrepreneurship, which aims for social and environmental development, and the resolution of socio-economic problems by means of sustainable strategies.

MATERIALS AND METHODS

The present research aims to generate a contribution to the theory on the process of transformation from fossil energy economies to hydrogen economies through social entrepreneurship using descriptive qualitative analysis. Qualitative research can be seen as an attempt to obtain a deep understanding of the meanings and definitions of the situation as people present it to us, rather than the production of a quantitative measure of their characteristics or behavior [7], in this particular case, the meanings and definitions of the relationship between social entrepreneurship and the hydrogen economy. To comply with this analysis, information is collected from various sources, mainly scientific, then critically analyzed and interpreted so that you finally realize the thematic development aimed at generating knowledge and understanding [8].

For the development of this research, a collection of documents on the subject was carried out through the search for scientific communications in different databases: Web of Science, Science Direct, Scopus, among others. Specifically, a document search is carried out using keywords such as “hydrogen economy,” “entrepreneurship”, “social entrepreneurship”, and “energy transition”. The search identified 710 documents. On applying inclusion/exclusion criteria shown in table 1, to title and abstract review 568 documents were excluded. Finally, 142 full texts were reviewed, and a further 66 were excluded. After reading the documents, a selection process is carried out and the information is analyzed following a tracking matrix.

Table 1 Inclusion and exclusion criteria

Parameters	Inclusion	Exclusion
Keywords: entrepreneurship, social entrepreneurship	The documents provide the pertinent guidelines or implications with regard to fields of social entrepreneurship, social enterprise management, social entrepreneur characteristics, and social entrepreneurial intention or orientation.	Non-relevant works and documents that only account for entrepreneurship activity from an income generation viewpoint were not considered.
Keywords: hydrogen economy, energy transition	The documents address issues pertaining to a hydrogen economy and energy transition from renewable energies under the social and environmental viewpoints.	Non-relevant works were excluded.
Type of publication	Due to the research scope itself, not only journal papers were included, but also books, book chapters, and reports of business success cases, that had passed through a peer-review process, ensuring quality criteria.	Documents that do not ensure a peer review process, and therefore, quality criteria.
Country of origin	Any country of origin	Geographical borders were not judged applicable.
Language	English and Spanish	Non-English or non-Spanish language studies were excluded due to the to resource constraints on translation.

RESULTS AND DISCUSSION

Geoffrey Edwin Hall Ballard, founder of Ballard Power Systems, supported the need for efforts together with the government, academia, and industry, for the transition of a fossil fuel economy to a hydrogen economy to be possible [9]. In this vision, where the government, academia, and industry are entrusted with the transition of a fossil fuel economy to a hydrogen economy, entrepreneurship must be prioritized as a key tool in the process, without forgetting that this entrepreneurship must emphasize the social aspect. In today’s world, all economic actors pursue their own ends, without considering the environment, and without considering the array of different types of companies; much less the previous work, experience, and knowledge provided by academia. Therefore, the current proposal links the hydrogen economy and social entrepreneurship in a manner that is pertinent, timely, and focused on innovative ideas from multidisciplinary sources from around the world. This allows for the structuring of business plans with higher chances of accessing public and/or private resources and converting them into sustainable companies with a greater impact upon any economy.

The proposal is based on the idea that it is possible to transform current fossil fuel economies using a multidisciplinary array of interdisciplinary ventures, an energy proposal that fits with the conditions of large economies and their ecosystems, the application of new technologies and good management practices, as well as the use of social networks and online learning communities as support strategies for knowledge diffusion between participants. The plan depends on support by the state (both its government and the population that benefits), industry (entrepreneur and intrapreneur), academia, and the environment (both the physical environment, as well as the social one) as a transversal axis. This proposal also considers the individual, in addition to corporations and the community.

The ecosystem that is suggested for this hydrogen economy must support the training of entrepreneurs and the creation of knowledge to improve the sustainability of start-up businesses over time. For [10], scientific and technological strategies must be implemented that revolve around human management, the creation of new knowledge, and dynamic and innovative social entrepreneurship that does not neglect productivity; all supported by robust institutions and the state, and a competitive environment conducive to business development. The current study is based upon this premise, as is shown in the following figure, where each one of the actors described above plays a fundamental role as explained in detailed in the final version of the research.

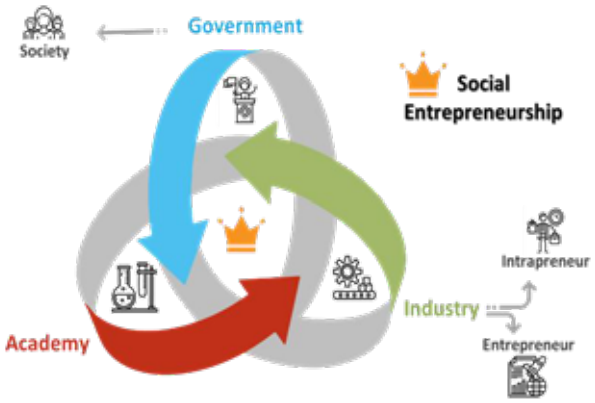

Fig. 1. Key players in the transition of a fossil fuel economy to a hydrogen economy. Source: Authors.

The proposed hydrogen economy, by means of social entrepreneurship, must meet the needs currently covered by the fossil fuel economy. The economy must be oriented towards those who are interested in creating firms with a social impact. According to [11], entrepreneurs who create firms are key agents of the economy, because they drive technological change, wealth generation, and job creation. Entrepreneurship is a way of life and is the ideal basis for the proposal in this study.

CONCLUSIONS

The current analysis is based on the transition of fossil fuel economies to hydrogen economies by means of social entrepreneurship and could be replicated for other types of clean energy. In this paper we analyzed the process of building an entrepreneurship with a social vision, however, social entrepreneurship can be studied in a world that is still in the process of constructing environmental protection scenarios and requires entrepreneurs who set forth and embody these values and propose new forms of environmental innovation [12].

Hydrogen economy represents a viable opportunity to replace that of fossil fuels in the medium to long term. The great powers of the world are showing considerable interest in implementing and enjoying the benefits thereof. Nevertheless, this will only be possible with the support of the three primary axes of each country; the state (including the government and society, as the ultimate end user), an industry which highlights the social entrepreneur as its principal agent, and of course academia, to lead and orient the required processes, interdisciplinary work, and collaborative networks.

In proposing such a drastic transition as that of a fossil fuel economy changing to hydrogen, it is necessary to give weight not only to the economic and financial costs of the projects that will make it possible, but also to consider other social costs, to make it a viable transition. It is in this sense that the role of social entrepreneurship plays a fundamental and essential role, which must be supported by academia, existing industry, and the state, in a joint effort for a sustainable economy that will guarantee the energy supply, decrease wealth inequality, and promote the efficient use of resources and an environment with lower levels of pollution.

ABSTRACT

At present, the development of China's hydrogen energy industry is beginning to take shape, and the high cost of hydrogen energy industry chain is the biggest obstacle to the development of hydrogen energy industry. Based on the analysis of the development background and current situation of hydrogen energy in China, this paper points out that the realization of economy of green hydrogen energy industry chain in China needs to start from the following four aspects: formulating policies, regulations and standards suitable for hydrogen energy; Promote the progress of hydrogen energy technology; Promote the localization and large-scale application of hydrogen energy technology, and strengthen international cooperation. The green hydrogen energy industry will also provide strong support for China to achieve the goal of carbon peak and carbon neutralization.

Keywords: Green Hydrogen, Economy, Sustainable Development

INTRODUCTION

In order to achieve the goal of carbon peak and carbon neutralization [1], a series of practical energy technologies are needed as support. Among them, hydrogen energy has gradually become the focus of international and domestic society because of its clean pollution, renewable and controllable safety. Hydrogen industry chain covers hydrogen energy production, storage and transportation, and downstream utilization. Currently, China's hydrogen industry chain has initially formed comprehensive pattern from basic research, application research to demonstration, and create a relatively complete hydrogen industry. According to the China Hydrogen Energy Alliance, hydrogen energy will account for at least 10% of China's final energy system by 2050, and hydrogen demand will be close to 60 million tons, of which the demand by transportation will be about 24.58 million tons, accounting for more than 40% of the total demand for hydrogen energy. Some researches also expect that China's demand for hydrogen energy in 2050 will reach to 80 million tons. It shows that hydrogen energy has a very broad development prospect in China. At present, most hydrogen energy comes from fossil energy (gray hydrogen). As a strategic emerging energy, it is necessary to promote and develop the production and application of green hydrogen. However, economy is the fundamental problem affecting the development of green hydrogen industry. Practical methods are needed to solve the economic problems in order to enhance the competitiveness of China's hydrogen energy industry.

CURRENT SITUATION AND DEVELOPMENT CHALLENGES OF CHINA'S HYDROGEN ENERGY INDUSTRY

China's hydrogen energy development policy

In April 2020, the Energy Law of the People's Republic of China (Draft for solicitation) issued by the National Energy Administration mentioned giving priority to the development of renewable energy [2], supporting the development and application of new fuels and industrial raw materials instead of oil and gas, and bringing hydrogen energy into the energy category. In December of the same year, the white paper "energy development in China in the new era" proposed to accelerate the development of hydrogen energy industry chains such as green hydrogen extraction, storage, transportation and application, and promote the development of hydrogen fuel cell technology chain and hydrogen fuel cell vehicle industry chain [3]. In September 2020, the Ministry of finance, the Ministry of industry and information technology, the Ministry of Science and Technology, the National Development and Reform Commission and the National Energy Administration issued the notice on starting the demonstration application of fuel cell vehicles. The notice proposed that the three urban agglomerations of Beijing, Shanghai and Guangdong become the key areas selected in the first batch of hydrogen fuel cell vehicle demonstration urban agglomerations, and the demonstration period is tentatively scheduled for four years [4]. In April 2021, the Ministry of science and Technology launched the "hydrogen into thousands of homes" science and technology demonstration project in Shandong Province [5]. The project will give full play to the advantages of infrastructure and hydrogen resources in Shandong Province, gradually promote the integrated development of innovation chain and industrial chain in the field of hydrogen energy, promote the application of hydrogen energy in terminal fields such as transportation, industry and household energy, accelerate the comprehensive utilization of hydrogen energy, promote the transformation of energy consumption to efficient and clean, and effectively reduce carbon emissions, Achieve "2030 carbon peak and

2060 carbon neutralization" and provide a demonstration model for building a "hydrogen energy society" in Shandong.

Challenges of green hydrogen industry development in China

At present, the development of China's hydrogen energy industry has started, but there are still some obstacles affecting competitiveness, such as high cost and insufficient infrastructure construction. Since China has strong infrastructure capacity, building hydrogen energy infrastructure is not a problem. Therefore, the high cost of hydrogen energy industry chain is the biggest obstacle. There are four reasons for the high cost of green hydrogen industry chain. First, China's existing policy system is not suitable for the development of renewable energy and hydrogen industry system, which increases the cost of green hydrogen industry chain. For example, the existing policy system treats hydrogen as a dangerous chemical. The hydrogen production plant must be built in the chemical park, and the hydrogen production plant and hydrogen refueling station should be built separately, which hinders the construction of integrated hydrogen production and hydrogenation station. In addition, it is required that the hydrogenation station must be built on commercial land, which also increases the construction cost of the hydrogenation station. Second, due to the limitation of renewable energy technology, the cost of hydrogen production from renewable energy is high. For example, the cost of hydrogen production from solar energy and wind energy is not competitive compared with that from fossil energy. Third, due to the low localization rate of hydrogen energy technology and the small industrialization scale of related products, it is difficult to reduce the cost of hydrogen industry chain. For example, in 2021, the output of fuel cell vehicles in China was only 1779, and hydrogen fuel cell vehicles were not popularized, resulting in high cost. Fourth, there is a gap between the existing green hydrogen industry technology and the international advanced level, indirectly pushing up the cost of the green hydrogen industry chain. For example, in terms of core technologies such as fuel cell stacks, the competitiveness of Chinese hydrogen energy enterprises is slightly insufficient.

MEASURES TO REALIZE THE ECONOMY OF CHINA'S HYDROGEN ENERGY INDUSTRY

Policy design

China's "14th five year plan" points out the specific direction for hydrogen energy, energy storage and other technology and industrial transformation fields, but it lacks strategic guidance and policy design for the development of hydrogen energy industry. Therefore, it is necessary to establish a special leading organization for hydrogen energy industry development planning at the national level to study and formulate China's hydrogen energy industry policy system according to the characteristics of hydrogen energy. For example, hydrogen can no longer be managed only as hazardous chemicals, but to strengthen the energy properties of hydrogen and formulate industrial, financial and tax policies to promote the development of hydrogen energy. Promote the research and development of hydrogen energy related specifications and standards, and promote the healthy development of hydrogen energy industry.

Promote the progress of hydrogen energy technology

To develop green hydrogen, key problems such as economy and technology maturity should be solved, and scientific and technological breakthroughs should be carried out to solve the technical bottlenecks of key materials and components. First of all, we need to promote the technological progress of renewable energy, so as to continuously reduce the electricity cost of renewable energy, so as to lay a foundation for the economy of green hydrogen. Secondly, we should strive to promote the development of hydrogen production technology from electrolytic water, increase the production capacity of electrolytic water equipment and reduce the cost of hydrogen production. Thirdly, we should promote the technological progress of fuel cell stack, increase the volume power density of fuel cell and reduce the cost of fuel cell. Fourth, we should pay attention to the application and progress of digital technology and intelligent manufacturing technology in the field of hydrogen energy, and improve the economy of the hydrogen energy industry chain. Developing green intelligent manufacturing is an important measure to develop China's hydrogen energy. Digital technology gives the hydrogen energy industry chain the ability to reduce production costs, reduce carbon emissions and realize green manufacturing by improving quality, reducing raw material consumption and shortening production cycle; Intelligent manufacturing improves production efficiency through automation, dynamic monitoring and control, and finally improves the economy of hydrogen energy industry chain.

Improve the localization and scale level of green hydrogen industrial chain

Generally, the unit product cost is negatively correlated with its output. The output increases and the unit product cost decreases. Improving the large-scale production of parts will promote cost reduction. China's domestic alkaline electrolytic cell technology leads the international advanced level. The capacity of a single electrolytic cell has

reached 1000 cubic meters of hydrogen / hour, and the cost has decreased to about 7000 yuan / kW, only half or even lower than that of developed countries. The localization of domestic upstream industry chain enterprises of fuel cell stack has achieved initial results: membrane electrode, proton exchange membrane and bipolar plate manufacturers have the localization ability, gas diffusion layer enterprises have begun small-scale production, catalyst enterprises are in the R & D stage, and metal bipolar plate enterprises have begun the localization stage. In the future, China should continue to strengthen the scale and localization of green hydrogen industrial chain, so as to bring more considerable economic benefits to the development of hydrogen energy industry.

Build standard system

Strengthening the research and formulation of standards and improving the precision of policy support will help the development of the hydrogen energy industry. In March 2020, the National Development and Reform Commission jointly issued the Opinions on Accelerating the Establishment of Legal and Policy System for Green Production and Consumption, studying and formulating standards and supporting policies for the development of hydrogen energy, marine energy and other new energy sources. By April 2021, there were 95 national standards related to hydrogen energy put into effect. But in order to further adapt to the rapid development of the hydrogen industry demand, it still need to accelerate the hydrogen standardization work, to further develop renewable energy hydrogen and high pressure hydrogen storage container inspection equipment, solid state hydrogen storage, hydrogen liquefaction and key equipment such as hydrogen station infrastructure level standard, at the same time as the hydrogen application in the field of innovation and development, the improvement of the relevant standard system construction.

Promote international cooperation

With the rapid advancement of global energy transformation, hydrogen energy is expected to become a new hotspot of international cooperation. From the perspective of resources and application scenarios, various conditions in China are relatively good. First, China should strengthen cooperation with hydrogen power countries (regions), such as Japan, South Korea, Canada, EU, etc. Meanwhile China should combine one belt, one road initiative and strengthen cooperation with the countries along the hydrogen industry, including leasing equipment, exporting hydrogen energy technology, producing green hydrogen, green ammonia, selling green hydrogen and green ammonia, and also sharing profits and realizing common prosperity with the countries along the route. Explore a green and low-carbon development path of win-win cooperation and common development, and make new contributions to promoting the global response to climate change and building a community with a shared future for mankind.

CONCLUSIONS

Improving the economy of the green hydrogen energy industry chain is the key to the development of China's green hydrogen industry. It is necessary to make a layout from the aspects of improving the policy system, promoting technological progress, improving the level of localization rate and strengthening international cooperation, so as to promote the healthy development of the hydrogen energy industry and provide support for China to achieve the goal of carbon peak and carbon neutralization.

H_2-INDEX FOR THE EVALUATION OF HYDROGEN PROJECTS IN MEXICO

[1] G. Ramos-Sánchez, [2] R.G. González Huerta*
[1]Universidad Autónoma Metropolitana- I IPH Department, Mexico City, Mexico

ABSTRACT

Hydrogen projects are being implemented all around the world, although at first sight all projects in which Hydrogen is involved appear appealing, in some cases other alternatives such as electrification and efficiency growth are better suited. In this work we have developed a methodology for the analysis of Hydrogen projects that assign a quantitative value to its implementation viability. The H2-index is based on the evaluation of 6 factors, social benefits, economic benefits, environmental benefits, national development, efficiency, and technical viability. A weighted factor will help to decide, in a simple manner, whether a project should be promoted and, moreover, what areas should be strength in order to make the project not only viable but worth to be financed.

Keywords: H2 Projects Evaluation, H2-Index, Positive Impact of Projects.

INTRODUCTION

Hydrogen is expected to play a substantial role in the following years, the immense advantages of its utilization such as null carbon footprint, flexibility to attend different uses and the possibility to decarbonize our society [1] make us think on Hydrogen as the only viable solution. Not only beginners, but specialized scientist and technologist tend to put Hydrogen as the first option in almost any energy project; however, in some cases Hydrogen does not represent a viable solution in front of other alternatives. In other cases, the Hydrogen project can represent serious disadvantages that make us think as an unviable option but strengthen in the weak areas can make it a viable alternative. The Mexican socio-politics this year is full of ideas for Hydrogen projects eager to be developed or to be financed. We must be aware that one of the main problems in the realization of projects is related to delusion, i.e., if a project is launched and implemented but the outcome results in more disadvantages than advantages Hydrogen might be discarded forever as a viable option in the society [2]. Viability analysis is a complex task that is performed by specialist in order to discern the main strengths and weakness of a project; however, the task is specialized and requires lots of data, while in some cases a simpler analysis is needed. The Mexican Hydrogen Society has launched a H2-index which intends to provide a simpler analysis of projects to decide whether a project is viable and represent advantages. Due to Hydrogen prices, in most of the cases to break market barriers the projects should be financed by government; thus, this strategy will allow evaluating the project viability and determine the existing opportunity areas to improve the project outcome.

METHODS

H2-Index is based on 6 factors which are listed in table 1, each project is weighted in a score based on the positive characteristics of the project. The factors evaluated, which are of interest for the Mexican sociopolitical characteristics are the following: 1) National benefits, this intends to evaluate if the project will benefit the growth of the economy, 2) Social impact, which measures the direct impact in society such as energy poverty elimination, jobs creation and wellness, 3) Economic, which evaluates if the project is economically viable in comparison to other options, 4) Technic viability, which evaluates if the technology is developed enough to be implemented or, if is expected to be developed in the future, 5) Efficiency, if the project represent advantages in efficiency in comparison to any other energy option, and 6) Environmental, if the project represent important improvements in comparison to the emissions of the system that is being replaced.

The specific scale for each factor goes from 0 to 5, at the end the score for all factors is averaged, resulting in the H2-index. If the project gets a 0 for each of the factors, the project is not viable; if the project receives an averaged H2-Index lower than 2.5 although not getting any zero, the project present serious limitations and most probably should be rejected. If the project receives an H2-index higher than 2.5 but lower than 4.0, the project is viable but should be revised to find opportunity areas that could make it increase its viability. If a project gets a 4.1-5.0 H2-Index the project is viable and should be promoted but also government financed. Table 1 shows each of the factors and its scale, to save space we have decided to include only the lowest and highest score.

Table 1. Factors and scores for the H2-Index, symbols and colors are included to make it visually appealing

	Minimum score	Maximum scoring
National	The project implies non-justified subsidies	Exist opportunities for the growth of the national industry and participation of several medium size companies
Social	The project represents a serious treat to civilians.	The project forecast a high number of new jobs, and academic opportunities.
Economic	The project is 30% more costly than the system that intends to replace.	The project saves at least 20% in production costs.
Technical	There are serious limitations in the technology at the present and, in the future.	Technology is ready to operate and does not exist another technology alternative.
Efficiency	The efficiency is lower than the system that intends to replace	Overall energy efficiency higher than 90%
Environment	Higher GHE than the system that intends to replace	Avoid GHE emissions in 100%

RESULTS AND DISCUSSION

H2-index was applied to two kinds of projects, the first is a barbeque hydrogen roaster (BH2) which has been proposed as and alternative to mitigate emissions in cities with cultural behaviours toward the use of charcoal to cook, while the other is Hydrogen forklifts (H2F) for industry indoor activities. The BH2 project has been promoted recently by local communities, the proposal sounds good as a great number of emissions could be avoided; however, other factors such as costs, technical viability and impact are serious treats to the viability. On the other hand, H2F have been long identified as one of the most viable projects for Hydrogen commercialization nowadays and their use is expected to be increased all around the world.

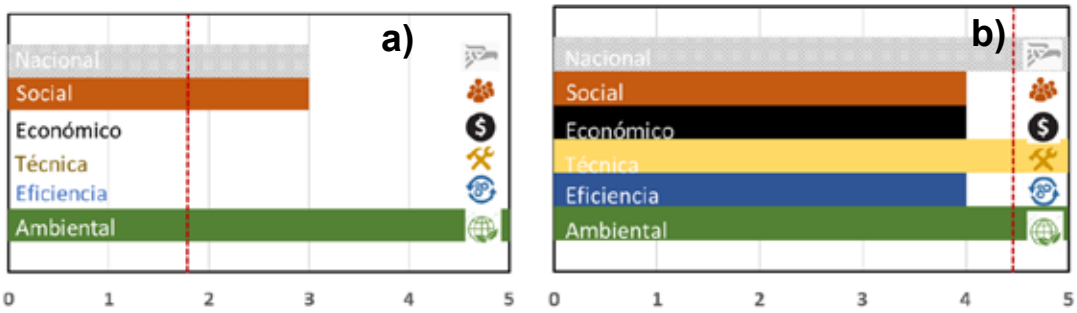

Fig. 1. H2-Index evaluation for a) BH2 projects and b) H2F projects

From the H2-index analysis, taking into account state of the art efficiencies, cost and technology status, we found that the main treat to the implementation of BH2 projects is the immense amount of efficiency lost, as the number of equipment is increased the efficiency is extremely lost; moreover the characteristics of Hydrogen make its flame not suitable for cooking as the radiative heat is lower; moreover the cost is unviable as small scale electrolysers are costly; although the environmental benefits are paramount, the overall H2-index indicates a value of 1.8 (red dotted line) which of course should rule out the implementation of such projects while electrification or sun cooking is becoming available. On the other hand, H2F present scores higher than four in most of the factors and a H2-index of 4.5 which indicates that the project is not only viable but represent important benefits, specially this represents the opportunity to create jobs and develop national technology to strength the value chain and enforce the realization of other projects.

CONCLUSIONS

H2-index was developed as a practical tool to evaluate Hydrogen projects, the multifactorial analysis which takes into account all the benefits and treats represents a simple but valuable tool to decide if a project should be promoted or financially supported. The analysis is being implemented for more complex systems and as a decidive tool to increment the impact of other hydrogen projects.

ABSTRACT

Hydrogen can be produced from biomass and eventually deliver largely needed negative emissions when combined with carbon capture and storage. The sugarcane industry in Brazil is well established and its main energy products – ethanol and electricity – are potential solutions but are still facing challenges related to decarbonisation. Aiming to contribute to the Brazilian matrix decarbonisation, this article estimates the hydrogen production potential for a current state-of-the-art sugarcane mill with an annexed distillery, based on 1G and 2G ethanol reforming, biogas reforming, and the use of surplus electricity for electrolysis-based process. This result is applied to the total sugarcane production in Brazil to compare the country's potential by using hydrogen in fuel cells to the equivalent in useful energy delivered by all fuels used in the transport sector. As a result, sugarcane-based hydrogen could deliver around 57% of total transport sector energy demand, compared to only 19% of current ethanol's contribution. In addition, ethanol is only used in passenger cars where pure electric vehicles are becoming increasingly competitive, and diesel oil consumption in the country is extremely high mainly for trucks; on another hand, hydrogen is more likely to play a role decarbonising these heavy vehicles. Hydrogen could become an option for the sugarcane industry to remain relevant under a battery electric-cars future and Brazil is well-positioned to develop a strategy around biomass-based hydrogen for heavy vehicles.

Keywords: Hydrogen, Biomass, Sugarcane, Transport Decarbonisation, Brazil

INTRODUCTION

Worldwide, hydrogen is expected to play an increasing role as a versatile energy carrier suitable to reducing greenhouse gas (GHG) emissions from different activities. The flexibility of hydrogen is the principle that creates the conditions for different hydrogen consumption and production models according to regional needs and resources. Low-carbon hydrogen can be produced from water electrolysis using clean energy sources, from fossil methane reforming or coal gasification with high carbon capture and storage rates, and from biomethane reforming or biomass gasification as well.

These last two routes involve biogenic carbon and can deliver negative emissions if CO_2 is captured and permanently stored. Technologies providing CO_2 removal from the atmosphere are key to achieving deep decarbonisation and keeping global temperatures below 1.5ºC and even 2ºC, as they provide a means to compensate for temperature overshoots and residual emissions from hard-to-decarbonise sectors.

Brazil's energy system relies on biomass from a diversity of feedstocks and for different purposes. The main product from biomass is ethanol used as fuel, covering more than 40% of the energy demand from passenger cars in 2020 [1]. Sugarcane is the feedstock used for over 90% of current ethanol production in the country, despite a recent growth in corn-based ethanol [2].

The sugarcane processing industry also generated around 37 TWh of electricity from bagasse-based combined heat and power (CHP) systems, with a net contribution for the Brazilian grid of around 20 TWh in 2020 [1].

A new product in this huge industry is biogas, produced from anaerobic digestion of ethanol processing residues such as vinasse and filter cake, which in some cases is being used for additional electricity generation. However, biogas upgrading to biomethane is receiving increasing attention due to the different energy uses such as diesel replacement, grid injection replacing natural gas and hydrogen production through reforming process.

However, the sugarcane sector's business model regarding its energy products is facing challenges.

First, vehicle electrification is a challenge to biofuel-based decarbonisation, threatening the projected ethanol's expansion over gasoline's market share. A distinguishing feature of electrification compared to internal combustion engines is increased energy efficiency, which can also be achieved by using hydrogen in fuel cells.

Secondly, auction-based long-term electricity contracts in Brazil are traditionally awarded based on a competition for the lower energy price, and bioelectricity has been struggling to compete with intermittent renewables such as solar and wind (which have strong subsidies) under this model.

Therefore, while it provides an alternative against the risks of its current business model based on electricity and ethanol, hydrogen is arguably an important way forward for the sugarcane industry to increase its contribution to transport decarbonisation without expanding sugarcane land area based on increased vehicle energy efficiency.

In addition, renewable electricity sources have the task of first decarbonising the electricity supply, and risk needing to be developed in a scale that could create challenges for the deployment of new projects if expected to also cover demand from other sectors. These challenges are linked to the intermittent characteristics of wind and PV-based electricity generation, exhaustion of the best available potentials, and public opposition to landscape impacts of large-scale wind and solar farms. Furthermore, by not possessing the capability of combining hydrogen production with negative emissions, hydrogen from solar and wind electrolysis may not be as desired as biomass-based hydrogen to deliver deep decarbonisation. These aspects create a demand for alternative forms of low- or negative-carbon hydrogen other than renewables-based electrolysis (i.e., green hydrogen), especially from biomass.

OBJECTIVES AND METHODOLOGY

In this context, the objective of this paper is to evaluate the potential for hydrogen production from products of a state-of-the-art sugarcane industry in Brazil. Additionally, we assess the impact of using hydrogen comparing it to the current contribution of ethanol considering the improvement in vehicle efficiencies. Based on the results, we discuss the role of switching to biomass-based hydrogen as a main fuel for decarbonising the Brazilian transport sector.

The feedstocks and processes considered for evaluating hydrogen production potential in sugarcane biorefineries are as follows:

- First- and second-generation ethanol reforming;
- Biomethane reforming;
- Water electrolysis from the biorefinery's surplus electricity generation.

We then use the hydrogen potential based on its conversion in fuel cells to assess the equivalent in energy and compare to the fuels it could replace in current internal combustion engine vehicles. The results are then used to discuss the increased contribution to decarbonising the Brazilian transport sector that hydrogen production combined with fuel cell vehicles can provide compared to the current system.

It is important to note that both ethanol and biomethane reforming can run all year around but surplus electricity generation for electrolysis can operate only during season, when 1G plant is in operation.

RESULTS AND DISCUSSION

The results of hydrogen production potential from sugarcane are provided in Table 1.

Table 1. Hydrogen potential from a state-of-the-art sugarcane industry using selected production pathways.

	Feedstock potential	Hydrogen potential from feedstock (kg/t)	Hydrogen potential per area (kg/ha)
Sugarcane	80 t/ha	-	-
Ethanol 1G	40 l/t	5.25 kg/t	420 kg/ha
Ethanol 2G	23 l/t	3.03 kg/t	242.4 kg/ha
Surplus electricity	49 kWh/t	0.89 kg/t	71.2 kg/ha
Biogas	8.9 Nm^3_{CH4}/t	0.92 kg/t	73.6 kg/ha
Total	-	10.09 kg/t	807.2 kg/ha

Based on the results from Table 1, the hydrogen potential from ethanol reforming, surplus electricity and methane in biogas can reach around 10.1 kg of hydrogen per ton of sugarcane (kg/t) or 807.2 kg per hectare (kg/ha), based on the average productivity for the state of Sao Paulo in the 2020/2021 harvest, according to [2].

Most of this contribution (52%) comes from first-generation (1G) ethanol, currently the main energy product in the sugarcane industry. The average sugarcane mill produces 1G ethanol and, therefore, this is not closely related to the potential from a state-of-the-art industry. This result considers the potential for 1G ethanol production in a typical

annexed distillery, i.e., when ethanol is produced in combination with sugar – the sugar content destination is around 50% for ethanol. Also, most mills also have surplus electricity produced during the season. However, biogas and second-generation (2G) ethanol are still produced by only a few of the nearly 400 mills currently in operation in Brazil, despite promising new projects being announced for starting production in the short-term.

The hydrogen potential can now be compared to the fuel use in Brazil, as in Table 2. It considers a total sugarcane production in Brazil of 654 million tons based for the 2020/2021 harvest [2].

Table 2. Fuel utilisation in the transport sector and the potential of hydrogen substitution in Brazil.

	Consumption (km^3, except H_2)	**Useful energy (GWh)**
Diesel	46,046	113,760
Gasoline	29,997	68,499
Hydrated ethanol (as E100)	19,385	28,771
Anhydrous ethanol (as E27)	10,214	15,881
CNG	2,210,770	14,431
Total	-	231,341
Hydrogen potential	6,598,860 t	132,260

Therefore, the hydrogen potential from sugarcane only could supply around 57% of total energy demand for transport in Brazil. Current ethanol's contribution is around 19% and could increase up to 30% if considered the production of 2G ethanol (as in the hydrogen case) but would still be short of what hydrogen could deliver.

CONCLUSIONS

Hydrogen can increase the useful energy delivered by sugarcane to the transport sector based on the combination of using the industry's main energy products (ethanol, electricity, and biogas) to produce a single energy carrier – i.e., hydrogen – but also due to a higher end-use efficiency in fuel cells. The contribution to decarbonisation is even more pronounced as currently ethanol is only used in passenger cars where pure electric vehicles are becoming increasingly competitive, while hydrogen is more likely to play a role decarbonising heavy vehicles which lacks large-scale, replicable solutions.

COULD GREEN HYDROGEN AND ITS DERIVATIVE IMPROVE ENERGY SYSTEMS IN NORTH AFRICA, CASE OF MORROCO, EGYPT AND TUNISIA

[1*] *Amin Lahnaoui,* [1] *Wilhelm Kuckshinrichs*

ABSTRACT

North Africa constitutes a strategic point at the door of Europe and the corridor of West Asia. Some common cultural aspects could facilitate collaboration to strengthen its position in the region in the energy sector. Adding to that an increasing concern regarding the environmental impact of the current energy system, and a big renewable resources potential, the region could build a more sustainable economy around new energy resources. However, opportunities and potentials do not automatically translate into successful and radical changes and it is therefore important, now that the hydrogen economy and its derivatives its peaking speed, to not overlook the structural change that should be done in local energy systems in favour of export-based economy. Looking back to the last 28 years, hardly any change has been made to the way energy mixes are defined and the importance of carbon sources in it and the energy economy. Therefore, it is important to analyse first the energy supply and what drives energy consumption to define where future sustainable energy systems should intervene locally.

Keywords: Energy System, LMDI Decomposition, Energy Supply, Green Hydrogen.

INTRODUCTION

North Africa is still highly dependent on solid carbon and liquid sources as the main supply is driven by oil, natural gas, and coal. However, the different countries differ in the energy mix and energy security. Thus, while natural gas is the second energy source in the majority of countries, Morocco still relies on imported coal along with oil. The region shows as well disparity regarding conventional natural resources, as Algeria and Libya are oil and natural gas producers and therefore show a positive energy balance.
Looking at the change in energy supply, to a certain extent, the energy mix did not differ that much from how it was in 1991. This shows the impact limitation on new technologies to penetrate the existing energy system in the region. However, green hydrogen and its derivative have the potential not only to change the energy mix but as well to influence the economic structure and diversify it.
To spot where green hydrogen could play a role both on the supply and the demand side, it is important to study what has been driving energy supply and demand in the region. This is done by a decomposition analysis to define the adequate drivers.

METHODOLOGY

Index decomposition analysis has been widely used in energy to analyze the relative impacts of changes in a group of industrial activities, activity structure of the group, and activity energy intensities on energy consumption [1]. Among methodologies, the logarithmic mean Divisia index decomposition method became dominant in recent years [2] and produces decomposition results without leaving a residual term. A simple decomposition of total energy consumption (or total energy consumption for a given sector) into consumption at the subsectors in its basic form is shown in equation (1).

$$E = \sum_i E_i = \sum_i A\, S_i I_i \quad (1)$$

Where A is the total sectorial activity level, and Si and Ii are respectively the activity structure or share and energy intensity of sector i. The methodology has been adapted to analyze different sector's and sub-sector's consumption and emissions including for instance the metal industry in China [3], the manufacturing sector in Korea [4], and across country analysis in the EU-27 [5]. The methodology is adapted to analyse the drivers of primary energy generation PEG by ratios including, primary energy supply PES, final energy consumption FEC, and the gross domestic product GDP as expressed in equation (2).

$$E = GDP\, \frac{EG}{PES}\, \frac{PES}{FEC}\, \frac{FEC}{GDP} \quad (2)$$

This allows defining four effects to investigate:
- The activity one (GDP) that measures the economic activity growth impact on increasing energy production.
- Energy security effect (EG/PES) that measures the impact on energy trade balance on local generation.
- Transformation effect (PES/FEC) that measures the average efficiency of the energy system.
- Intensity effect ($FEC/\ GDP$) that captures changes in the structure of the economy.

As the final consumption is aggregated, an additive decomposition was more relevant [6], and a change in primary energy production can be decomposed on the change of the different effects as detailed in equation (3).

$$\{\Delta E = \Delta E_{activity} + \Delta E_{security} + \Delta E_{transformation} + \Delta E_{intensity} \quad (3)$$

The four effect changes $\Delta E_{\times}$ are defined by an additive logarithmic mean Divisia index decomposition method using the log men function $L({E_{i,j}}^{t}, {E_{i,j}}^{0})$ for a given initial and final year [2] expressed by equation (4).

$$\Delta E_{\times} = \sum_t L(E^t, E^0) \ln(\frac{\times^t}{\times^0}) \quad (4)$$

RESULTS AND DISCUSSION

Energy supply

Figure 1 show the results of primary energy production decomposition for Egypt, Morocco and Tunisia between 1991 and 2019, the main change in production in ktoe is represented as a change of the different effects represented in the vertical axis.

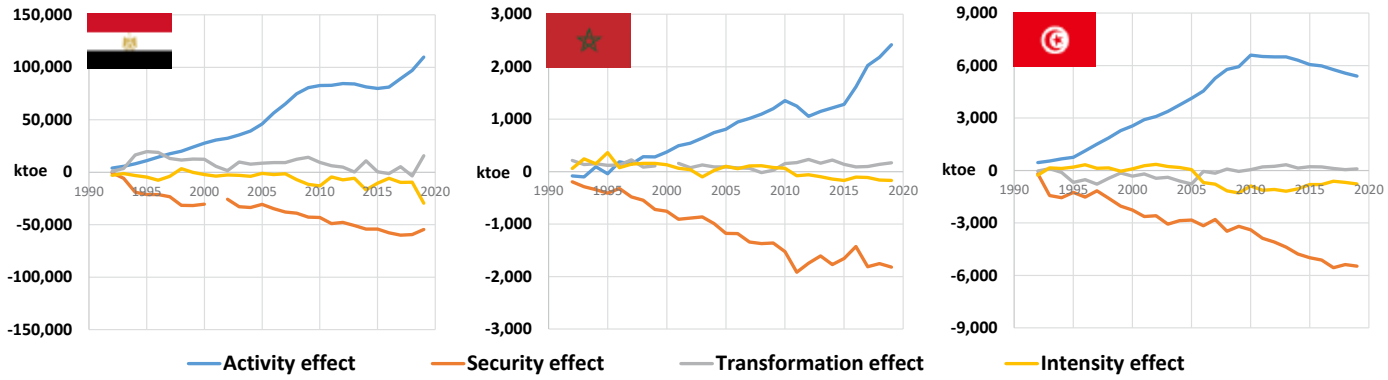

Fig. 1. Yearly additive LMDI decomposition results in ktoe for Egypt, Morocco and Tunisia between 1991 and 2019

Looking at the three countries, similarities can be deduced regarding the driver of primary energy consumption between 1990 and 2019, mainly economic growth has increased energy demand, but that was counterbalanced by an increase in net import, which limited the deployment of new sources of energy generation. The intensity effect reduction was negligible and didn't manage to reduce the demand and thus the supply, suggesting that hardly any change in economic structure was made, nor a substitutional transition to new sources was made. Finally, transformation gain was minimal as well, which suggests a slight improvement in energy efficiency.

However, a closer look at the case of Morocco and Tunisia, since 2010 shows divergences. Thus the Decomposition of changes for the two countries between 1991 and 2019 for two equal periods was done and the results shown in Figure 2.

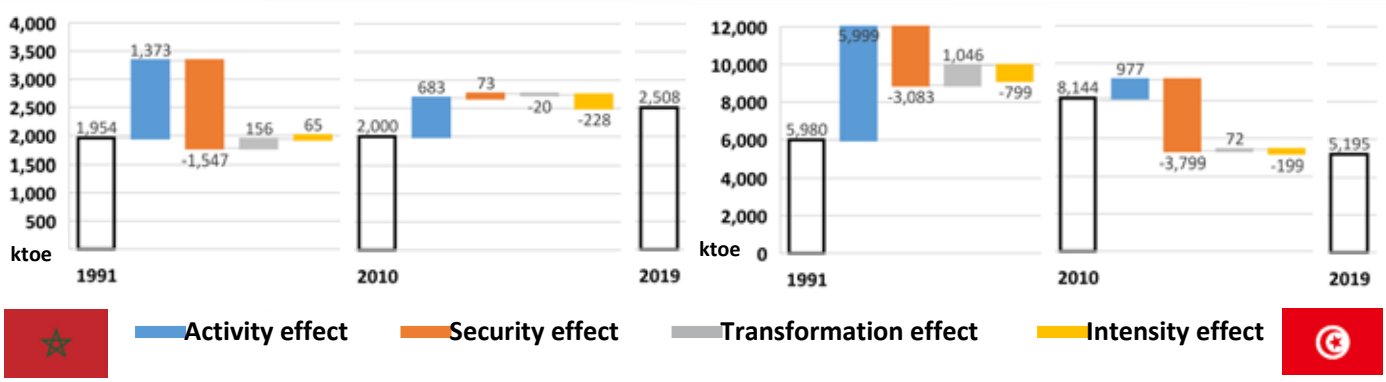

Fig. 2. Decomposition of changes in Moroccan and Tunisian primary energy production (ktoe) in 1991-2019 using the additive Logarithmic Mean Divisia Index approach (LMDI)

Fig. 2 shows that the impact of the spring Arab didn't go unnoticed in the case of Tunisia with the slowdown of the contribution of the activity effect to improve the energy system, which was worsened as well with an increase in imports translated by a negative effect of energy security on generation. Thus, all the gain between 1991 and 2010 on generated energy was canceled in the following 9 years.

The case of Morocco was to a certain extent less impacted by the Arab spring, more importantly, different policies that were taken to promote renewable energy reduced the balance deficit and reversed the energy security impact in favor of newly installed capacity. Moreover, this shift in technology as well allowed a noticeable reduction in energy intensity compared to the same previous period.

Energy demand

Concerning the final consumption balance per sector and source, Table 1 shows that oil demand is mainly driven by the transportation sector. However, differences could be noticed between the countries regarding the other sectors.
The industrial sector consumption is mainly fuelled respectively by electricity, oil, and natural gas.
For residential, services, and other sectors, the fuel mix priority highly diverges. Thus, it is mainly fuelled by electricity in Egypt, and oil in Morocco and Tunisia.
Finally comparing the final energy consumption and the total supply, energy efficiency averages 65.1 %, and varies to as high as 76.1 % in Morocco.

Table 2. *Energy final consumption balance for 2017*
** NG correspond to natural gas*
*** Other sectors include mainly household and services*

in ktoe		Final consumption balance for 2017					
		Electrcity	Biomass	Coal	Oil	NG*	Final demand
Egypt	Industrial	3,467	1,493	177	5,452	9,547	**59,206**
	Transport	50	0	0	17,900	283	
	Other**	6,436	0	0	0	0	
Morocco	Industrial	962	125	18	1,810	61	**15,091**
	Transport	30	0	0	5,511	0	
	Other**	900	0	0	0	0	
Tunisia	Industrial	466	0	0	881	786	**7,718**
	Transport	8	0	0	2,155	231	
	Other**	398	0	0	0	0	

CONCLUSIONS ON THE ROLE OF GREEN HYDROGEN

Looking back at the energy supply in the region for the last 28 years, oil has been and still is the main vector of the energy economy in Algeria and Libya, and the main imported source in Egypt, Morocco, and Tunisia.
So switching gradually to a sustainable energy vector-like hydrogen and its derivatives could be an economical added value for the last three countries, but as well a challenge for Algeria and Libya to transform their energy system, but as well adapt to their energy economy. However, its energy transformation could benefit mainly to increase lower efficiency

in the two countries. The sectoral analysis shows that importance should be given to decarbonizing the transportation sector as half of the oil and natural gas consumption is driven by transport. Thus, a first focus could be to finalize electrifying the rail system in the region and switching clean fuel alternatives in the public transport system. Most importantly, the focus is still first on the direct use of renewable electricity with alternatively hydrogen storage and thus upgrading and replacing existing coal and oil plants. Thus, a complementary analysis should focus on the power mix, and how to overcome the traditional centralized production without penalizing the level of access in the region. Moreover, an analysis of the industry sector-specific to each country should be undertaken to define the level of priority given to green hydrogen and the main used derivative (for instance ammonia for the fertilizer industry).

ABSTRACT

This paper discusses the development of future green ammonia supply chains in China with the theory of complex system engineering, taking account of technical system, actors and institutions in future energy systems featured socio-technical systems as a whole. The energy condition in China identified features a spatial imbalance between renewable energy supply and demand, which cannot be fully addressed by the current power system-centric solution. This calls for hydrogen to make a concerted effort in the energy transition. By comparing major hydrogen delivery options, we argue that green ammonia can play a feasible role for large-scale energy distribution and long-term energy storage. The development of green ammonia supply chains and direct use of ammonia are proposed to avoid large uncertainties and initial investment in the early stage. The market creation will be key in the supply chain development. A long-term bilateral contract between buyer and seller and a joint investment in an integrated supply chain by several stakeholders are advised to share risks and ensure capital recovery. In addition, government participation is crucial in the early development phase by setting regulatory and financial institutions to support the market creation and supply chain development.

Keywords: Hydrogen Economy, Green Ammonia, Supply Chain, China, Complex System Engineering

INTRODUCTION

China pushes towards peaking emission by 2030 and reaching neutrality by 2060 [1]. Investments in wind and solar energy grew significantly and accounts for one-third of the world's total capacity [2]. However, the divergence between installed capacity and renewable power generation grows due to the gird inflexibility and insufficient transmission [3]. Lately, China step a move to green hydrogen produced from renewable energy. Mid and long-term targets was set for achieving carbon reduction goals and supporting the energy transition [4]. In the upcoming hydrogen economy, green ammonia increasingly draws attention as a reliable and efficient means to storing and transporting hydrogen [5, 6]. Therefore, an assessment of the development of future green ammonia supply chains is necessary.

A review of current literature reveals that recent studies have paid attention to assessments of green ammonia supply chains. Most of them have discussed cases beyond China (e.g. see [7-9]), and a limited number of studies are in the scope of China (e.g. see [10]). Moreover, these studies concentrate on the techno-economic evaluation. However, modern supply chains comprise of technical infrastructure, actors, interactions, etc. [11]. No research has discussed socio-technical supply chains. This paper aims to analyze the development of green ammonia supply chains in China with the theory of complex system engineering.

The remainder of this paper is arranged as follows: the methodology of complex system engineering is introduced in Section 2. Section 3 discusses green ammonia to advance the energy transition in China, while Section 4 presents our conclusions.

METHODOLOGY

Energy transitions are defined as long-term structural changes in energy systems [12]. Today's energy system is essentially a supply chain, known as a socio-technical system, as it is not only a technical matter, values of individual actors, policies, regulations and markets also shape the system [11, 13]. Complex system engineering addresses not only challenges in technical dimension, but also multi-actor complexity of socio-technical systems [14]. The framework proposed in works [14, 15], which is improved from previous works [16, 17], identifies three key pillars in handling complex socio-technical systems, including: technical system, actors and institutions, as shown in Fig. 1. In general, technical system refers to technical components in energy systems; institutions are the devised rules, while actors are the entities making decisions and participating in the process; the connections emphasizes the interactions between each other that should be considered simultaneously. Actors build and operate technical systems, which in turn influence actors' decisions. Institutions such as: norms, strategies influence actor behaviours, which in turn reshape institutions. The theory is used to view system behaviours as a results of interactions between social and technical components of energy systems.

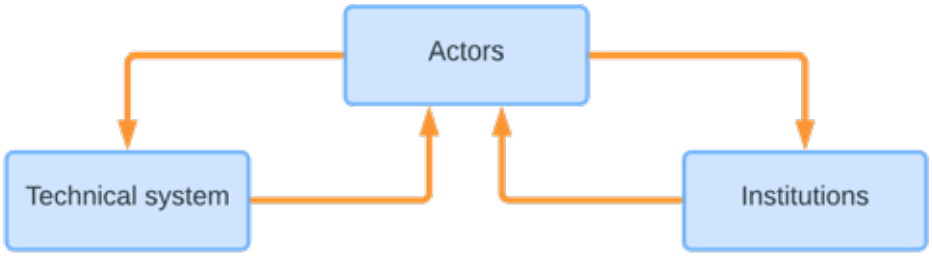

Fig. 1. Framework for analysing socio-technical systems

GREEN AMMONIA TO ADVANCE THE ENERGY TRANSITION IN CHINA

This section is discussed separately from the aspects of the energy condition in China, the current power system centered solution, and the development of green ammonia supply chains as follows.

The energy condition in China

China's economy still relies heavily on coal. The coal-dominant primary energy supply has made China the world's largest coal consumer and CO2 emitter [18]. The government targeted to phase out fossil fuel use by increasing the share of non-fossil energy in total energy consumption, in which, renewable energy is expected to play a key part [19]. China outpaces the rest of the world in wind and solar energy. The aggregate wind and solar generation capacity reached over 500 GW by 2020, and a massive renewable energy projects are in planning [20]. However, the energy condition in China presents an obvious spatial mismatch between renewable energy supply and potential demand, as shown in the Fig. 2. The aggregate wind and solar energy generation capacity in the north, northwest and northeast of China accounts for around 60% of the total capacity in China by 2020, thanks to the abundant renewable resources in these regions [20]. In contrast, economic clusters are generally located in the east and south of China. Therefore, large-scale and long-distance renewable energy distribution is fundamental to facilitating the energy transition in China.

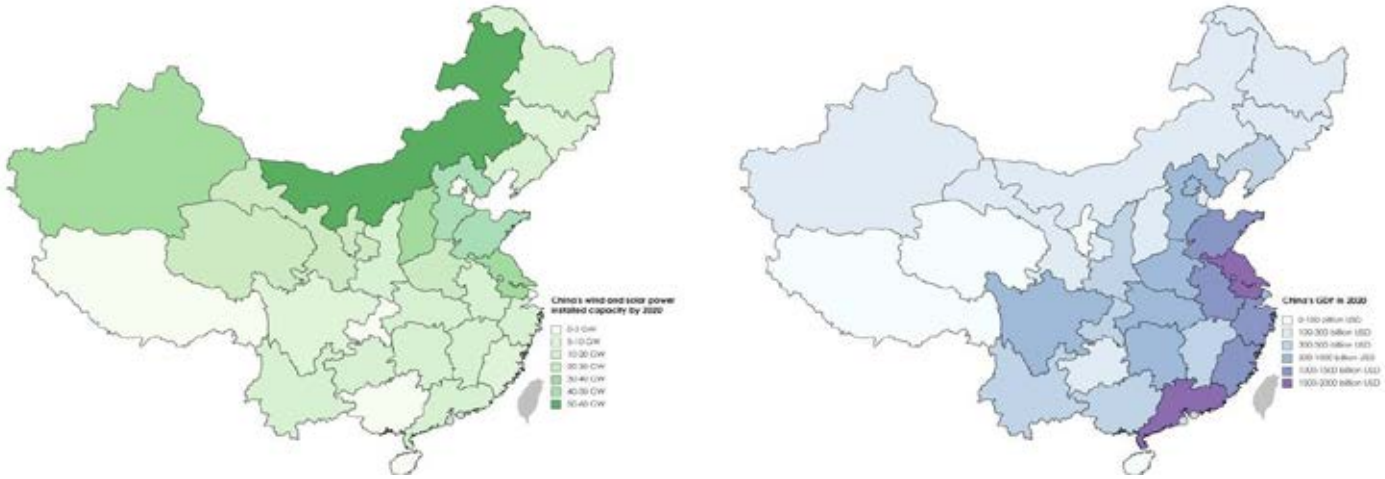

Fig. 2. Spatial mismatch between renewable energy supply and economic development

The power system centered solution

The spatial imbalance has led to serious renewable power curtailment, which declines the use of renewable energy. The further development of power system has been the focal point to address energy distribution and facilitate the energy transition declared in the 14th Renewable Energy Development Five Year Plan [21]. By 2020, China's national grid companies: China State Grid and China Southern Power Gird have built 20 ultra-high voltage lines to transmit renewable energy to load centers accounting for around 30% of total installed capacity of wind and solar energy, which is still not sufficient considering the fast expansion of renewable power bases in recent years [22]. Meanwhile, the intermittent power aroused challenges for grid integration that the overall operating rate of these lines was lower than 40% in 2019 [23]. Therefore, smarter power system is urgently needed by incorporating energy storage technologies. In addition, introducing market-based solutions is encouraged to eliminate institutional barriers.

The development of green ammonia supply chains

Meanwhile, these challenges also call for a concert effort. Revealed from the latest published 2021-2035 Hydrogen Development Plan of China, green hydrogen is expected to play a leading role for large-scale energy storage and long-distance energy distribution [4].

Fig. 3 shows hydrogen distribution costs we estimated for the most promising options. Although pipeline transportation appears to be the ultimate solution, distribution cost is influenced dramatically by volume and distance due to the high capital and operating expenses required. In contrast, liquid hydrogen and ammonia are more flexible options which have similar costs and limited influences by distance and volume. Ammonia defeats liquid hydrogen in terms of safe transportation and long-term storage due to much lower flammability and mild storage conditions [5, 6]. In addition, the transportation will be more efficient if ammonia can be directly used. Therefore, these advantages enable transporting hydrogen as ammonia a flexible, economical and safe option. Since infrastructure for ammonia is already in place due to a century of use in agriculture, the development of green ammonia supply chains and direct use of ammonia are proposed to avoid large uncertainties and significant initial investment in the early stage.

A supply chain comprises upstream production, midstream transportation and downstream wholesale and retail markets. The creation of green ammonia markets is essential in the development of future supply chains, given that green ammonia costs double that of grey ammonia [10]. Considering the large capital investments required in the infancy stage, the upstream and midstream with the participation of hydrogen producers, ammonia producers and ammonia transport operators can be operated with a joint investment to optimize the supply chain and reduce risks. Similar to the practices in renewable power generation [24], the creation of a long-term bilateral contracts between producer and consumer is proposed to share risks between both sides and guarantee investment recovery. Besides, government participation in the early stage is essential to support market creation and development of supply chains, e.g. incentivizing supply and demand, designing a clear and consistent regulatory framework, achieving ancillary policies, etc.

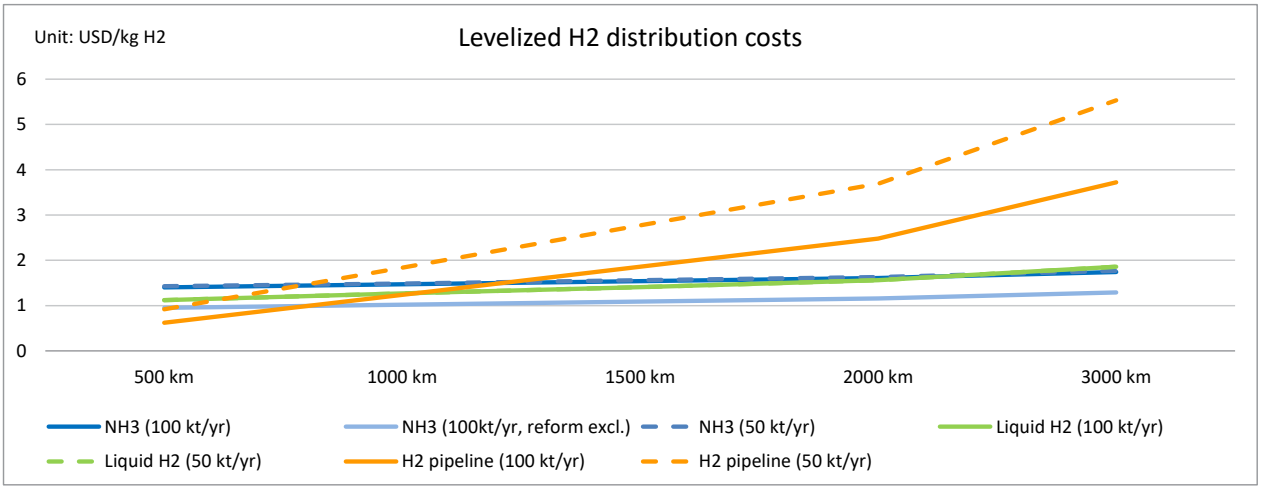

Fig. 3. Hydrogen distribution costs by distance and volume

CONCLUSIONS

Green ammonia is expected to play a key role in the transition to a hydrogen economy. The development of green ammonia supply chains to advance the energy transition in China was analyzed with the theory of complex system engineering. We considered the components of technical system, actors and institutions in the analysis of future energy systems featured socio-technical systems. We identified the spatial imbalance between future energy supply and consumption in China which cannot be fully addressed by the development of power systems. As a prospective hydrogen carrier, we argued that green ammonia can play a feasible role for large-scale energy distribution and long-term energy storage. The development of green ammonia supply chains and direct use of ammonia were proposed to avoid large uncertainties and significant initial investment in the early stage. Market creation will be key to the supply chain development. A joint investment in an integrated supply chain by several stakeholders and the creation of long-term bilateral contract between buyer and seller were also proposed to share risks and ensure capital recovery in the early phase. In addition, regulatory and financial institutions are essential to support supply chain development, which well requires government participation.

ABSTRACT

Contaminations in hydrogen have a strong impact on the long-term stability and thereby performance of proton exchange membrane (PEM) based fuel cells for mobile applications. While these influences have been intensively studied, particularly the purity of the hydrogen provided at public hydrogen refuelling stations (HRS) which is well-defined in ISO standards is rarely analyzed. We intend to take samples of hydrogen at HRS with a specially designed mobile refuelling module enabling the sampling at 70 MPa. With a method specifically developed and explicitly described in this paper, we seek to ensure that other sources of contamination can be excluded during the probe sampling. With analysis techniques able to determine concentrations of contaminants down to the parts per billion (ppb) level the hydrogen samples will be investigated in the laboratory. While single routes of contamination, such as the synthesis route, have been individually studied in detail elsewhere, the provision of hydrogen with different storage processes, as well as transport and compression at the HRS will be considered in these investigations as a holistic system. Finally, it can be stated whether the dispensed hydrogen meets the high-quality requirements of fuel cells for mobile applications.

Keywords: Contamination, Hydrogen Refuelling Station, Purity Analysis, Hydrogen Sampling

INTRODUCTION

Establishing sustainable and cost-optimized options for the energy supply is a key task during the energy transition process from fossil to renewable energy generation of the coming years. Particularly in the transportation sector, locally emission-free vehicles are attracting more and more attention in urban areas. In addition to battery electric vehicles (BEV), the fuel cell electric vehicle (FCEV) powered by hydrogen offers the option for zero emission driving with fast refuelling capability even for long range travels [1]. The needed hydrogen can be synthesized by a variety of methods; up to now it is produced mostly by steam reforming of natural gas. For emission-free fuel cell mobility, however, the production of hydrogen via electrolysis plants using renewable energy sources is needed [1]. For the provision of inter-seasonal energy storage of green hydrogen, salt caverns can be used to store relevant amounts of energy also for the other energy sectors. Stationary fuel cells can consequently use the chemically stored energy in hydrogen to balance seasonal fluctuating power generation sources as needed [2, 3]. It is known that contaminants or noxious gases in hydrogen are responsible for numerous degradation modes within the fuel cell [4, 5]. To avoid damage processes initiated by these compounds, international standards for the quality of hydrogen set precise limits for contaminations present in hydrogen. These are namely SAE J2719, ISO 14687 and EN 17124 [5, 6]. The simultaneous analysis of all contaminants in hydrogen is not trivial due to the very small concentrations in the low ppm and ppb range. The high purity requirements are not only barely measurable with a single method at the same time, but also the influences of the supply chain to the HRS or storage of hydrogen in salt caverns are little studied as an integral system.

For the investigation of hydrogen in the ppb range at HRS only a couple of devices for sampling at 70 MPa exist. Furthermore, there are also no general protocols available for the contamination-free sampling of hydrogen. Especially for sampling on a kilogram scale at 70 MPa, transport to the site of the analysis poses a challenge since no conventional gas cylinder can be used. In this study, a hydrogen sampling method was developed and used for hydrogen quality analysis. Extensive investigations on influencing parameters will be carried out and finally, estimated whether the hydrogen provided at public refuelling stations meets the purity requirements of the fuel cells.

EXPERIMENTAL

For the sampling of hydrogen at HRS a high-pressure hydrogen tank (shown in Photo 1) similar to that in fuel cell vehicles is used. With this tank, it is possible to use the standardized dispenser at public HRS to carry out a non-communicative refuelling according to the standard SAE J2601 [7]. With up to 70 MPa, this 37-liters carbon woven pressure vessel can be filled with hydrogen. Temperature, pressure and flow sensors are included to monitor these parameters. The fuel sampler does not contain an infrared communication interface and due to the small tank volume, the non-communication filling method specified in the mentioned protocol of the HRS is automatically used. A procedure has been developed to ensure that the refuelled hydrogen and the subsequent analyses of the contaminants are referable to the so-sampled hydrogen. In that regard, the first kilogram of hydrogen is fuelled and subsequently, the

tank is carefully emptied. We make sure that the hydrogen released to air is in a safe distance from possible ignition sources. The described procedure ensures that ISO 14687 and EN 17124 targeted constituents [5] will be removed from within the module and sampling lines [8]. Especially residues of water and sulfur components are avoided thereby. Finally, the module is refuelled with the amount of hydrogen necessary for the analysis.

Photo 1: Composite type IV high-pressure tank with receptacle for sampling of hydrogen at hydrogen refuelling stations.

For investigating the purity of hydrogen, a high-performance gas analyzer from the company V&F of the type AirSense will be used. The measurement principle is based on Ion-Molecule Reaction mass spectrometer (IMR-MS) and allows determining the concentrations of many contaminations in the parts per trillion (ppt) range. IMR means the use of an ion source for primary ions (e.g. Xe^+) with a particularly low energy level of 10 to 14 eV to completely ionize the gas sample. Without molecule fragments and interferences, the quadrupole mass filter separates the molecules for further detection at the fast pulse counter. [9] Even the smallest entrained impurities affect the actual quality of the hydrogen so any contamination of the sampled gas has to be avoided by an accurate selection of the materials and transport lines used. For the supply of hydrogen with concentrations of contaminants in the ppb range from the refuelling module to the gas analysis, conventional stainless steel tubes or PTFE lines cannot be used, as particularly contaminants with amounts of sulfur or ammonia adhere on the walls of the lines and tubes. Significantly more meaningful alternatives are hoses made of perfluoroalkoxy alkane polymer (PFA) or stainless steel tubes, which are coated with inert non-reactive silicon [10]. Due to the flat surface and the avoidance of interactions between the material of the tube and the contaminant, stable measurements of the concentrations are reached much faster [10].

RESULTS

Since we are still at the beginning with the investigations described above, results obtained are not presented in the following. Instead, an outlook on the results is depicted below. Selected HRS in Germany will be approached and hydrogen will be sampled with the mobile tank. Some HRS are supplied with hydrogen from steam reforming of natural gas via delivery by a trailer; others produce the hydrogen directly at the refuelling station by on-site electrolysis without necessary use of trailers. Thus, by investigating the hydrogen with the gas analysis in the laboratory a dependency of the manufacturing processes on the purity can be expected. Especially hydrogen produced by on-site electrolysis is likely to have only minor contaminations, e.g. in the form of water and oxygen [10, 11]. In contrast, hydrogen produced by steam reforming is expected to have significantly more contaminants, primarily considering the amount of total organic carbon (TOC) and inert gases, e.g. nitrogen [10, 11]. Since carbon dioxide and carbon monoxide are additional products in the steam reforming process, at least small concentrations in hydrogen after the mandatory purification with pressure swing adsorption are also anticipated here. By comparing the supply of hydrogen to the HRS, a negative impact from transport can probably be found. Further estimated influencing factors will also be identified, such as dependencies of the refuelling station's year of construction or the technology supplier (Linde, Shell, etc.) on the quality of hydrogen. The latter is also associated with a probably important parameter of the type of compression. Especially in reciprocating compressors and compressors working with ionic liquids an influence on the purity is expected.

Another factor influencing the purity of hydrogen is the inter-seasonal storage. In particular, the storage of hydrogen in salt caverns offers many unknown parameters, which give so far unconsidered possibilities of entrained contaminants. Due to the humid, alkaline environment with the brine present in the bottom of the cavern, the hydrogen stored under high pressure will come into contact with numerous ionic compounds. Besides, full saturation with water (designated contaminant in ISO 14687) is a reasonable consequence of the storage. Another path of contamination is the formation of methane by bacteria. These methanogenic bacteria convert carbon dioxide or carbon monoxide with hydrogen according to Sabatier’s reaction into methane and water [12].

Concerning all the above-mentioned paths of contamination, it is fairly obvious that examining the ongoing processes, e.g. synthesis route and compression separately is not an all-encompassing approach. Moreover, it is essential to consider the provision of hydrogen at the HRS with the numerous influencing factors as a holistic system.

CONCLUSIONS

By studying the quality of hydrogen provided at hydrogen refuelling stations, it will be estimated whether the purity of the hydrogen meets the high-quality requirements of mobile and stationary fuel cell applications. For this, extensive considerations for contamination-free sampling at 70 MPa with a specially designed mobile refuelling module were established. With a highly accurate trace gas analysis, the probed gas samples are to be investigated in the laboratory regarding critical components for fuel cells. Detection of contaminants in the ppb range is challenging but feasible by a reasonable selection of used materials (e.g. silicon-coated stainless steel tubes). As a result of the analyses, dependencies from the production process on the quality will be highlighted. Only minor contaminations are assumed to occur in hydrogen produced via PEM water electrolysis. However, further influences from the transport of hydrogen and the inter-seasonal storage in salt caverns will similarly be considered.

ABSTRACT

This work addresses the potential of hydrogen injection into the transmission high pressure natural gas grid as way to decarbonise the gas system and gas uses. To achieve this potential, knowledge gaps have to be covered considering the current know-how on how different concentrations of hydrogen gas could affect the infrastructure and its components. The activities are developed within the frame of HIGGS (FCH 2JU funded project, No. 875091). An R&D platform working at high pressure has been developed in HIGGS to achieve advance the knowledge on operation of hydrogen admixtures in the high-pressure natural gas grid, simulating the operational conditions from selected equipment, gas quality, etc. The admixture levels consider various hydrogen concentrations until reaching pure hydrogen. So far, the impact of H_2/NG blends with up to 20 %vol H_2 on steels and equipment has been studied through a mechanical and chemical characterization after been exposed to the blend. Membrane technology has also been tested for hydrogen recovery, using a Pd-based membrane prototype installed in the platform.

Keywords: Admixture, H_2 Injection, Power to Gas, Gas Transmission, Decarbonisation.

INTRODUCTION

The Paris Agreement aims to limit global temperature increase and requires a global deep decarbonisation of many sectors of the economy. Nowadays, the European Union (EU) is updating its energy policy framework to facilitate the clean energy transition, introducing the national energy and climate plans, encouraging investments and empowering the EU consumers to become active players in the energy transitions. The new policies and the revised renewable energy directive [1] are fixing ambitious targets for 2030: renewable energy target of at least 32% and an energy efficiency target of at least 32.5%. When the policies are fully implemented, they will lead to a great reduction on emissions for the whole EU. The EU framework towards greenhouse gases (GHG) emissions reductions is based on six key areas of action, including the deployment of renewable energy production, decarbonising heating and cooling applications, and reducing the emissions on the transport sector. Therefore, the integrated energy markets in the EU shall allow important transformations to provide more flexibility and be better placed to integrate a greater share of renewable energies, allowing also a more independent energy system. In this context, hydrogen can play a pivotal role as energy vector allowing coupling the energy sectors and as an alternative fuel in hard to electrify sectors. To facilitate that a high amount of hydrogen is produced by renewable energies (RE), existing gas infrastructure could be a way of transporting hydrogen between production point and final use.

This is precisely the main goal of the HIGGS project “Hydrogen in Gas Grids: A systematic validation approach at various admixtures levels into high-pressure grids” The HIGGS project, which is funded by the Fuel Cells and Hydrogen Joint Undertaking (GA No. 875091) is a collaborative project involving four research institutions, a technical-scientific association and a transmission system operator (TSOs). HIGGS’ main objective addresses the potential of hydrogen injection into the transmission high pressure natural gas grid, as way to decarbonise the gas system and gas uses, and one of its most important tasks is the design and development of a R&D platform for the experimental validation of components of grid. To achieve this potential, knowledge gaps have to be covered considering the actual know-how on how different concentrations of hydrogen gas could affect the infrastructure and its components. Specific technical objectives are defined as intermediate goals in order to achieve the strategic objective:

1. Implement of an injection and admixture system.
2. Test gas separation systems based on membrane technology.
3. Design/execute a testing loop to validate components and materials identified.
4. Elaborate an impact assessment document (operation, maintenance procedures).

The present abstract explains the design and operation of this R&D platform (see Figure 1), an innovative system to advance the knowledge on operation of hydrogen admixtures in the high-pressure natural gas grid, with varying conditions, simulating the operational conditions from selected elements, components, gas quality, etc., to simulate conditions that differ at EU level. The first results of the tests performed with this platform are also explained, focusing on the characterization of materials after hydrogen exposure and gas separation tests with membrane technology.

Figure 1. Picture of the R&D platform developed in HIGGS

METHODOLOGY

HIGGS approach is based on implementing a project vision that allows the systematic validation systems and components, typically present in high pressure gas grids. The R&D platform consists in an admixture system, a testing platform (test loop) and a gas separation prototype. It is designed with a capacity of injecting over 5 kg/h H_2 at 80 bar to retrieve information on the impact of hydrogen in the transmission gas network equipment and deal with deblending issues to recover the injected hydrogen in end-uses. The admixture system produces the blend to study. Flow controllers and pressure regulators ensure the preparation of the blend with the desired composition at low pressure (15 bar), which is afterwards compressed up to 200 bar and stored in a buffer that feeds downstream the different parts of the testing platform (i.e. gas injection).

Figure 2. Pictures of the dynamic (left) and static section (right) of the testing platform

The testing platform allocates representative components that can be found in the transmission grid, as well as pipes of different API 5L steel grades. It considers two different sections: i) A static section, where leakages and hydrogen permeance is tested in components (valves of different nature) and connections (threaded joints, flanges, etc.) and ii) a dynamic section, where materials and components failure/degradation is investigated. In all cases the setup is pressurized up to 80 bar, a pressure level present in transmission gas grids. In the static section there is no flow of gas. The lines are pressurized and closed afterwards, and pressure drop and gas quality are then monitored during the tests. In the dynamic section, however, the gas flows through several branches in a closed-loop system using a compressor and a regulator to create the pressure difference in the setup (driven force). The different lines contain several steel grades, and typical components of the transmission gas grid (filters, flowmeters, flow regulators…). The steels considered for the tests range from API 5L X42 to X70. They are fresh materials incorporated in the platform as welded pipes and as strained specimens that will be allocated inside a pig trap for hydrogen exposure at high pressure.

During the experimental campaign, various hydrogen/natural gas admixtures will be investigated. The natural gas used is a “simplified gas” based on the use of methane as carrier mixed some common impurities in natural gas, such as

hydrogen sulfide or carbon dioxide. This simulated natural gas follows the gas quality according to the agreed standards in the trans-European gas grid. Pure hydrogen will also be injected in the setup, covering the most likely injection scenarios thought for the near future in the European gas grid. The testing campaign consists in exposing the testing material to the hydrogen blend at high pressure for several months. So far H_2/NG blends with up to 20 %vol H_2 have been studied and the effect of hydrogen on the steels and main elements of the equipment has been checked at the laboratory after dissembling them from the platform. Finally, to meet cases where users cannot accommodate the presence of hydrogen, test separation systems have been studied. In this regard, membrane technology has been tested for hydrogen recovery from H_2/CH_4 mixtures with a hydrogen content ≤ 20% and at a pressure of 40-80 bar, using a Pd-based membrane prototype installed in the R&D platform.

RESULTS AND DISCUSSION

HIGGS started 01/01/2020. The Project has a duration of 36 months and a budget of 2 million Euros from European Funding. To evaluate how different degrees of natural gas and hydrogen mixture behave in relation to the transport infrastructure, simulating different operating conditions by varying the flow, composition and quality of the gas, a testing platform has been developed at the facilities of the FHa where all the elements are tested up to 80 bar. The design and selection of components for the testing facility, the developed membrane technology and the preliminary project's results during the first months of the experimental campaign will be shown at the conference.

So far, 20 %vol H_2 blends in natural gas have been studied and the impact of hydrogen on steels and components have been ascertained. This has been achieved by disassembling the testing components in the platform (steel pipes, joints, seals, etc.) and performing characterization tests at the laboratory, including visual inspection for crack detection, mechanical tests (e.g. tensile strength test) and chemical characterization. The leakage rate of hydrogen through components has also been monitored, obtaining meaningful graphs that explain the tightness of the natural gas components for the new gas conditions. Results on gas separation consist in monitoring the composition of the permeate stream (i.e. the stream rich in hydrogen) by gas chromatography to asses the quality of the separation during the test.

CONCLUSIONS

HIGGS project, funded by the Fuel Cells and Hydrogen 2 Joint Undertaking (FCH 2JU) under Grant Agreement no. 875091, aims to pave the way to decarbonisation of the gas grid and its usage by hydrogen injection. The R&D platform developed in the project will help to perform experiments with materials and equipment present in the transmission gas grid to check their readiness for the transport of hydrogen in the near future. So far, blends with 20% vol hydrogen content has been tackled and the suitability of membrane technology to recover the hydrogen blended in end-uses has also been studied, showing promising results for understanding how prepared the natural gas grid is for the new tendencies of the market.

ACKNOWLEDGEMENT

This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking under Grant Agreement No. 875091. This Joint Undertaking receives support from the European Union's Horizon 2020 Research and Innovation programme, Hydrogen Europe and Hydrogen Europe Research.

SOLENCO POWER: HYDROGEN FOR THE DECARBONIZATION OF THE ENERGY SECTOR

[1] *Hugo Vandenborre*, [1*] *Francisco López*
[1]Solenco Power NV, Slachthuisstraat 112 box 2 - 2300 Turnhout, Belgium

*Corresponding author e-mail: francisco.lopez@solencopower.com

ABSTRACT

Solenco Power NV (SP) is a fast-growing Belgian SME active in the energy storage sector, with systems that combine generation, storage, and usage of pressurized hydrogen. SP was founded in 2015, as a spinoff of Vandeborre Energy Systems NV, company with an extensive career in the hydrogen sector. SP was launched having as a first objective, the commercialization of an integrated hydrogen solution capable of absorbing excess of a renewable energy sources, when available, for hydrogen generation, store that hydrogen in a pressurized form for unlimited periods and use that hydrogen for the cogeneration of electricity and heat, when needed. For reaching that objective, since its foundation SP has matured this concept towards a product called Solenco Powerbox (SPB) [1] and its certification.

Keywords: Renewable Energy, Energy Storage, Seasonal Storage, Hydrogen, Proton Exchange Membrane.

INTRODUCTION

The SPB is the first commercialized product of SP. It is targeting residential, commercial, and industrial installations. At is inception, the SPB was conceived as a system to be primarily integrated in households due to the growth of solar photovoltaic (PV) installations, coupled with homes, and the imperative need of both, electricity and heat. These characteristics and energy profiles of the residential sector made a perfect match with SPB's inputs and outputs. Electricity generated by the Solar PV will be directly consumed by the users. All the surplus of that production, instead of being injected to the grid, will be used for the electrolysis of water inside the SPB. Through that electrolysis process, water will split in oxygen, safely release to the atmosphere and hydrogen, which will be pressurized in certified cylinders as a renewable energy storage. When the users will require electricity, hydrogen will be used as a fuel for the fuel cell process, cogenerating electricity and heat. The complete process describes an installation with two main pillars, firstly the SPB or power unit and the renewable hydrogen storage or energy unit. Since power and energy are decoupled, SP installations based on the SPB can adapt their energy capacity in function of user requirements. This flexibility has allowed SP to mature the SPB not solely as home solution, but rather as product for the residential, commercial, and industrial sector.

MATERIALS AND METHODS

The process of shaping SPB's concept into a prototype, towards a commercialized product, has had as an outcome several generations of the same. Those intermediated steps were fundamental for the complete definition of the system, components, and processes part of the SPB. In general lines, all starts with renewable electricity and water as inputs for the SPB. The intermediate output is pressurized hydrogen, and the ultimate outputs are electricity and heat. Through out that chain, several processes like electrical rectification, inversion and conversion, water deionization, water heat exchange and electrochemical water and hydrogen oxidation. Moreover, those processes must be monitored and controlled for their optimal execution.

RESULTS AND DISCUSSION

During the development of the SPB, SP's team went through four generations where the processes mentioned above were steadily integrated across each generation for the completion of the technology readiness level (TRL) 9. Several of the described steps and milestones accomplished by the Solenco's team were supported by national and European projects [2] [3]. In the full paper, the four generations will be described, including field tests.

ABSTRACT

The European Union and the Japan Science and Technology Agency awards 2.9M€ to 4AiCRAFT “Air Carbon Recycling for Aviation Fuel Technology”, for helping the aviation sector to reach the EU 2050 climate-neutrality targets.

4AirCRAFT, a H2020 funded project in International Cooperation with Japan for Research and Innovation on alternative renewable fuels, offers a novel cascade reactor for sustainable aviation fuel synthesised from H_2 and CO_2. The conversion to high-density hydrocarbons will be achieved at mild conditions and based on an intensified cascade reactor.

Key to the process is the combination of highly efficient electro-, chemo- and bio- catalysts. Synergy between hybrid catalysts which are selectively embedded within advanced porous carriers including hierarchical scaffolds are expected to raise selectivity and energy efficiency. In this project the technology readiness level is raised from TRL 2 to 3.

Keywords: Hydrogen-Based Fuels, Sustainable Fuel, Jet Fuel, Cascade Synthesis, Process Intensification.

INTRODUCTION

Climate change and the resulting global environmental threat are the main drivers for the efficient use of resources and transition to renewable energy sources. For this reason, researching alternative renewable fuels for transport sector by moving to a clean and circular economy constitutes, currently, one of the main priorities in Europe long-term ambitions for a better society. To achieve the overarching objective of “Climate neutrality” by 2050, the European Commission set up two years ago the Green Deal Commitment [1].

Aviation is a strong sector for the European Union’s economy and an increasingly important means of transport for EU citizens and businesses. However, as a capital-intensive industry characterised by a high-dependence on a global supply of energy-dense fuels, greenhouse gas (GHG) emissions due to aviation industry account for 13 % of the emissions for transport [2] emitting more than 900 million tons of CO_2 per year. [3] Therefore, energy transition should break the link between economic growth and GHG emissions. However, aviation is one of the most challenging sectors when it comes to reducing CO_2 emissions. One of the reasons it that common alternatives such as electrification or hydrogen propulsion are not expected to be a suitable substitute to kerosene for long haul flights in a short period of time. Therefore, sustainable production and use of low-carbon footprint alternative fuels produced from non-fossil resources could be a key skeleton to unlock “net zero” flying in the near term.

Alternative fuels synthesis by process intensification for hydrogen as feedstock and carbon dioxide conversion technologies along more energy-efficient processes can substantially contribute to mitigating the current and future impact of aviation on the environment. The combination of hydrogen production by renewable sources with recycling carbon dioxide from various sources leads to a renewable synthetic fuel with low carbon footprint, as illustrated in Figure 1.

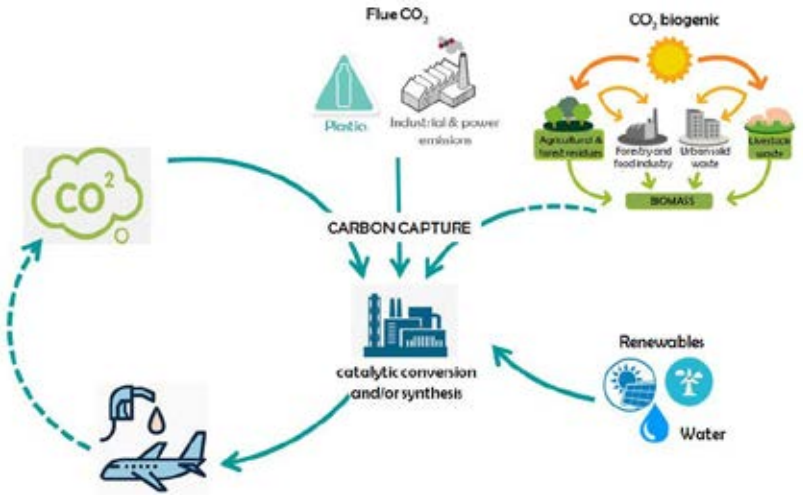

Fig. 1. CO_2 conversion cycle for sustainable production of jet fuel.

Launched in May 2021, the EU-JAPAN-BRAZIL cooperation will enable the development and prof of concept of the disruptive concept for jet fuel direct production.

4AirCRAFT's ultimate goal is to develop a next generation of stable and selective hybrid catalysts for the direct CO_2 and H_2 conversion into C_8-C_{16}. 4AirCRAFT will overcome the current challenges by combining three main reactions into one cascade reactor to increase the CO_2 conversion rate and simplifying the process. By achieving this we will be able to circumvent the need for further steps for hydrocracking or hydrorefining of Fischer–Tropsch waxes.

4AirCRAFT technology aims to deliver a highly innovative process which produces alternative fuel at mild conditions and high energy efficiency, reducing energy consumption and contributing to a circular economy, leading to a decrease in greenhouse gases emissions and reduced dependence on fossil fuel-based resources.

In summary, 4AirCRAFT combines hybrid catalytic conversion and process intensification to bring out an efficient, precise, flexible and scalable unique technology to direct convert water and recycled CO_2 into sustainable and clean liquid fuels, thus making flying carbon neutral.

RESULTS

4AirCRAFT moves beyond the state-of-the art by precisely integrating and taking advantage of biocatalysts, inorganic nanocatalysts, electrocatalysts, and their controlled spatial distribution within application tuned catalyst carrier structures. These catalyst carrier structures are based on metal-organic frameworks and engineered inorganic scaffolds with hierarchical porosity distribution. This will unravel the activity of catalytic active phases and materials based on earth-abundant elements allowing us to achieve high CO_2 conversion percentages and selectivity towards jet fuels.

In terms of inorganic catalysts, size and shape of metal NPs, metal clusters, and single atoms at the surface of catalyst carrier structures are being developed, and precise structure-performance-selectivity relationships will be established.

In terms of biocatalyst, special emphasis is given to assure the long-term stability of deployed enzymes through programmed anchoring and shielding from detrimental reaction conditions. Together application tuned catalyst carrier structures will be employed to steer selectivity towards C_8–C_{16} molecules.

CONCLUSIONS

4AirCRAFT project aims to pave the way to decarbonisation of aviation sector by developing alternative sustainable fuels. The 4AirCRAFT technology uses an innovative catalytic reactor which will be validated at lab scale to conduct the conversion in: a) precise synthesis and high yield of jet fuel and b) unprecedented low temperature.

ACKNOWLEDGEMENT

This project has received funding from the European Union's Horizon 2020 research and innovation programme under Grant Agreement No 101022633. This work is supported by Japan Science and Technology Agency (JST) under Grant Agreement No JPMJSC2102. This project is developed in the frame of a Mission Innovation Challenge.

ABSTRACT

This paper presents the results of an international collaboration on the analysis of the production of green hydrogen for a fleet of fuel cell electric vehicle mining trucks for use in a remote open-pit copper mine in Peru. For this research, HOMER Pro® microgrid software was used to simulate, optimize, and analyze the renewable energy system integration into the operation of fueling a fleet of 300-tonne mining trucks for the copper mine based on a 30-year life of the remote mine. The optimization results shows that the electrolyzer provided a mean output of 29.4 kg/h per truck for an operational schedule of 8,097 h/y with 46.4 kWh/kg specific energy. The system architecture of the green hydrogen production microgrid includes wind turbines, AC-DC bidirectional power converters, a battery energy storage system, electrolyzers, and compressed hydrogen storage tanks. The two loads were the electric load for the balance of plant and the hydrogen load to fuel the fleet of mining trucks. To meet the two loads, the optimized microgrid powered one 1,505 kW electrolyzer having a specific energy of 46.4 kWh/kg resulting in a mean hydrogen output of 29.4 kg/h to fuel one 300-tonne mining truck.

INTRODUCTION

This paper presents the results of an international collaboration between Purdue University, the University of Engineering and Technology (UTEC), and the National University of Engineering (UNI) in Lima, Peru. The focus of this international research collaboration was on the production of green hydrogen to fuel cell electric vehicle (FCEV) powertrain for open-pit mining trucks [1] for use in a remote copper mine in Peru. The mining industry accounts for 60% of Peru's exports and Peru is the world's 2nd largest producer of copper, silver, and zinc. New to mining in Peru, Anglo American has the potential to help Peru transition to a hydrogen economy. To help the energy transformation needed by the mining industry in Peru, the authors are developing new workshops using Game Based Learning (GBL) to navigate the complexities of the emerging clean energy systems and understand the full potential of green hydrogen as a key enabler for the energy system transition to a sustainable future.

Recently the Hydrogen Council, a global CEO-led initiative of 120+ leading companies with a united vision and long-term ambition for hydrogen to foster the clean energy transition for a better and more resilient future, published their report *Hydrogen Insights* [2]. This report presented a Total Cost of Ownership (TCO) analysis of a 300-tonne open-pit mining truck used in operations in Chile with 6,200 operational hours per year and a lifetime of 12 years, based on the truck power requirements of approximately 2,000 kW comparing conventional diesel fueled engines, hydrogen fueled engines with mechanical drive and hydrogen fuel cell electric-drive powertrains. The *Hydrogen Insights* report showed that the FCEV mining truck has a TCO breakeven with both other powertrains before 2030. Hence, mining companies are transforming. For example, Anglo American, plans to replace their entire global fleet of 400 diesel-engine, mechanical-drive mining haul trucks with hydrogen fuel cell electric-drive mining trucks over a ten-year period as part of their ambition of achieving carbon neutrality by 2040.

For this paper, HOMER (Hybrid Optimization Model for Multiple Energy Resources) Pro® microgrid software was used to simulate, optimize, and analyze the renewable energy system integration into the operation of the hydrogen fueling of a fleet of 300-tonne mining trucks for the copper mine based on a 30-year life of the remote mine [3-4]. HOMER Pro® provides insight into the complexities and trade-offs of designing cost-effective, reliable microgrids. The renewable electricity for this copper mine is provided from the Punta Lomitas wind farm. The system architecture of the green hydrogen production microgrid modeled by HOMER Pro® includes land-based wind turbines [5-7], advanced AC-DC bidirectional power converters, advanced battery energy storage system, proton exchange membrane (PEM) electrolyzer, and compressed hydrogen storage tanks. The two loads were the electric load for the balance of the plant and the hydrogen load to fuel the fleet of FCEV mining trucks. To meet the two loads, the optimized microgrid powered one 1,505 kW electrolyzer having a specific energy of 46.4 kWh/kg resulting in a mean

hydrogen output of 29.4 kg/h to fuel one 300-tonne FCEV mining truck. Figure 1 illustrates a HOMER Pro® microgrid schematic diagram of the green hydrogen production for the fleet of FCEV mining trucks at the remote copper mine in Peru.

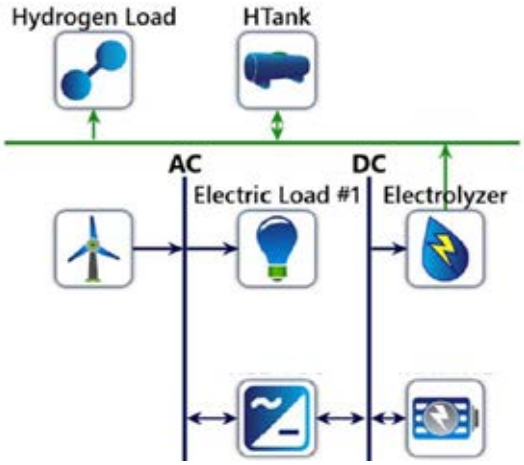

Fig. 1. HOMER Pro® microgrid schematic diagram of green hydrogen production for FCEV mining trucks

ANALYSIS

The HOMER Pro® microgrid software was used to analyze the feasibility of green hydrogen production using wind energy in Peru to support the fueling of a fleet of FCEV electric-drive mining trucks at a large, new, remote, copper mine. The results of this optimization analysis show the selected sizes of the microgrid components in Table 1.

Table 1. Microgrid Components

Component	Size	Unit
Li-Ion batteries	4.0	MWh
Punta Lomitas wind farm	260	MW
AC-DC converter	2,175	kW
Electrolyzer	1,505	kW
Hydrogen tanks	3,900	kg

Table 2 provides the performance parameters of the set of 1.5 MW PEM electrolyzers. Hence, each electrolyzer is dedicated to fuel a single 300-tonne mining truck. These electrolyzers have a specific power of 46.4 kWh per kilogram of hydrogen. The annual green hydrogen production per electrolyzer is over 250 tonne per year with a mean hourly production rate of 29.4 kg based on a 90.5% capacity factor.

Table 2. Electrolyzer Performance Parameters

Electrolyzer	Value	Unit
Mean output	29.4	kg/h
Minimum output	0	kg/h
Maximum output	32.4	kg/h
Total production	257,191	kg/y
Specific energy	46.4	kWh/kg
Rated capacity	1,505	kW
Mean input	1,362	kW
Minimum input	0	kW
Maximum input	1,505	kW
Total input energy	11,935,030	kWh/y
Capacity factor	90.5	%
Hours of operation	8,097	h/y

CONCLUSIONS

The conclusions of this optimization study show the feasibility of a microgrid powering the production of green hydrogen to fuel a fleet of FCEV mining trucks for use in a remote open-pit copper mine in Peru. HOMER Pro® microgrid software was used to simulate, optimize, and analyze the renewable energy system integration into the mining operations by selecting 1.5 MW PEM electrolyzers to fuel the fleet of the 300-tonne mining trucks. These electrolyzers have specific power ratings of 46.4 kWh per kilogram of hydrogen, each producing over 250 tonnes of green hydrogen annually.

ABSTRACT

Hydrogen is indispensable for decarbonisation through the expansion of renewable energy as its energy carrier. The organic chemical hydride method is key technology of hydrogen carrier to store and transport hydrogen under normal temperature and pressure in the liquid form by incorporating hydrogen atoms into the molecular structure of liquid organic hydrogen carrier (LOHC). Chiyoda started the development of innovative catalyst technology of LOHC method to establish hydrogen supply chain system since 2002, named "SPERA Hydrogen™" and the system has successfully demonstrated the international massive hydrogen supply chain from Brunei Darussalam to Japan in 2020. It is the only system that has completed the international demonstration of the entire value chain from production to utilization, and has moved to the commercialization stage. This system enable to storage and transport hydrogen safely, economically with its proven technology and existing petroleum infrastructure, and also has a high potential for cost reduction towards the future.

Keywords: Hydrogen, Storage, Transportation, LOHC, SPERA

INTRODUCTION

Expanding the use of renewable energy is essential for the decarbonization, and the role of hydrogen, which can be used as a clean energy and feedstock converted from primary energy including renewable energy, is indispensable. In order to expand the use of hydrogen, technologies that can "store" and "transport" hydrogen on a large scale are essential, as similar as fossil fuels such as oil and natural gas. The method of liquid organic hydrogen carrier (LOHC) enable to store and transport hydrogen under normal temperature and pressure in the liquid form by incorporating hydrogen atoms into the molecular structure of LOHC, with safe and lower risk .

Chiyoda started the development of innovative catalyst technology of LOHC method to establish hydrogen supply chain system since 2002, named the system "SPERA Hydrogen™" and the system has successfully demonstrated the international massive hydrogen supply chain from Brunei Darussalam to Japan in 2020[1)]. It is the only system that has completed the international demonstration of the entire value chain from production to utilization and has moved to the commercialization stage. In addition, the organic chemical hydride method, which uses LOHC as a hydrogen carrier, is a chemical method that allows for innovative technological improvements such as simplification of the process to integrate with hydrogen production or its demand applications. Those will lead the system to have a high potential of cost reduction towards the future. In this presentation, we will introduce the outline of this method, key features of "SPERA Hydrogen™" system as well as the efforts toward its commercialization.

SPERA HYDROGEN SYSTEM

Hydrogen is reacted with toluene (TOL) to produce methylcyclohexane (MCH), which is a liquid with hydrogen in its molecule enables that hydrogen to be "stored" and "transported" in a liquid form at normal temperature and pressure. Hydrogen can be generated at the place of use through dehydrogenation reaction. TOL is recycled and used repeatedly. Figure 1 shows scheme of SPERA Hydrogen System.

KEY FEATURES

TOL and MCH are used in household paints and correction pens, non-corrosive, low toxicity, and easy to operate. TOL and MCH are chemically stable substances, energy loss is extremely low even when stored in a large-scale for a long period of time since storage condition is under ambient temperature and pressure. Key features of this technology are,

i. **Safest method** for mass H2 storage and transportation, and easy to handle
ii. **Proven technology** and ready for commercialization
iii. **Largest cost reduction potentials**, including utilization of existing infrastructure and chemical process

Hydrogen can be also stored as national stockpiling. Using common MCH for both in large-scale and small-scale that makes it possible to establish a total and inexpensive hydrogen supply chain network.

Fig.2 shows an example of a comparison for hydrogen supply cost estimation by third party[2]. It shows the overall costs of producing green hydrogen in South America and shipping it to Rotterdam in different forms: liquefied Hydrogen, ammonia and two LOHC's. LOHC-MCH method is estimated around 3 €/kg-H_2.

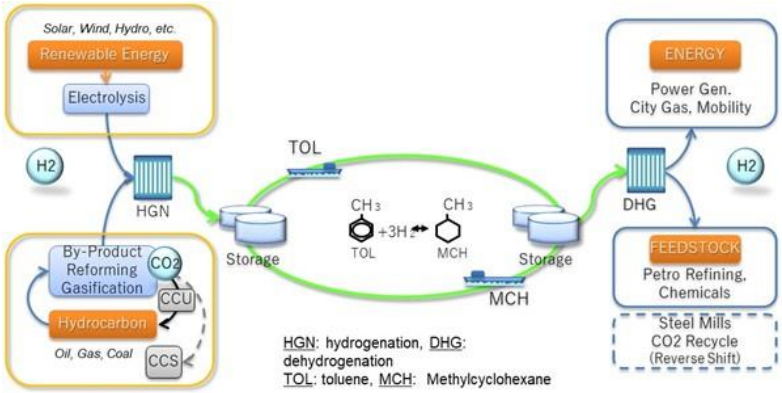

Fig. 1. Scheme of SPERA hydrogen system

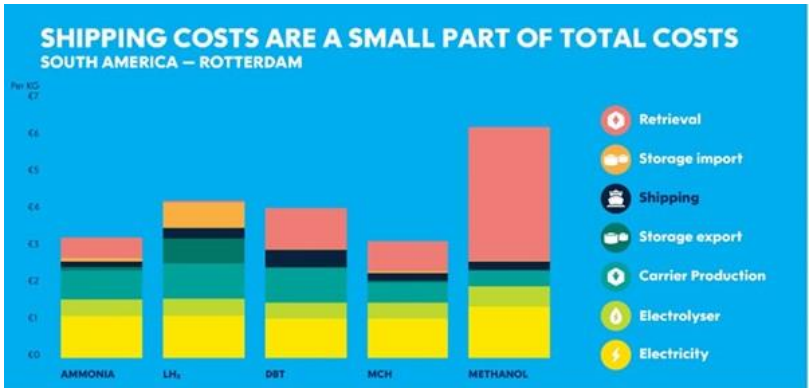

Fig. 2. Example of comparison for H_2 supply cost

COMMERCIALIZATION

Based on the success of global hydrogen supply chain demonstration project between Brunei Darussalam to Japan, SPERA Hydrogen System is in the process toward the commercialization.

Chiyoda joined the "Hydrogen Utilization Study Group in Chubu" to study the potential for large-scale hydrogen use, and construct a supply chain for stable utilization of hydrogen, in the Chubu region, Japan[3].

In South East Asia, Chiyoda has already started the collaboration with 5 Singapore partners since March 2020, and signed a MOU on 4 Oct. 2021 with Sembcorp industries (Singapore) and Mitsubishi Corporation for strategic partnership to explore the feasibility and implementation of a commercial scale supply chain to deliver decarbonized hydrogen to Singapore[4].
In addition, Chiyoda, Port of Rotterdam (PoR), Koole Terminals, Mitsubishi has signed MOU in July 2021 to conduct a joint study of importing hydrogen on a commercial scale to European market through Rotterdam by a MCH[5].

CONCLUSIONS

SPERA Hydrogen System has shifted to commercialization phase. It is the only system that has completed the international demonstration of the entire value chain from production to utilization at scale. The technology is ready to contribute to deliver hydrogen to the global society, "safely", "environmentally", "economically" and "stably". Chiyoda believe that we are ready to contribute the hydrogen business and economy through this technology globally.

ABSTRACT

Hydrogen is attracting attention as a future fuel for automobiles and power generator because it does not emit carbon dioxide (CO_2) during the utilization phase. For example, when hydrogen is adapted as a fuel to a stationary engine generator, it is expected to be able to operate with higher thermal efficiency and cleaner exhaust emissions than those of conventional engines. Further improvement in efficiency is expected by adapting argon (Ar) gas with high specific heat ratio, to the working gas of hydrogen engines. The objective of this study is to optimize operating conditions of Ar power cycle of a spark ignition premixed hydrogen engine for achieving high efficiency and high power. In this study, the effect of Ar concentration added to the working gas on hydrogen combustion characteristics and engine performance was investigated with a single-cylinder test engine. The result shows that thermal efficiency was greatly improved as Ar concentration in the working gas was up to 40 mol% in comparison with the air cycle. On the other hand, some technical issues relating abnormal combustion were revealed.

Keywords: Hydrogen Engine, Argon Addition, High Thermal Efficiency

INTRODUCTION

Toward the realization of decarbonized society, hydrogen is attracting attention as the next generation of energy. Hydrogen has high expectations as a fuel for automobiles and power generator because it does not produce environmental load substances such as CO_2 in combustion process. When hydrogen is adapted as a fuel to a stationary engine generator, the excellent combustion properties of hydrogen are expected to be able to operate with higher thermal efficiency and cleaner exhaust emission than those of conventional engines. Theoretical thermal efficiency of Carnot cycle is defined in $\eta_{th} = 1 - (1/\varepsilon^{\kappa-1})$, so theoretical thermal efficiency improves with increases in the compression ratio ε and specific heat ratio κ. In other words, high thermal efficiency can be expected by using noble gases with a high specific heat ratio for the working gas of the engine. Argon (Ar) is monoatomic molecule so its high specific heat ratio is difficult to degrade even in high temperature combustion ambient. Namely, a significant improvement in thermal efficiency is expected by adapting argon gas as a part of the working gas. However, in previous studies of spark ignition hydrogen engines with Ar as the working gas, operation was limited by abnormal combustion, stable hydrogen combustion and improving thermal efficiency are supposed to be difficult [(1)].

This study aims to find the optimal operating conditions when adding Ar to a spark ignition premixed hydrogen engine for high efficiency and high power. In this study, the effect of Ar concentration on hydrogen combustion characteristics and engine performance is investigated with a single-cylinder test engine.

MATERIALS AND METHODS

A schematic diagram of the single-cylinder test engine apparatus used in this study is shown in Figure 1. The engine specifications and hydrogen supply conditions are shown in Table 1. The engine was modified from the base engine in terms of compression ratio, piston geometry and valve train, etc. A hydraulically actuated valve train system was installed to reproduce several kinds of engine system with changing timing of intake and exhaust valves, and the effective compression ratio and expansion ratio can be changed as desired. The engine speed is controlled by an AC electric dynamometer (HORIBA, DYNAS3 LI145), and fresh air is supplied by an electrical compressor. Ar and oxygen (O_2) are supplied from each cylinder to the intake pipe by controlling flow rate of each gas to reproduce desired compositions of the working gas. Hydrogen is supplied from cylinders to about 0.4 MPaG using a pressure reducing valve, and then supplied intermittently via a thermal mass flow meter (Bronkhorst, EL-FLOW) by an injector located near the intake port. Intake and exhaust gas components were measured by two types of gas analyzers (HORIBA: MEXA-ONE, Best Sokki: BOB-2000FT) with a time response speed of about 200 ms In-cylinder pressures of the test engine measured by a piezoelectric pressure transducer was recorded during 100 cycles for each condition by the combustion analyzer.

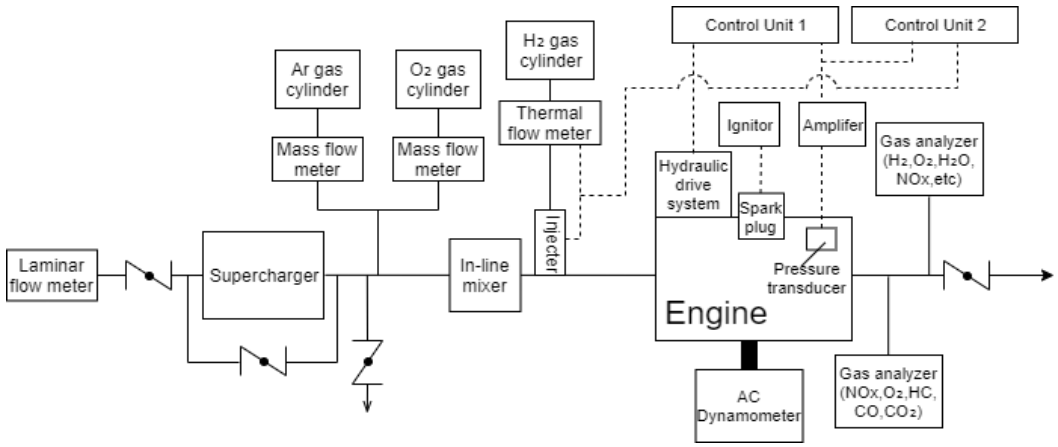

Fig. 1. Experimental apparatus for the single-cylinder engine test with hydrogen, Ar, and oxygen supply system

RESULTS AND DISCUSSION

Effect of effective compression ratio on maximum in-cylinder gas temperatures in motored cycles

Maximum in-cylinder gas temperatures in motored cycles is supposed to rise with increasing geometric compression ratio and Ar concentration. While an increase in maximum in-cylinder gas temperature due to Ar addition induces premature ignition, a higher geometric compression ratio is better from the viewpoint of thermal efficiency. Therefore, in order to improve thermal efficiency while reducing the risk of premature ignition due to the addition of Ar, it is considered to be effective to set the geometric compression ratio high and to vary the effective compression ratio depending on the timing of intake valve closing to suppress in-cylinder gas temperature.

Since there is a need to reduce in-cylinder temperature, the effect of changes in the intake valve closed timing (IVC), or effective compression ratio on the in-cylinder gas temperature was investigated in motoring experiments. In the experiments, the geometric compression ratio was set to 13 to keep high thermal efficiency. Figure 2 shows the relationship among the experimental conditions, IVC, effective compression ratio, and maximum in-cylinder gas temperature. Since the intake air flow rate varies with the change of IVC, it was kept by using the electrical compressor. As seen in Figue2, maximum in-cylinder gas temperature was reduced by advancing or delaying IVC from about IVC: -120deg.CAaTDC.

In addition, motoring experiments were conducted by changing Ar concentration in the working gas to investigate the effect of Ar addition on maximum in-cylinder gas temperature. The top-right corner of the dotted square is the maximum in-cylinder gas temperature of the engine in the air cycle (without Ar addition), which is about 750 K. The addition of Ar up to 60 mol.% increases maximum in-cylinder gas temperature by about 200 K compared to the air cycle. Therefore, it is necessity to optimize the in-cylinder temperature by changing the effective compression ratio in the actual test. Maximum in-cylinder gas temperature was lowered by decreasing the effective compression ratio. In

order to reduce the in-cylinder temperatures effectively, the IVC was set at an advanced crank angle from the bottom dead center of the intake stroke, and the single-cylinder engine experiments were conducted as described below.

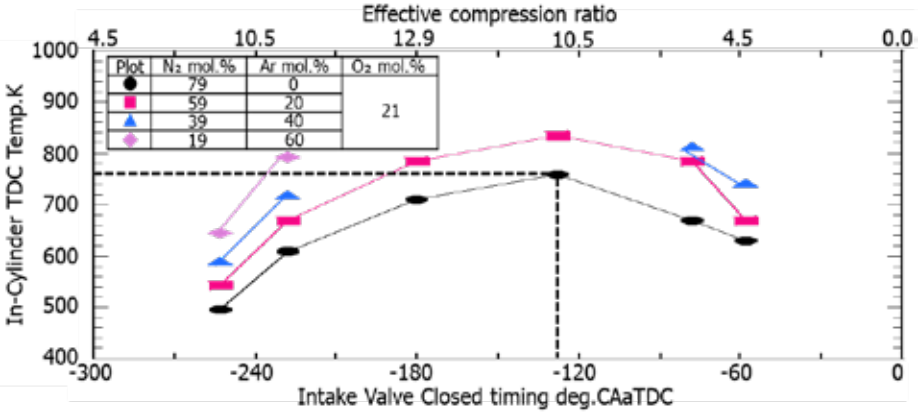

Fig. 2. Effect of IVC timing or effective compression ratio and Ar concentration on in-cylinder gas temperature

Effect of Ar concentration in the working gas

In this section, the effects of Ar concentration in the working gas on engine performance and combustion behavior are investigated. Fired engine experiments were carried out at constant hydrogen frow rate and IVC: -128 and -228 deg.CAaTDC with spark ignition timing as a variable. Figure 3 shows the experimental conditions and results. At IVC: -128 deg.CAaTDC, even with Ar: 20 mol.%, abnormal combustion with an intense heat release was observed with spark ignition timing at -20 deg.CAaTDC. It is supposed that the combustion temperature increases with an increase in Ar concentration. Moreover, the addition of Ar increases the laminar burning velocity with an increase in combustion temperature, that is thought to have led to shorted combustion period (CA10-90). The temperature of the unburned mixture including Ar increases more easily than that without Ar (the air cycle) duo to that the specific heat of Ar is small. It can be assumed that adiabatically compressed unburned gas during the combustion process could reach spontaneous ignition temperature of hydrogen during combustion process. Therefore, when IVC was at -128 deg.CAaTDC where the maximum in-cylinder gas was high as shown in Figure 2, the spark ignition timing could not be advanced due to frequent abnormal combustion. As a result, the amount of Ar added to the working gas was limited by the abnormal combustion and the thermal efficiency could not be improved.

Figure 4 shows the in-cylinder pressures and rate of heat release in case of IVC: -228 deg.CAaTDC and spark ignition timing: -36 deg.CAaTDC. In the air cycle, at IVC: -228 deg.CAaTDC, lowering maximum in-cylinder gas temperature slows down the combustion and prolongs the combustion period. On the other hand, as the Ar concentration increases, the rate of heat release became steeply and the combustion phasing was advanced with shortened combustion period. Even when Ar is increased to 40 mol.%, knocking does not occur. As shown in Figure 3, improvement of about 18 % in thermal efficiency was obtained in case of Ar: 40 mol.% compared with the air cycle. Although there was concern that the increase in Ar concentration would lead to an increase in NOx due to the rise in combustion temperature, there was almost no increase in NOx in any of the Ar concentration conditions with in the experiments.

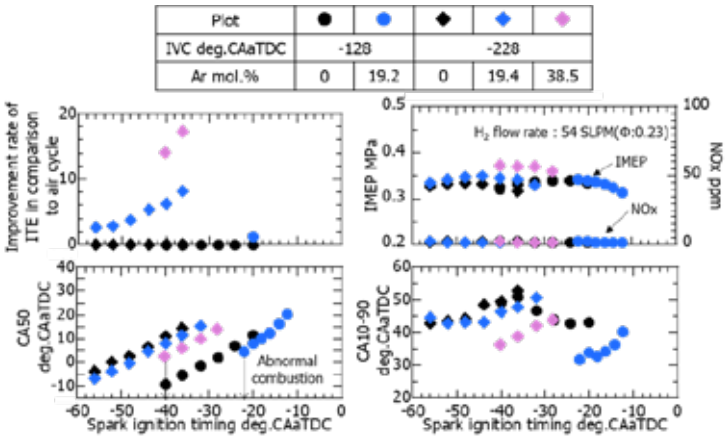

Fig. 3. Effects of IVC timings and Ar concentrations on engine performance

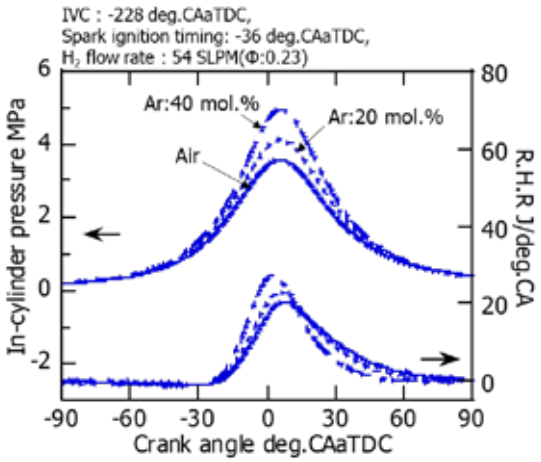

Fig. 4. In-cylinder pressures and rates of heat release with changing Ar concentrations

CONCLUSIONS

The effect of Ar addition to the working gas on the combustion characteristics of a spark ignited premixed hydrogen engine was investigated by the single-cylinder engine experiments.

- Increasing Ar concentration improves thermal efficiency of the test engine. On the other hand, the specific heat capacity becomes smaller, and the combustion temperature and burning velocity become higher. Then the rise of rate of heat release becomes steeper and the operative range is limited by knocking.
- Lowering maximum in-cylinder gas temperature with advanced IVC timing makes it possible to operate the engine system without premature ignition, and higher Ar concentration in the working gas could improve thermal efficiency more.

ABSTRACT

Energy transition will push more and more the use of hydrogen for mobility and to heat industrial furnaces with other fuels where radiation has the major contribution. Consequently, the need for adequate radiation model parameters to account for gas radiation from mixtures of hydrogen/methane combustion in high-temperature furnaces is of major importance. The proposed model is a modified weighted sum of grey gases (WSGG). The model validation is presented for a 1D gas column and also on a 2D domain with walls.

Keywords: Industrial Furnaces, H_2/CH_4 Mixture, Thermal Gas Radiation, Numerical Modelling

INTRODUCTION

In the coming years the role of hydrogen will become increasingly important not only for mobility but also for energy storage and for industrial applications. Hydrogen will be more used to heat industrial furnaces with a mixture of natural gas or other fuels. It should be noted that thermal radiation is the major contributor for total heat flux on the cold load for the different high-temperature industrial furnaces (steam methane reformer, glass furnaces, reheating steel furnaces...). Moreover, with the presence of combustion gases (*e.g.* H_2O, CO_2) one has to take into account these hot gases as a radiative participative medium. In order to do numerical simulations inside these furnaces, gas and wall radiation heat transfer should be calculated with enough precision and affordable computing time. For this purpose, the WSGG model is often used to carry out the radiative part of the heat transfer modeling inside the different industrial furnaces. For most applications [1][2], the WSGG absorption coefficients are constants with regard to the gas temperature.

The objective of this paper is to explain the method used for the determination of WSGG model parameters applied for hydrogen mixture combustion, which are all dependent of gas temperature. When dealing with high temperatures, radiative heat transfer has to be taken into account through the calculation of the radiative power in the energy balance equation, for participating media. This power mainly depends on the spectral absorption coefficient κ_ν ($atm^{-1}.m^{-1}$), the spectral directional intensity I'_ν ($W.m^{-2}.sr^{-1}$) and the spectral intensity for a black body I^0_ν ($W.m^{-2}.sr^{-1}$).

Solving the Radiative Transfer Equation (RTE) necessitates two integrations; a spatial one and a spectral one. This makes it very difficult and time consuming to solve, especially for real gases. Several spatial resolution methods are available (Monté-Carlo, zonal, Discrete-ordinates, ray tracing...). This part of the resolution is not the concern of this paper (in this work, the discrete transfer radiative (DTR) method [3] is used). Concerning spectral integration, mainly two kinds of models exist to compute radiative heat transfer for combustion matters; Spectral models and global ones. Spectral models are more accurate than global ones, since they take into account spectral dependency of the radiative parameters, but these models are also CPU time expensive, and thus hardly compatible with industrial requirements. The most accurate of these methods (Line-by-Line [1]) is used mainly by academics for creating benchmarks of reference results. The principal limitation of this method is its CPU cost since it computes absorption/emission coefficient every 10^{-2} cm^{-1}, leading to about 10^6 resolution of the RTE. Other spectral methods exist (*e.g.* Statistical-Narrow-Band SNB [1], correlated-K [4]), keeping the spectral dependency but for a wider discretization of the total spectrum ($\Delta\nu$=25 cm^{-1} or bigger), making them good candidates for almost affordable spectral models (about 360 RTE resolutions for the full spectrum). However, they are still highly computationally expensive for industrial furnaces. Despite a lower accuracy, global models (*e.g.* WSGG [2], spectral-line-based WSGG (SLW-WSGG) [5],[6]) have a reasonable time response, which makes them good candidates for multi physics approaches like the one treated for industrial processes.

MATERIALS AND METHODS

When dealing with gases as participating media, in industrial context, thermal radiation is often treated through the WSGG model. In this model, the real gas emissivity is expressed as a weighted sum of N_g grey gas emissivities. In

WHEC-2022
23rd World Hydrogen Energy Conference
June 26-30, 2022 - Istanbul

our case, one chooses N_g = 4 gases and a gas temperature dependence of $a_i(T_g)$ the weighted factor for gas i [-], but also for $\kappa_i^{H2O}(T_g)$ and $\kappa_i^{CO2}(T_g)$ the absorption coefficients for gas i [$atm^{-1}.m^{-1}$]. Thus, the total emissivity is written:

$$\varepsilon_g(T_g, x^{H2O}, x^{CO2}, \ell, p) = \sum_{i=1}^{N_g} a_i(T_g)\left[1 - e^{-\left(\kappa_i^{H2O}(T_g)\, x^{H2O} + \kappa_i^{CO2}(T_g)\, x^{CO2}\right)\ell p}\right], \quad (1)$$

with ℓ the gas column length [m], x^{H2O} and x^{CO2} the molar fractions of gas [mol_i/mol_{tot}] respectively for H_2O and CO_2 and p the total pressure [atm]. Moreover, the following conditions have to be respected:

$\sum_{i=1}^{N_g} a_i(T_g) = 1$ and considering the transparent gas $\kappa_4^{H20} = \kappa_4^{CO2} = 0$. (2)

The emissivity parameters (weighted factors and absorption coefficients) are sought as 5th order polynomials as $P(T_g) = \sum_{j=0,5} c_j\, T_g^j$ (where the c_j coefficients are the unknowns). Then, an optimization method is used to determine these c_j coefficients which minimizes the root-mean-square difference of the gas emissivity between the one calculated by the SNB model and the modified WSGG model, using a gradient descent method. Hence, a database for emissivity values is generated for 1D gas columns, thanks to a SNB model, as a function of the input parameters T_g, x^{H2O}, x^{CO2} and ℓ (in our case, p = 1 atm).

The following procedure has been followed:

1. Choose a range for each input parameters, and a sample rate for each range (this freezes the validation range of the final approximation for the emissivity)
2. Calculate the emissivity values ε^{SNB} for each value of the input parameters (according to the sampling rate used). This generates a database for training our model.
3. Use the database to fit the c_j coefficients for the expression of a_i, $\kappa_i^{H2O}(T_g)$ and $\kappa_i^{CO2}(T_g)$ and so for ε^{fit}.

A first validation is made using a gas emissivity database, different from the one used to train the modified WSGG model. The approximated values of emissivity ε^{fit} is compared to the one from the SNB model ε^{SNB}. A second validation uses a numerical code that solves the radiation in a 2D domain with walls, using either a SNB or a WSGG model. This will be presented in the final paper.

RESULTS AND DISCUSSION

A comparison between the fitted gas emissivity and the SNB gas emissivity over the temperature range is given on Fig. 1a, using the training set of data. The detailed comparison, for each temperature will be also presented. A validation has also been carried out, using the testing set of data, and is presented on Fig. 1b. Overall results, shown a good agreement with the SNB model, and an error under 10% on the range of interest (T_g > 1000K). Comparison with 2D modeling should be presented at the conference.

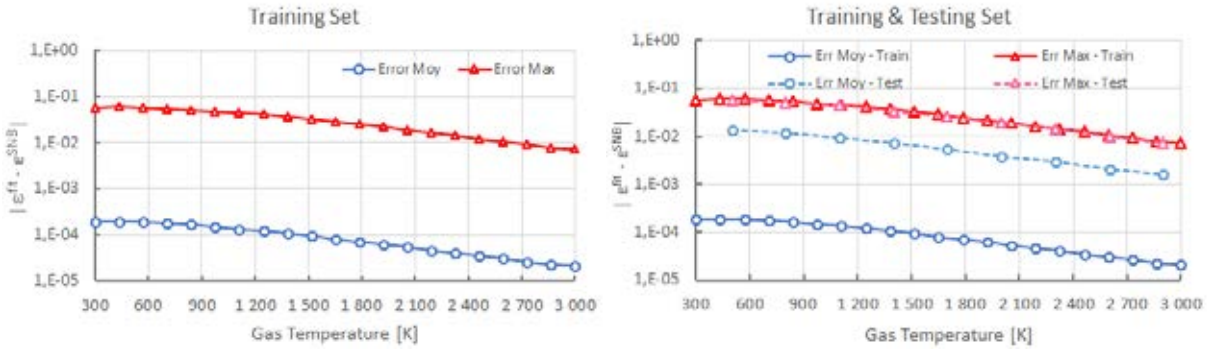

Figure 1: Error between fitted and SNB emissivity, for the training set on the left a), and on testing set on the right b).

CONCLUSIONS

A modified WSGG model is proposed with a set of new coefficients for the combustion of H_2/CH_4 mixtures. The mixing range admitted goes from 0% to 100% for H_2 and 100% to 0% for CH_4. Results show good agreement with the spectral model and a maximum error lower than 10% and an average error under 1%. This modified WSGG model has been implemented in a 2D numerical model. Next step should be to implement this model in a 3D software taking into account radiation, fluid dynamics and combustion for high-temperature industrial furnaces.

HYDROGEN-METHANE MIXTURE STORAGE IN DEPLETED RESERVOIRS: AN OPTION FOR CONVERTING DECOMMISSIONED OFFSHORE PLATFORMS

ABSTRACT

With several oil or natural gas offshore reservoirs depleting in different areas of the world, the producing platforms which insist on them are becoming a challenge for companies and governments: on one side they represent infrastructures that are ageing, and that most legislative frameworks impose to remove, while on the other side they represent a valuable opportunity for supporting the energy transition, thanks to their position, technical and structural characteristics.

The paper presents the outcomes of a basic design to reuse a natural gas production platform under decommissioning to inject and extract alternatively and seasonally a mixture of 10% hydrogen and methane in a depleted reservoir. The reuse brings along the idea of removing the equipment that are not useful anymore from the various platforms decks while preserving those major components that can still be fruitfully exploited: typical examples are represented by wellheads and separators. The exploitation of a depleted reservoir is a delicate matter and deep knowledge of the specific features of each reservoir is mandatory to dimension the single components. This paper focuses on the engineering philosophy of this kind of reconversion providing guidelines, included environmental and HSE safeguards to be considered.

Keywords: Reuse, H_2+CH_4 Mixtures, Platform Conversion, Safety, Temporary Storage

INTRODUCTION

The increasing attention devoted to hydrogen/methane mixtures is due to their role as “transition” fuels from a pure fossil infrastructure exploitation to a full hydrogen one. Criticalities linked to the fast approval, installation and exploitation of a full hydrogen network are well known but the 2050 decarbonisation targets cannot prevent from considering hydrogen in the mix. The entry point, thus, is the insertion of hydrogen in existing infrastructures. Percentage is the key as it is under demonstration that low percentages of hydrogen in the mixture do not pose significant challenges to materials and equipment in the network. The role of hydrogen as a storage option for intermittent renewable sources can be further coupled with the role of natural gas as a seasonal or strategic energy storage in underground deposits. The mix of the two represent a win-win solution when stored together in dedicated infrastructures.

At the same time, another energy related challenge is looming with Oil&Gas offshore platforms ageing as their reservoir become depleted. As an example, in Italy, of the existing 138 platforms, only 7 were built after 2010 which means that very soon companies and authorities will have to tackle the issue in a consistent way throughout the seas. It is evident, however, that these infrastructures offer a variety of opportunities also in the energy transition phase we are entering. Their position, the technical and the structural characteristics make them exceptional landmarks for hosting new and strategic energy systems. The Italian Ministerial Decree Feb. 15, 2019 [1] is an example of guideline for managing the transition of an aged platform toward a reused/revamped infrastructure, also considering the removal option when more appropriate. The Italian Ministry of Economic Development has also supported further research on specific options to reuse platforms, which include hosting desalination units supplied via PV electricity from panels installed onboard [2], or the option of hosting injection and extraction facilities for mixtures to be stored in the depleted reservoir the platforms are installed on. The paper presents a summary of concepts and solutions for this second option and an application on a sample platform, called GREEN1, which has the characteristics of an average Mediterranean platform.

METHODOLOGY

Design philosophy

This option foresees the installation on the representative GREEN1 platform of all the equipment necessary to exploit a reservoir to store temporarily a mixture of hydrogen and methane. The considered mixture contains a maximum of

10% of hydrogen, assumption taken after industrial tests have been performed as demo trial with success [3]. The mixture is stored to fulfil the needs during the cold season when the request is at its maximum; complementarily, the injection phase happens during the warmer period. The passage from the injection to the extraction phase is, then, alternated every six months.

To prepare the infrastructure to host the new equipment needed for the injection and extraction of the mixture, a fundamental criterion is the minimisation of interventions, adopting the following rules of thumb:

- The pre-existing equipment is dismissed only in case there is a clear need of more space or in case the sum of the old and new equipment is excessive for the stability of the platform
- Dismissing and removal of old equipment must be carried out in such a way to minimise environmental impacts and the risks connected to the operation
- All submarine interventions (e.g., wells inspections, structural integrity of the piles) must be reduced to a minimum, again to limit damages to the (submarine) ecosystem which has already developed around the structure.

An additional assumption for the reconversion is the conception of an unmanned platform, where the operators only get onboard for maintenance reasons. This choice is preferred under the safety and economic point of view, and it is also beneficial for the reduction of the loads onboard as the living quarter becomes an unnecessary structure. At the same time, a guiding principle is the maximisation of the availability of the system achieved by installing redundant equipment such as pumps and compressors and applying a preventive maintenance philosophy to reduce unplanned interventions. Onboard, only necessary equipment are installed, leaving to the onshore destination those which can fruitfully operate there: for example, electric power supply is achieved via a submarine umbilical avoiding onboard power generation and allowing easier renewable energy harvesting onshore. Also waste fluids are released onshore via an umbilical connection to a treatment plant which allows the reduction of loads onboard, reduces the possibility of accidental releases and eases the recovery of reusable fluids such as water.

Process design

The platform is converted to perform two activities:

- Injection in a reservoir of a hydrogen and methane mixture taken from the national grid. During this phase, the pressure in the reservoir increases as the volume of the gases injected increases and it is subjected to the petrographic and geo-structural characteristics of the reservoir and by the capacity of the onshore (grid connected) compression stations
- Production of a hydrogen and methane mixture taken from the reservoir and injected in the national grid. During this phase, the pressure in the reservoir decreases while the gas volumes are extracted. Again, the way the production takes places is influenced by the reservoir features.

During injection, the mixture from the national grid is pressurised by two centrifugal compressors which operate in parallel working each on 50% of the total flow. No gas treatment is needed in this phase as it is taken directly from the grid where the conditions are optimal. Compressors gas turbines are supplied by a small quantity of gas mixture taken form the total to be injected in the reservoir.

During production, there is no need to compress as the reservoir pressure is already enough for the grid, but the mixture must possess the quality required by the grid. This means the gas extracted from the reservoir has to be processed to remove any impurity. If not already existing on the original platform, some additional equipment must be installed for this purpose: a separator on top of the wellheads which removes most of the production water content, a MEG (Monoethylene Glycol) injection unit which improves the water separation, a demister which removes both water and MEG, a heater which increases the gas temperature needed by the following and last separation unit where a flow of TEG (Triethylene Glycol) absorbs the last drops of water. Water and MEG are shipped via umbilical onshore to be processed, while TEG is regenerated onboard.

CASE STUDY

The concept of reuse of an Oil&Gas platform to inject and extract a mixture of hydrogen and methane in the depleted reservoir has been applied to a sample platform GREEN1 composed of five decks (boat landing, lower, cellar, mezzanine and weather decks) and supported by four legs. The underlying reservoir maximum operating pressure has been assumed equal to 145 bar, based on average values of a family of reservoirs already assessed for reinjection [4,5]. After a first phase when the depleted reservoir must be filled in with the mixture in a regulated way, to maintain structural and fluid-dynamic stability of the reservoir, the extraction and injection volume of the mixture is calculated to be about 135 SMm^3 every six months. During the production phase, both pressure and flow rate

decrease in controlled intervals (e.g., the pressure drops from about 145 bar to about 80 bar). During injection, of course, the pressure increases, while the flow rate decreases as the filling completes.

The main additions to the platform are the couple of compressors on the weather deck, the demister and the heater on the mezzanine deck, dehydration unit and TEG regeneration units on the lower deck (Fig. 1). An estimation of the final variation of weight of the structure, after the removal of old equipment, when necessary, and the installation of the new ones is negative: the post-conversion platform would weight 60t less.

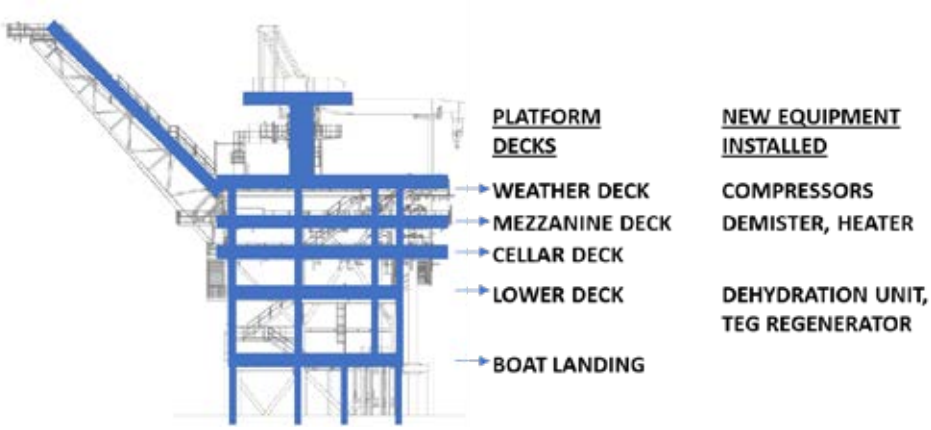

Fig.1 – Structure and interventions in the reconverted gas extraction offshore platform

An environmental assessment has been performed on this converted platform and the main preliminary finding is related to the use of compressors. They are the most important contributors to the emission of CO_2 in the atmosphere (as the heater has a very small capacity), but they operate only during the injection phase and the presence of hydrogen in the fuelling mixture helps abating the relative amount of CO_2. A HAZOP (HAZard and OPerability Analysis) has been performed to identify accidental initiating events and the preliminary outcomes show that there is no additional specific hazard posed by the presence of hydrogen (in comparison with traditional Oil&Gas installations) while recommendations can be implemented in the design phase to take care of the high pressure involved in the production phase so that any of the new equipment dedicated to dehydration may be affected.

CONCLUSIONS

The conversion of an Oil&Gas platform under decommissioning into a structure to store a mixture of hydrogen and methane mixture underground has been addressed. From the exercise performed, some guidelines on the philosophy which should drive this kind of intervention are drawn and can be fruitfully applied in several other similar installations. It is clear that the conversion is technically feasible once the data on the reservoir are known and a suitable platform is available but from the safety and environmental assessment risks can be maintained under control with usual safety systems and procedures and with conventional maintenance routines.

REAL-WORLD ENERGY MEASUREMENTS AND LOCAL HYDROGEN COST AS INPUT PARAMETERS FOR REGIONAL VEHICLE FLEET OPTIMIZATION

[1] Rittmar von Helmolt, [1] Martin Rothbart, [2] Hans Beck, [2] Florian Bindges [3] Loic Lerminiaux*

ABSTRACT

When changing vehicle fleets from Diesel to a zero-emission alternative, the change involves the vehicle but also the fuel supply chain. For an informed decision on choosing vehicles fuelled by either hydrogen or direct electricity, this is a decisive factor which needs to be predicted as accurately as possible for a quite long time in the future, ideally for the lifetime of the intended infrastructure. For supply of green hydrogen, we have considered scenarios that incorporate either a local or domestic production or an import of hydrogen. The hydrogen is assumed to be transported in pressure vessels from the point of generation to the filling station. Also, possible alternative routes via Ammonia or LOHC are indicateded.

We furthermore describe a method for TCO optimization for a regional vehicle fleet, which is based on real-world measurements on the vehicle. Measurements have been done on a bus fleet in daily operation with focus on the thermal energy flow, and monitored for an extended period of 2 years in order to cover a wide range of climate and traffic conditions. These data are the basis for a simulation for an operation of battery electric as well as hydrogen vehicles, and the layout of respective infrastructures.

Keywords: Hydrogen Transport Cost, Hydrogen Bus Fleet, Regional Hydrogen Cost, Vehicle TCO, Fleet Monitoring and Simulation

INTRODUCTION

Vehicle fleets renewal will incorporate an increasing share of zero emission vehicles, primarily battery electric and hydrogen fuel cell. For public services and public procurement of vehicles, this transformation is mandatory, as laid out in the European Clean Vehicles Directive [1].

However, this change is not as easy as it seems since a zero-emission bus can not replace a Diesel bus 1:1. In particular, it is several times more expensive and in addition will require some significant infrastructure investment. Furthermore, in the near future, this will probably not, or at least not fully, be compensated by lower operating expenses.

We are describing our method to approach the main factors that are decisive for comparison of future vehicle fleet, infrastructure and energy scenario.

DEMAND CALCULATION

When changing from a Diesel vehicle to a zero-emission powertrain, there is no simple equation for correlating energy consumption. In a diesel vehicle, as well as in a fuel cell vehicle, energy for heating the passenger compartment comes “for free”, while in an electric vehicle, it has to be provided by the battery. On the other hand, energy for mass acceleration can be partly recuperated during deceleration in an electric vehicle, which is lost in a diesel vehicle.

As an example, we have measured a city bus fleet from Holding Graz over an extended period of time 2019-2021, operated on all lines, all days of week and all seasons, particularly all climate conditions of the year. Measurement focus was drivetrain energy as well as all anxilliaries, and, in particular, the cooling/heating circuits. Data from the measurement have been used for evaluating the energy demands.

Battery Electric Vehicles

Based on the calculated energy demand for propulsion, thermal requirements and anxilliaries, electric bus simulations have been performed and been “deployed” on particular routes of the day and days of the year. Electric energy demand and vehicle range has been determined, as well as potential recharging strategies anticipated.

Hydrogen Fuel Cell Vehicles

Similar considerations have been made for hydrogen fuel cell vehicles. For lack of real bus data, we are working from own assumptions as could be gained from fuel cell heavy duty powertrain integration.

For a first assessment of a vehicle fleet, not all vehicle measurements need to be performed. The data that have been obtained in Graz could be used for any other bus fleet that is operated in similar climate or profile, using a driving profile that is available e. g. from GPS data.

HYDROGEN COST

We did calculations of different scenarios for hydrogen supply to a filling station, including hydrogen production from an electrolyzer, conditioning for transport either by compression, or converting to Ammonia, or by hydrogenation of liquid organic carriers (LOHC), as well as re-conversion at the point-of-use. We however did not consider the cost for the hydrogen station itself (CAPEX and OPEX for the hydrogen filling station).

Local production

In the first scenario for hydrogen supply, we don't consider transportation cost at all. Assumed is the direct consumption of the on-site produced hydrogen, for supply to a hydrogen filling dispenser, underlying a 200 MW electrolyzer capacity. The levelized energy costs for green hydrogen are assumed with 100 €/MWh.

For a local production, with these assumptions, levelized costs of 5,51 €/kg CGH_2 have to be considered. As no conversion, filling or transportation is needed, the risk of dependencies is reduced. As operational costs equal for 94,2% of the levelized costs, fluctuation in energy costs must be observed closely.

Continental production

Beneficial use of reduced costs for green energy at the point of production is levered at the continental production scenario. Levelized energy costs from wind generated energy is assumed with 60 €/MWh, whereas for the re-conversion efforts still 100 €/MWh apply. Transportation is now needed and provided by trucking at a total of 520 km. We have considered transportation as compressed hydrogen gas, as well as conversion and re-conversion from ammonia and LOHC. For all three carriers, all cost categories are considered. Within the conversion CAPEX cost, the levelized initial investment for the LOHCs is included in accordance with the estimated shipping time. In the transportation cost, the return shipment of the de-hydrated LOHCs is considered.

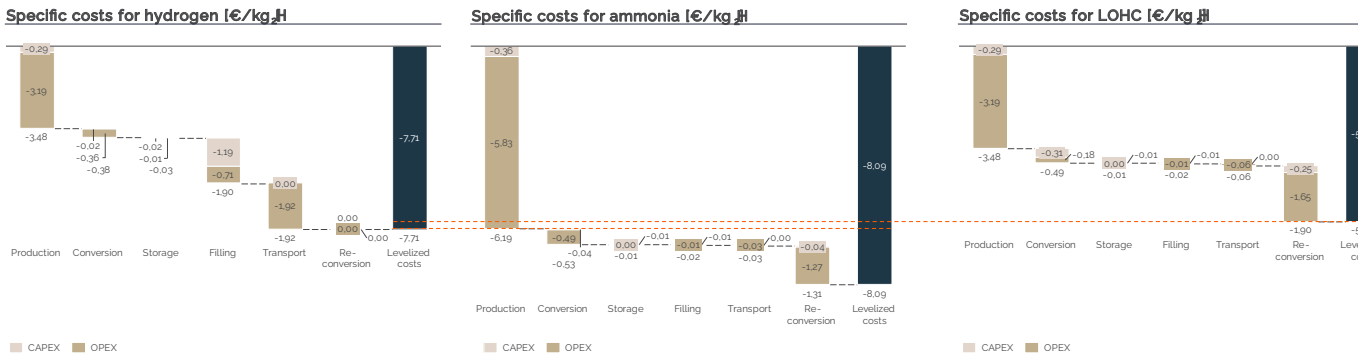

Figure 1. Levelized costs for hydrogen derivates at continental production [€/kg]

Intercontinental production

Further decrease of the levelized costs for energy by levering the intercontinental production scenario with 40 €/MWh, secured by either wind or solar generated electricity. Electricity used for re-conversion is again calculated with 100 €/MWh. Transportation is done by sea vessel port-to-port, covering 4080 km (2676 nm) and trucking, covering 520 km. Again, for all three carriers all cost categories are considered. Similar to the continental scenario, within the conversion CAPEX cost, the levelized initial investment for the unsaturated LOHCs, with the prolonged transportation time, is included. In the transportation cost, the return shipment of the de-hydrated LOHCs is considered, too.

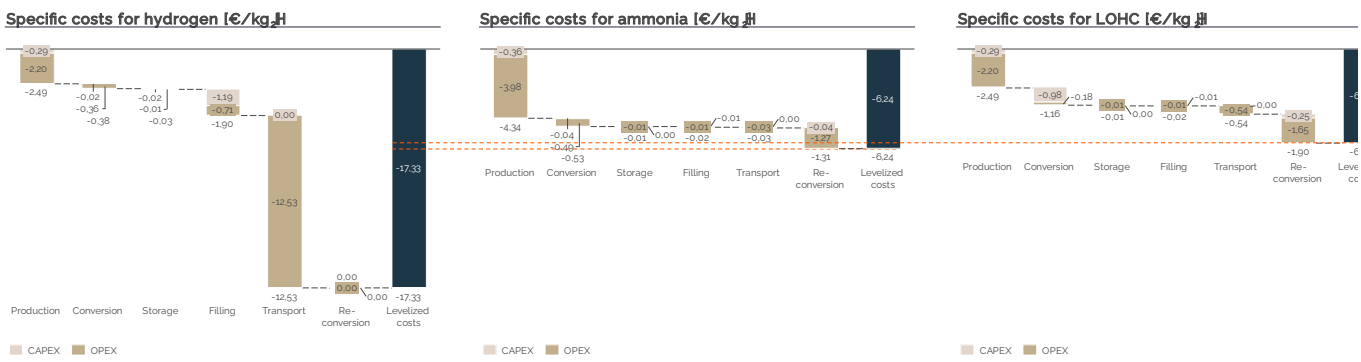

Figure 2. Levelized costs for hydrogen derivates at intercontinental production [€/kg]

RESULTS AND CONCLUSIONS

There is no general right answer for deciding on the right strategy for selecting and fueling a regional fleet of zero emission vehicles. While in general, longer operation times and distances and demanding climate conditions might exclude battery electric vehicles, the cost for hydrogen could be a no-go for fuel cell vehicles in some regions either. Analysis of existing fleet and simulation of alternative zero-emission vehicles can provide a good basis for further considerations on infrastructure. This is the basis for further detail planning on recharging scenarios, which is a complex issue on its own, i. e. combination of opportunity charging and depot charging, intelligent route planning and battery residual value monitoring.

Cheap green electricity could help both electric vehicles as well as local hydrogen production. Hydrogen transport is a major cost factor if local hydrogen production is not possible and no connection to a regional hydrogen pipeline network is available. This might gradually change in future, as scenarios and national strategies for decarbonization include hydrogen as a clean energy carrier for many other applications which are more cost sensitive that transportation.

ABSTRACT

The three Fraunhofer Hydrogen Labs in Bremerhaven, Leuna and Görlitz, aim to provide digitally cross-linked research infrastructure with testing capacities for hydrogen technologies with over 27 MW electrical power supply. The focus of the test fields is to investigate the efficiency and performance of electrolysers powered by renewable energy, building on the combined expertise of the Fraunhofer Institute for Wind and Energy Systems in collaboration with the Institute for Machine Tools and Forming Technology (IWU) and Center for Chemical-Biotechnological Processes (CBP). These integrated research facilities will enable evaluation and appraisal as the key basis for driving the market ramp-up of hydrogen technologies.

All three hydrogen Labs are digitally interconnected and cover the whole green hydrogen process: starting from renewable power generation with on- and offshore wind turbines, the optimization of electrolysis and manufacturing of electrolysers, as well as storage, transport, and electricity generation from green hydrogen. Therefore, the Fraunhofer Hydrogen Labs can offer a worldwide unique spectrum of pilot plants, covering the complete value creation chain of the hydrogen economy.

Keywords: Hydrogen, Electrolyser, Storage, Fuel Cell

INTRODUCTION AND MOTIVATION

The German government committed itself to limit the global warming to 1.5 K and therefore to reduce the carbon dioxide emissions to 20 percent in 2050 compared to the year 1990, with steps of 45% until 2030 and 30% until 2040. In order to fulfill this goal, all sectors, that is energy supply, mobility and transport, industry, housing and agriculture, need to contribute. Electrification is one of the solutions, using renewable hydrogen is another one. For both solutions a great amount of renewable energy is needed. [1, 2, 3]

The joint venture of the three Hydrogen Labs enables, for the first time, a cross-sector demonstration of wind-based energy generation towards the impact and modeling of the interplay of large regional energy generation, storage and consumer units. Plant and component manufacturers will have the opportunity to test new equipment developments on an industrial scale or to evaluate chemical processes and syntheses. Therefore, the Fraunhofer Institute for Wind and Energy Systems makes a significant contribution to the decarbonization of the sectors by mapping the entire value chain of green hydrogen, which can be studied at the Hydrogen Labs on the scale necessary for the success of the energy transition in Germany.

PROJECT OVERLOOK

To achieve a rapid market ramp-up of hydrogen technologies in all sectors and to establish corresponding value chains, research along the entire value chain of hydrogen production is needed. The three megawatt-scale Hydrogen Labs of the Fraunhofer IWES meet this requirement and have clear unique selling points: In Leuna, the electrolysis pilot plant is directly connected to the H_2 pipeline and infrastructure of the regional chemical industry. The Hydrogen Lab Leuna also enables the study of process chains of corresponding syntheses and Power-to-X (PtX) process on an industrial scale. In Görlitz, the focus is on the decarbonization of industrial processes, the consideration of components and systems along the entire value chain - generation, storage, and reconversion to electricity. The Lab also enables the research on production processes for system components. This aims to make automated production of high-performance electrolysers and fuel cells possible. In Bremerhaven, the special feature is the direct connection to an onshore wind turbine and a powerful grid emulator. Thereby the HLB focuses on coupling green electricity with

green hydrogen production. The laboratories are complemented by overarching competencies in the field of modelling and control of decentralized and local energy systems as well as materials science and diagnostics.

SCOPE OF PLANNED WORKS

Hydrogen Lab Bremerhaven (HLB)

Research with hydrogen technology (especially electrolysers) produces a large amount of hydrogen that should not remain unused. The HLB's task is also to adapt the technology to the location and to integrate it into the local economic conditions. This includes, on the one hand, the use of the generated green hydrogen, and on the other hand, the investigation of how the by-products of the processes - oxygen and heat - can be used sensibly. In this way, cross-sectoral solutions are created that can be used as a blueprint and transferred to other regions or other fields of application.

The focus is on combining the individual elements into an overall system. In the long term, all conventional power plants in Germany will be shut down and the energy system will be fundamentally changed. The changeover to a completely renewable energy system poses many challenges. One of them is the necessity of stability of the power grid, although the primary energy sources – wind and sun – cannot be switched on and off at will. Here, HLB is looking at the interaction of wind energy and hydrogen generation, as well as the reliability of the plants, even if a fault occurs in the power grid.

Another research topic at the IWES is offshore wind energy. This includes site assessment. For this purpose, so-called LiDAR buoys are used, which measure the wind conditions at any given offshore location. As part of the project, a fuel cell is being developed for the emergency power supply of the measuring buoy. In the future, it would be worthwhile to be able to produce or use hydrogen directly offshore. Here, however, there are other requirements than on land. In particular, the supply of ultra-pure water is an obstacle. The HLB will serve as a test and validation platform to test and then reliably establish the technology.

Hydropgen Lab Leuna (HLL)

At HLL, industrial-scale electrolysers of any type – polymer electrolyte membrane- (PEM), alkaline- (AEL) or solid oxide electrolyser (SOEC) – can be tested in continuous operation, by simulating dynamic load profiles when operating with electricity from photovoltaics and wind turbines, to investigate performance, cost-effectiveness and long-term behavior in real operation and time-accelerated aging tests.

The green hydrogen generated at HLL can be used on site in Power-to-X processes for the sustainable synthesis of chemical feedstocks, such as methanol. Due to the Integration of the HLL into the Leuna chemical site, model processes for sector coupling can thus be demonstrated directly at the chemical site and tested under realistic conditions, on an industrial scale.

Hydrogen Lab Görlitz (HLG)

The HLG will provide a research and development platform for the power-to-H2-to-power value chain, which is crucial for the energy and mobility sectors as well as industry. For this purpose, a multi-strand chain of electrolysers, pipeline systems, H2 storage and fuel cells with a total electrical capacity of 12.3 MW will be installed. In this chain, individual links can be replaced by test plants and prototypes to evaluate their real operation in the overall context of the hydrogen value chain - without having to rebuild the entire chain for individual development projects.

In addition to the development of production technologies for electrolysers and fuel cells suitable for large-scale production, the focus of research activities lies on the digitization of hydrogen technology. The modeling of individual components and their digital integration into a virtual overall model along defined interfaces allows distributed development of optimized plants, supported by modern database systems. At the same time, sensors for real-time monitoring of both production and operation of electrolysers and fuel cells will be developed to ensure quality and longevity and to detect faults at an early stage and initiate countermeasures by comparison with databases.

PRESENT STATUS AND OUTLOOK

HIB

At the start of operations at the end of 2022, the Hydrogen Lab Bremerhaven (HLB) will be able to produce up to one ton of hydrogen per day with two megawatt-scale electrolysers. By using a nearby wind turbine as a renewable energy source, green hydrogen will be produced. In the area of application technologies, a fuel cell and a hydrogen combined heat and power plant (CHP) will be constructed. In addition, the test field offers the possibility to connect further plants according to a modular principle. This will allow permanent extensions of the infrastructure or temporary test campaigns with industrial customers. In addition to the connection to wind energy, the HLB also has a connection to the virtual power grid of Fraunhofer IWES. Up to now, this realistic grid simulation has been used to test the electrical components of wind turbines for their grid compatibility and reactions to certain fault conditions in the power grid. At the HLB, this procedure can now also be applied to hydrogen technology to assess the performance of electrolysers under realistic 'green' operating conditions.

HLL

The Hydrogen Lab Leuna consists of an outdoor testing area as well as a laboratory and a technical center. The HLL is fully integrated within the chemical industry site Leuna and operates 24/7. The outdoor testing area was completed in May 2021 and comprises 4 separate test pads with 5 MW power supply each, designed for long-term system tests of all types of electrolysers (PEM, SOEC, AEL, AEM) as well as demonstrator systems for the utilization of hydrogen in chemical synthesis (PtX). Completion of the technical center including the laboratory is expected in spring 2022. The building will primarily be used for the performance and assessment of electrolysis system components on the kW scale as part of the H2Mare and H2GIGA projects. Fraunhofer IWES is currently developing a pilot process for producing methanol from CO2 and green hydrogen at the HLL together with "Total-Energies" and Sunfire in the eCO2Met project.

HLG

The Hydrogen Lab Görlitz will be constructed by the end of 2023 and will contain test facilities of industrial scale to generate, process, store and utilize hydrogen. Within the framework of research projects, the hydrogen production by PEM- and AEL-electrolysis as well as the development of an electrolyser design for fully automated mass production is addressed. Furthermore, characterizations on system-, stack-, cell- and component-level regarding performance and aging behavior under real conditions are planned. For hydrogen compression further development of electrochemical compressors towards systems with variably adjustable discharge pressures, exceeding 900 bar, are in progress. Chemical Storage for Hydrogen such as ammonia (NH3), Liquid Organic Hydrogen Carriers (LOHC) and metal hydrides are planned to be tested once the construction phase is finished. Additionally, physical storage of hydrogen for stationary use in high pressure tubular storage systems will be tested within the H2Mare project in Görlitz. Moreover, the test infrastructure in Görlitz is laid out for long-term testing and certification of hydrogen technologies.

ABSTRACT

Among the various approaches for decarbonization of the steelmaking industry, two main routes should be considered, based on the intensive use of hydrogen (H_2) (CDA) and capture and use of CO_2 (CCU). One consists of the progressive conversion of the BF-BOF facilities to direct reduction-electric arc furnace (DRI-EAF). The second alternative is the production of hot metal (HM) by installing a gas-based direct reduction plant feeding DRI to an open slag bath furnace (DRI-OSBF). Schemes for liquid steel production with reduced or practically nil carbon input by using H_2, its equivalent cost for DRI production and the reduction of CO_2 emissions are analysed.

Keywords: Hydrogen, Direct Reduction, ENERGIRON process, Electric Arc Furnace, Open Slag Bath Furnace.

INTRODUCTION

The ENERGIRON DR process is the most flexible for sustainable production of suitable DRI quality for steel production via EAF or hot metal via OSBF using natural gas (NG) and/or H_2 as energy replacement of coal (Fig. 1).

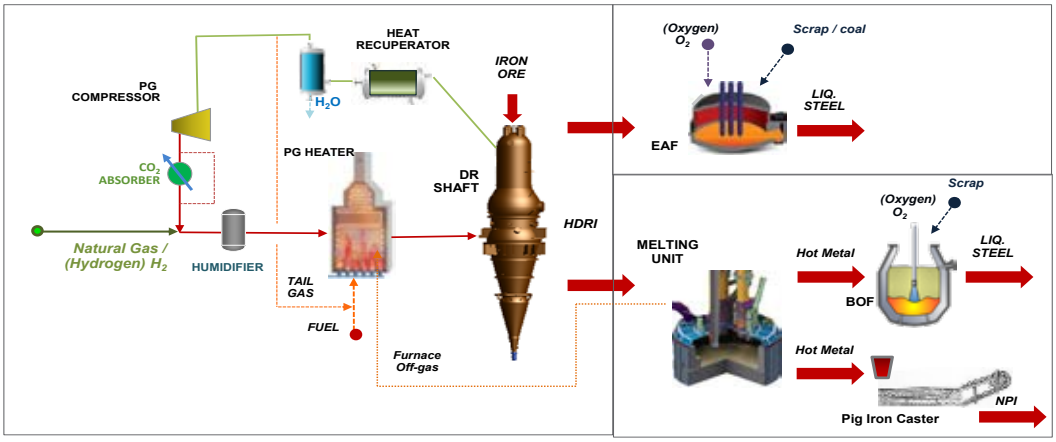

Fig. 1. Routes for Sustainable SteelmakingENERGIRON Process + EAF for Liquid Steel / OSBF for Hot Metal Production

The DR process consist of the reduction of iron oxides for production of direct reduce iron (DRI) using H_2 and CO as reducing gases. In general, the higher the temperature the faster the extent of the reduction process, whether the reducing agent is H_2 or CO. However, the reduction of iron ore with H_2 is more than 4 times faster as compared to CO. The ENERGIRON process is based on high operating temperature; >1,050°C with 100% NG and 950°C with 100% H_2, high operating pressure; 6-8 barA and selective CO_2 removal from the recycling gas. A unique feature of this technology is that when using 100% NG, ~62% of total carbon input to the process is selectively removed for CCU applications.

Although there is long lasting industrial experience of HYL/ENERGIRON plants with intensive use of H_2 for DRI production, typical H_2 concentration in the reducing gases is ~70% vol., using reformed gas as source of reducing gas through steam/NG reformer.

The approach for green steel production is based on the replacement of NG by fossil-free H_2, generated through electrolysers powered by renewable energy sources. In the 1990´s, Tenova HYL carried out extensive campaigns in its pilot plant using ~100% H_2 as reducing gas for production of highly metallised DRI. These tests provided all necessary information to define:

- Process and design parameters, mainly related to optimized flow-temperature correlation.
- DRI quality in terms of metallization and carbon content.

- Optimization of operating pressure, reactor L/D ratio, solids residence time (τ), to consistently achieve the DRI quality, determination of fluidization factor (f) to ensuring proper gas velocities and distribution through the solids bed, among others for the proper gas distribution and design of the scheme for H_2 utilization.

These campaigns at demonstration/pilot plant tests with high-H_2, simply reflect the fact that the ENERGIRON technology is already available for the use of 100% H_2. Main challenges when using 100%H_2 are related to the use of DRI with very low or 0%C in EAF and its energy equivalent cost in terms of electricity.

DRI-EAF SCHEME ANALYSIS

In general, the ENERGIRON ZR scheme provides a significant flexibility as compared to other DR technology. For the HYL/ENERGIRON DR technology, there are some characteristics which makes this process scheme the most suitable for H_2 use:

- The ZR process scheme is inherently suitable for any reducing gas make-up, specifically H_2.
- H_2 make-up directly replaces NG in the process. Same process/plant for any combination of NG/H_2 and reversible operation at any time. For H_2>70% (%energy), CO_2 removal is not required and can be by-passed.

In terms of DRI quality, the process is characterised by:

- Wider flexibility for significant %C in DRI with high concentrations of H_2. Using H_2 in the DRP to up to 35% (%energy) or ~70% vol. as process energy combined with NG, for achieving ~3.3%C in DRI.
- Efficient and safer high operating pressure (6-8 bar A) to better handle H_2-rich gases.

Energy consumption figures for DRI production and %C for different NG/H_2 ratios for the ENERGIRON process are presented in Fig. 2. The expected energy consumption for this process with H_2 is as low as 6.6 GJ/tDRI as H_2 for process plus 1.7 GJ/tDRI of fuel and about 55 kWh/tDRI for the core plant. This exceptionally low electricity consumption is not only because of the H_2 use but also due to the high operation pressure of the ENERGIRON system (≥6 barA @ top gas).

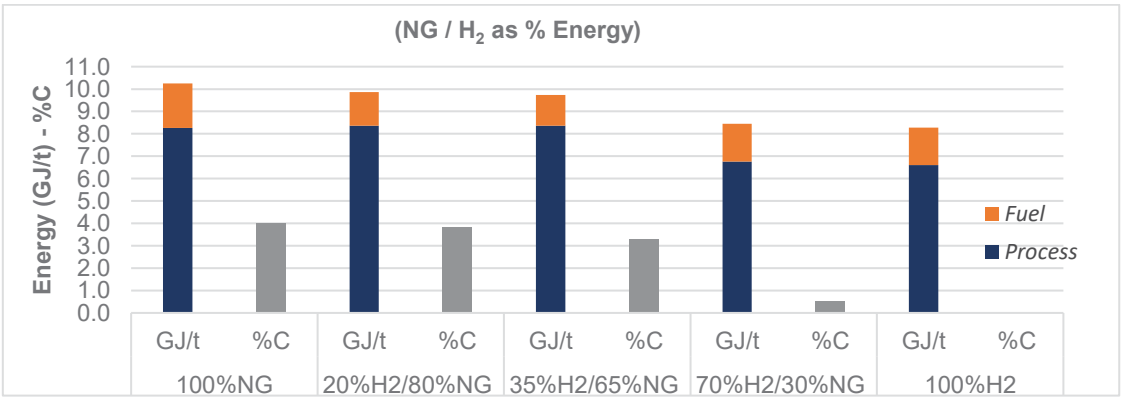

Fig. 2. DR Process schemes for different %NG/H_2

RESULTS AND DISCUSSION

In general, EAF's operations to melt DRI are based on certain DRI characteristics for reducing remaining FeO and promoting foaming slag. The optimum %C in DRI is based on the amount of DRI in the mix feedstock for certain steel quality, specific cost scenario, among others. H_2-based DRI will imply to feed low or 0%C DRI, which will require particular EAF melting practices. Fact: a minimum carbon content in DRI or carbon injected separately is required for EAF steel production operations.

Options:

1) To produce DRI from high Fe content premium iron ores, with the optimized/highest metallization (~96%), thus minimizing the FeO content. Considering the stoichiometric requirements for reduction of remaining FeO and minimum melting needs, the %C in DRI will be ~ 0.8 – 1.2%. This will imply certain NG injection to the DR plant, which is possible for the ENERGIRON process operating with ~90% (vol.) H_2, as already demonstrated in Tenova HYL pilot plant.

2) To produce DRI from selective iron ores chemistry with 100% H_2 and 0%C, which will be fed to an EAF, requiring a minimum carbon injection of 12-15 kg C/t steel, with particular melting operations and slag engineering practices.

While option 1) will result in emissions of about 150 kg CO_2/t steel, option 2) will represent just about 50 kg CO_2/t steel. In terms of overall decarbonisation, Option 2) would be the preferred choice for H_2-based steelmaking. However, longer tap-tap time and higher power consumption may be expected for option 2) as compared to option 1).

On the other hand, for OSBF, DRI with >3.0%C is possible with 70% vol. H_2 with the ENERGIRON technology as differentiating factor vs. other DR technologies. With this DRI carbon content, it is possible to produce hot metal in the OSBF with 4%C to be further processed in existing BOF's in integrated steelmaking facilities.

The analysis of CO_2 emissions for the schemes DRI-EAF/OSBF, as compared to BF-BOF, is presented in Fig. 3. Locations is carbon-neutral electricity, including CCU for CO_2 in DRP, which is selectively removed from the ENERGIRON DRP as inherent characteristic of the process. CO_2 emission factor for iron ore (typically Scope 3) is not included in this analysis; for all others inputs as per Scope 1, 2 and 3 as applicable (CO_2 Emissions Data Collection User Guide, Version 7. WSA). In case iron ore is included as Scope 3, all figures will be ~+10% vs. BF-BOF (100%).

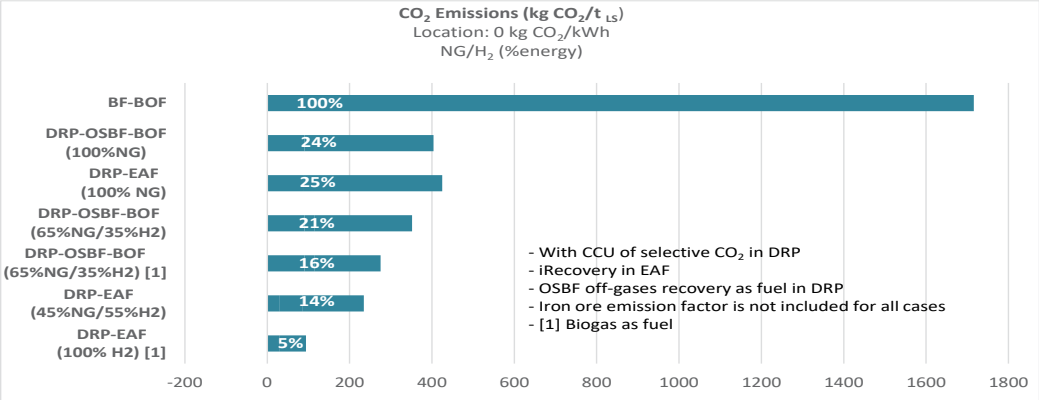

Fig. 3. CO_2 emissions for DRI-EAF/OSBF-BOF schemes

As related to fossil-free H_2 generation and supply, in general, the Alkali Electrolysis (AAE type) provides a cost-effective solution for large scale H_2-production based on an established supply chain. The largest module capacity is of 4,000 Nm^3/h H_2 with a total energy consumption of about 4.6 kWh/Nm^3 H_2. Lower consumption figures are expected with Proton Exchange Membranes (PEM) and High Temperature Electrolysers (HTE) type electrolysers.
As observed in below Fig. 3., H_2 cost, as compared to NG cost scenario, depends on the local electricity cost.
In general, to be competitive vs. NG, electricity cost for H_2-based DRI production shall be < $20/MWh.

CONCLUSIONS

The ENERGIRON DR technology is a very efficient process in terms of energy consumption and scheme simplicity. This scheme is the most flexible and proven technology for sustainable production of suitable DRI quality for steel production via EAF or hot metal with intensive use of H_2, up to 100% for the case of EAF.

Production of hot metal through DRI-OSBF with ~70%H_2 vol. allows the integrated mill steelmaker to optimise investment costs by keeping its downstream facilities in operation while replacing only the BF ironmaking installation.

ABSTRACT

For reducing greenhouse gases, the introduction of machines (Mobility and Power plants) that operate on hydrogen as a fuel has been under way. For hydrogen to be produced in a carbon-free way, water electrolysis using renewable energy is one of the methods implemented in the industry. Since continuous power generation is not committed from solar and wind power, stable production of hydrogen can be challenging as well. Therefore, we considered the efforts to stably produce green hydrogen by water electrolysis using geothermal power generation, and in 2021, New Zealand's first megawatt-class hydrogen production plant using geothermal power generation started its operation. This report describes the hydrogen production equipment, its operating conditions, and the utilization of hydrogen produced.

Keywords: Green Hydrogen, Geothermal Power Generation, Supply Chain

INTRODUCTION

For global warming countermeasures, it is important to use machines (Mobility and Power plants) that operate on hydrogen which does not generate any greenhouse gas in the production process. Water electrolysis using renewable energy can be considered and the efforts to stably produce green hydrogen by water electrolysis using geothermal power generation have been studied. As a result, in 2021, a green hydrogen production plant using geothermal power generation was put into operation at two locations in New Zealand and Japan. This report shows New Zealand's effort.

GREEN HYDROGEN PLANT

Fig. 1 shows a view of the hydrogen production plant. The plant is located near the MOKAI geothermal power plant in New Zealand, from which power lines are connected. Fig. 2 shows the system flow diagram of the plant. Using the green power generated at the MOKAI geothermal power plant, the water electrolyzer is operated to produce stable green hydrogen at approximately 22 kg/h. The produced hydrogen can be filled in gas curdles after being compressed to 20 to 45 MPa or 70 MPa for fuel cell vehicles. In addition, the system can grasp the amount of hydrogen produced by the Coriolis type flow meter.

Figure 1. View of the Hydrogen Production Plant

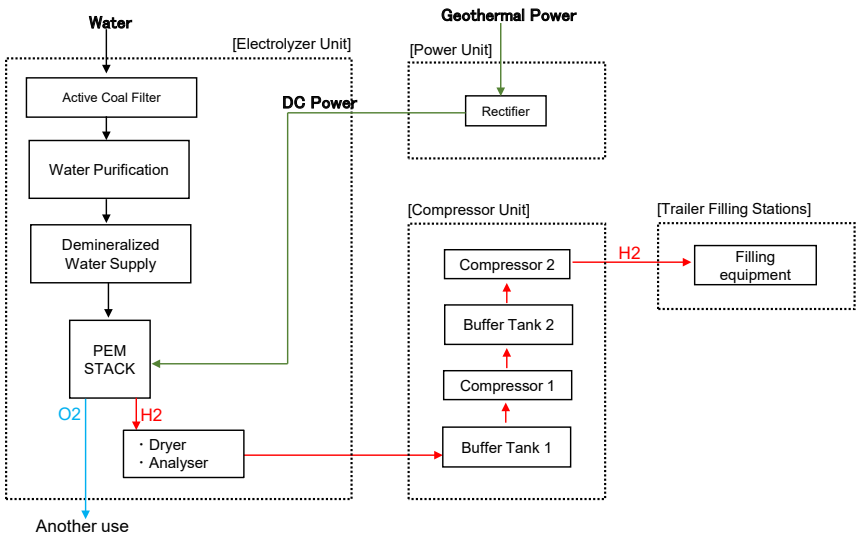

Figure 2. System Flow Diagram

PLANT OPERATION

At the plant shown in Fig. 1, stable green hydrogen production and compression to gas curdles are carried out. The produced hydrogen is supplied to fuel cell vehicles and leveraged for other use. The relations between the amount of hydrogen produced and that of electricity used are being investigated by actual measurement. Based on the measurement results, an economic evaluation of hydrogen production by geothermal power generation is being performed.

HYDROGEN SUPPLY CHAIN

We aim to build an overall hydrogen supply chain from production to supply to the off-takers. In this supply chain, green hydrogen, being stably produced from geothermal power generation, will be steadily supplied to each market shown in Fig. 3. We intend to maximize its economic efficiency by supplying hydrogen to fit the need of each market, by building a system that enables a producer/supplier(s) to grasp the market and transportation status with accuracy.

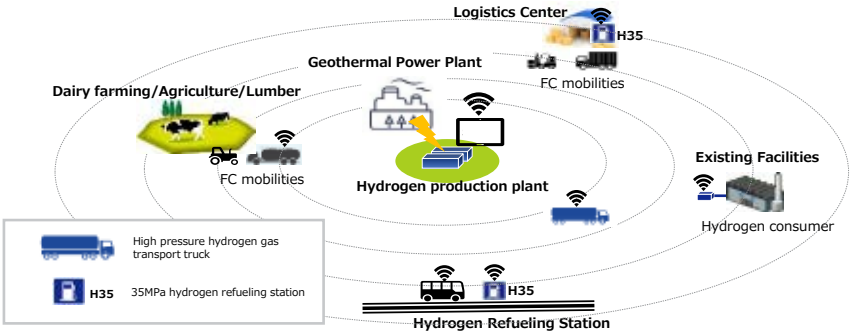

Figure 3. System Diagram

CONCLUSION

Water electrolysis produces green hydrogen using electricity from the Mokai geothermal power plant in New Zealand. This has made it possible to stably supply 200 tonnes of green hydrogen annually. Further, the amount of electric power required for hydrogen production and compression was successfully grasped through this plant operation, and the economic efficiency has been evaluated. We are thriving to build a consistent hydrogen supply chain from manufacturing to supply. This is how Obayashi can contribute to the prevention of global warming by converting geothermal energy into green hydrogen with stable and efficient operation.

GREEN HYDROGEN PRODUCTION USING GEOTHERMAL POWER GENERATION (2) PROJECT IN OITA, JAPAN

[1*] *Hitoshi Nagatsugu,* [1] *Kiyoshi Shima,* [1]*Tsuyoshi Ito,* [1] *Moriya Kajiki*

ABSTRACT

Japan has the third-largest geothermal resource in the world. Geothermal power generation is one of the renewable energy sources being an excellent energy source with a stable supply. Unfortunately, however, commercialization has been delayed due to several reasons. Because geothermal power generation facilities are in mountainous areas, the capacity of the power grid is often insufficient. In addition, since the development period is rather long, the capacity of the commercial power grid to apply for the feed-in tariff (FIT) gets filled earlier by other renewable energy projects which require a mere short development period. Accordingly, there exists difficulty for geothermal power to be connected to the transmission line. Therefore, we considered promoting the use of green hydrogen and establishing its economic efficiency along with the development of geothermal power generation. This project demonstrated a scheme in which hydrogen produced by geothermal power in Oita Prefecture is transported to various parts of Kyushu by land.

Keywords: Green Hydrogen, Geothermal Power Generation, EMS, Hydrogen Transport System, Supply Chain

INTRODUCTION

Japan's policy positions hydrogen as a key carbon-neutral technology that can be utilized in a wide range of applications, including power generation, industry, and transportation, and thus, the diverse policies and support are being implemented nationwide. The significance of hydrogen production using geothermal power generation with renewable energy is expected to be economical by using the electricity of solar and wind power, which will be introduced in large quantities in the future, and to contribute to stabilizing the grid power. We have challenged various hydrogen demonstrations to create new socially meaningful value in the view of carbon neutrality. This report shows Japan’s first demonstration project of hydrogen production and transportation using geothermal power generation.

FACILITY OVERVIEW

Fig. 1 shows the panoramic view of the plant. The plant is located in a mountainous area in Kokonoe Town, Oita, Japan. Table 1 shows the main facilities. The electrolysis unit operates with 100 kW of generated power from a binary turbine generator and produces 10 Nm3/h of hydrogen. The produced hydrogen is charged in a gas bundle with a pressure of 19.6 MPa and transported to neighboring areas by land.

Fig. 2 shows the system flow diagram of the plant. A mixed vapor blowing out of the 700-meter deep production well is separated into steam and hot water by the steam separator, which passes heat to the binary generator through each heat exchanger. The characteristic of binary generators is that the low potential source such as low temperatures of about 100°C can be applied. This system uses hot water for preheating to improve overall power generation efficiency.

ENERGY MANAGEMENT SYSTEMS(EMS)

The energy management systems (EMS) have the function of continuous operation efficiently without handling the plant systems according to a transportation schedule from the GPS terminal mounted on the hydrogen carriers. The operation pattern is calculated and instructed in Excel as needed so that hydrogen production, transportation and supply can be carried out without wasting time. E Operation modes (shown in Fig.3) are the inexpensive hydrogen production cost mode, prioritizing the Hydrogen greenness and maximizing the hydrogen production amount.

CONCLUSION

The green hydrogen produced at this demonstration plant is transported to nearby hydrogen stations and hydrogen research facilities for effective use as a local energy resource. In addition, by studying various ways to utilize the green hydrogen and geothermal power generated in this demonstration project, we will continue our challenge to make many people including local residents realize the use of renewable energy and the advent of a hydrogen

society. Based on the knowledge from the demonstration experiment, we conduct to establish the economic efficiency in the supply chain from production to supply of green hydrogen.

ABSTRACT

Hydrogen represents a viable alternative as fuel for future power generation plants. Different uses include but are not limited to partial substitution of coal in boilers, an energy source for preheating air, and fuel for starter-diesel boilers. The objective of power generations plants is to reduce emissions to fulfill national and international commitments before 2050. To speed up the use of hydrogen in established power plant generation systems, it is necessary to evaluate the current combustion technology and its flexibility to handle hydrogen due to the large difference in hydrogen thermophysical properties compared to other fuels such as natural gas or diesel. One of the main components that are calling the attention of researchers is the injection-mixing technology. The micromix hydrogen combustion injector allows a fast and intense mixing of hydrogen and air. As a result, micro flames are developed, and the residence time of the NOx-forming reactants is reduced. This study aims to evaluate the effect of air-fuel ratio on flame structure and stability in a micromix hydrogen combustion injector.

Keywords: Micromix Burner, Hydrogen, Combustion, Flame Temperature

INTRODUCTION

Advances in fuels such as hydrogen or mixtures of gaseous hydrocarbons with hydrogen have attracted attention in the scientific community. For example,Yilmaz investigated the effect of the air-fuel ratio, thermal energy produced, and the fuel composition in the combustion chamber using hydrogen-methane mixtures [1]. It was observed that the increase of hydrogen in the fuel mixture increased the temperature in the combustion chamber, while by increasing the air in excess, the temperature in the combustion chamber decreased. This behavior is crucial because it enables temperature control by manipulating the air mass flow rate.

The composition of the fuel mixture impacts the gases produced by the reaction. Increasing the amount of hydrogen in the fuel mixture reduces CO and CO_2 emissions; however, as the hydrogen share increases, the amount of H_2O and NO_x in the combustion gases increases [2], [3].

In the study presented by An et al. [4], the effect of hydrogen on the flame structure was analyzed in a low-swirl injector (LSI) burner. Depending on the design of the LSI and the operating conditions, the shape of the flame varies. The operating conditions that can be manipulated are volumetric flow, equivalent air-fuel ratio, and fuel composition; however, few studies exist. Carrying out this type of research is of vital importance in the context of the transition to clean, low-carbon energy, where the substitution of hydrogen for fossil fuels is a promising alternative. Furthermore, successful integration of H_2 in LSI-type burners requires a greater understanding of the role of hydrogen in flame stabilization.

The recent concept of Micro-mixing Combustion (MMC) is a combustion technology for hydrogen-enriched gas turbines. The objective is to achieve low NO_x emissions by reducing the size of the area in which the mixture between fuel and air occurs, thus achieving greater uniformity in the process reducing the residence time of combustion gases [5]. In this type of technology, conventional nozzles are replaced by numerous micro-nozzles, which evenly distribute fuel and air within each nozzle for mixing and subsequent injection into the combustion chamber.

Haj Ayed et al. [6], [7], studied the effect of various design parameters and combustion models on flame structure, hydrodynamics, and NO_x emissions in hydrogen combustion using micro-mixers. It had been reported that increasing the energy density in the burners produced more NOx emissions; however, a proper selection of the burner and injector geometry allows emissions to be reduced by approximately 80% through manipulating the shape of the flame and its stabilization. This is accomplished by adjusting the mixing length, the length of the flame, and the length of the shear boundary layer.

MODELING

The study aims to evaluate the potential use of a computational fluid dynamics (CFD) model as a tool for understanding the performance of a micro-mix burner. The CFD open-source software OpenFOAM v9 is used to simulate the combustion process using the reactingFoam solver.

The mass conservation is given by Eq. (1),

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \left(\rho \vec{U}\right) = 0 \quad (1)$$

Eq. (2) gives the momentum balance equation,

$$\frac{\partial (\rho \vec{U})}{\partial t} + \nabla \cdot \left(\rho \vec{U} \times \vec{U}\right) = \nabla \cdot \left[\left((\mu + \mu_T)\left(\nabla \vec{U} + \nabla \vec{U}^T\right)\right) - \frac{2}{3}\nabla \cdot \vec{U}\,\bar{\bar{I}}\right] - \nabla p + \rho \vec{g} \quad (2)$$

where $\rho\,[kg/m^3]$ is the density, $\vec{U}[m/s]$ represent the local velocity components, $\vec{g}[m/s^2]$ the gravitational acceleration, $p[Pa]$ the pressure and $\mu[Pa \cdot s]$ and $\mu_t[Pa \cdot s]$ are respectively the dynamic and turbulence viscosity.

The energy balance equation, using the enthalpy form, is given by Eq. (3),

$$\frac{\partial (\rho h)}{\partial t} + \nabla \cdot \left(\rho h \vec{U}\right) + \frac{\partial (\rho k)}{\partial t} + \nabla \cdot \left(\rho k \vec{U}\right) - \frac{\partial p}{\partial t} = -\nabla \cdot q + \nabla \cdot \left(\tau \vec{U}\right) + \rho r + \rho g \vec{U} \quad (3)$$

where h is the total enthalpy, k is the kinetic energy, q is the heat flux, τ is the mechanical source, and r is the radiation.

The turbulent scale-resolving strategy used in the numerical simulation is Large-Eddy Simulation (LES). LES is based on unifying the phase averaging concept and the turbulent-scale filtering operation into one single process [8]. The eddy or turbulent viscosity μ_t in Eq. (2) is estimated using the Smagorinsky (1963) [9] turbulence model

The computational domain consists of a 2D simplified model of a micromix burner with the air-inlet at the left and the gas mixture outlet at the right. The hydrogen is injected vertically; thus, a proper mix with the air stream is accomplished. The mesh is composed of hexahedral cells with a level 0 size of 0.627mm, see Figure 1.

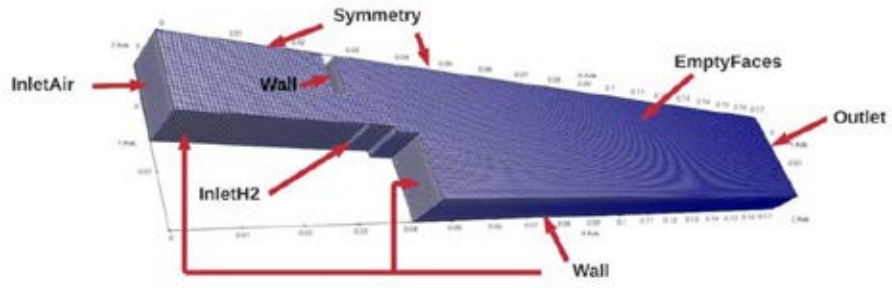

Figure 1 Computational domain. It is composed of hexahedral mesh with a level 0 size of 0.627mm.

During hydrogen combustion, Nitrogen Oxides (NO_x) are present in the emissions produced by the chemical reactions. NOx production is strongly related to high temperatures and the residence time of reactants in the combustion chamber. This study aims to assess the effect of the air and hydrogen velocity on the temperature and residence time of reactants. We use LES turbulence modeling to obtain a reliable velocity field; previous literature has only used Reynolds Average Navier Stokes (RANS) turbulence modeling. Table 1 presents the run cases.

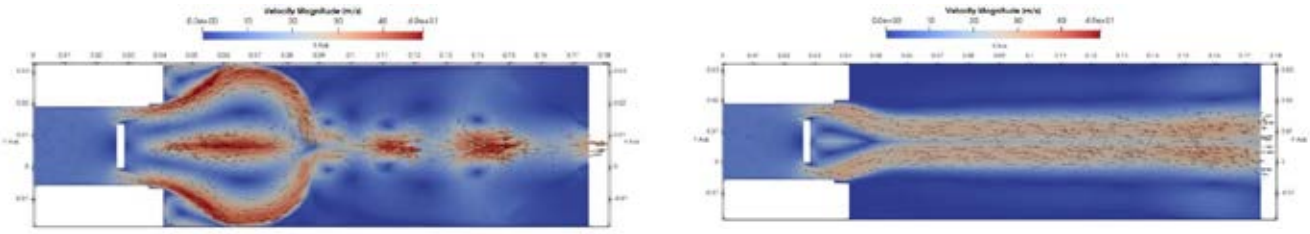

Table 1 Numerical Simulation Cases

Case ID	Air Flow Superficial Velocity [m/s]	Hydrogen Flow Superficial Velocity [m/s]	Air-Fuel Ratio
01	8.1	6.23	285.25
02	4.05	6.23	142.63
03	8.1	3.11	573.27

The computational time required by each case was approximately 24 h for 2 seconds of simulation. The actual CPU time depended on the velocity field because of the restriction imposed by the global Courant number [10]. The time step was adjusted continuously and was in the order of $1e^{-6}\,[s]$.

RESULTS AND DISCUSSION

Case 01 in Table 1 results are presented as follows. Air flows along the positive x-direction from the air inlet located on the left side. There is an obstruction to divert the flow and increase the gas velocity. In this high-speed zone, the hydrogen is injected vertically and is mixed with the air, see Figure 2a. It is essential to mention that this hydrodynamic behavior has not included the reaction between the species.

a) Velocity field at 0.3 seconds.

b) Velocity field at 1.5 seconds.

Figure 2. Velocity field before a), and after b), of ignition.

Once the flow was developed, a spark was implemented to promote the reaction between hydrogen and oxygen. This reaction increases the temperature to 2,300 K, and the gas mix is expanded. As a result, there is a zone of high-speed in the center of the micromix burner, see Figure 2b, and vortices are generated in the low-speed zone. Because of the high-speed zone, a large amount of air has a short residence time in the combustion chamber. In consequence, it is expected a relatively low NO_x generation.

Interaction between vortex and flame is an important mechanism for reducing NO_x formation. Vortex size determines the residence time of particles; therefore, a vortex of smaller diameter reduces NO_x formation. The geometry of the micromix burner used in this study promotes the generation of small vortices. This result explains why NO_x formation is lower than in larger flames. Figure 3 presents the Residence Time Distribution results for each case. The residence time for case 02, which uses a lower air flow rate, has a longer residence time.

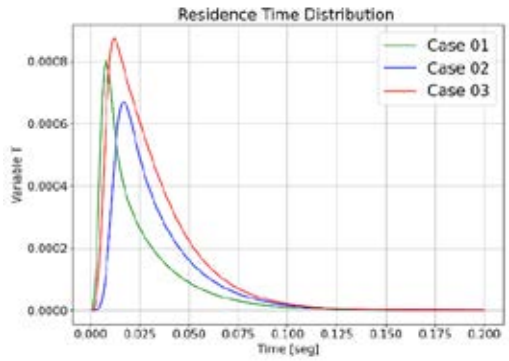

Figure 3 Residence Time Distribution for each simulation case.

CONCLUSIONS

- Increasing the amount of hydrogen increases the maximum temperature in the combustion chamber.
- There is a high-speed zone in the center of the micromix burner, and vortices are generated in the low-speed zone.
- Micromix geometry promotes a short residence time, expecting a reduced amount of NOx.
- It is necessary to evaluate the effect of hydrogen injection location on maximum temperature and residence time.

ABSTRACT

The effect of hydrogen induction (0-5 liter per minute) in to the intake manifold of the small bore Gasoline Direct Injection (GDI) Engine is investigated experimentally. The intake manifold is slightly modified to accommodate the hydrogen induction system, where premixed mixture of hydrogen and air is formed in the intake manifold; attaining the excess air ratio of 1.0 to 1.2. With the increment of hydrogen fraction the fuel leaning (Gasoline) is attained and achieving economical fuel consumption rate. The decrement in torque characteristics is compensated with the increase of hydrogen fraction. The hydrogen induction improves the combustion rate and mean effective pressure; shortens the flame propagation, maximize the heat release rate and peak pressure attainment. On the emission side consistent decrease in CO and HC emission; and increase of NO_x emission since the mean gas temperature has increased. The cycle to cycle variation during the lean operating condition at 1.2 shows the combustion stability and effective flame propagation.

Keywords: Hydrogen Induction, Small Bore, Gasoline Direct Injection,

INTRODUCTION

The reputation of Internal Combustion Engine in recent days with fossil fuel as the working fuel has been has been in the downfall as the intense promotion of electric vehicle technology. The transportation sector contributes to 10% of the greenhouse gas (GHG) emission which makes it meager when compared to the energy sector [1]. The 100 years of scientific improvement in the engine technology makes it more mature than other recent alternative technologies. It is clear those alternatives to compete with IC engine do not cover the vast range of application. A lot of times the blame of the IC engine is about the source of the working fuel and not on the IC engine technology. Compared with the conventional fossil fuels hydrogen pose superior characteristic and more suitable for SI engine, where it offers wider flammability range with high diffusivity and low ignition energy. With the safety precaution and advancement towards the storage of hydrogen makes it viable option for alternate for fossil fuels. From the prior arts it is found that adding little quantity of hydrogen with the conventional fuels offers better heat release rate, stable lean mixture formation and improved combustion efficiency. Further it shortens the delay period and offers peak pressure attainment close to top dead center (TDC). The cycle to cycle variation of the engine operating behavior was also reduced with the addition of hydrogen with the gasoline. On the emission side significant reduction in CO and HC emission was noticed; with some penalty on NO_xemission, but particulate emission in the direct injection gasoline has consistent reduction with addition of hydrogen. The implementation of direct fuel injection technology in SI engine is one of the advancement that pushes the limits of SI engine in terms of its thermal efficiency, power performance, emission and lean operating limits [2]. The gasoline direct injection (GDI) engines are getting more robust since the research advancement was towards various combustion modes, alternate fuels, dual spark ignitions, plasma ignition, dilution techniques to treat emission, in-cylinder water injection, fuel injector study, dual fuel injection, combustion diagnosis and furthermore [3]. The Gasoline Direct Injection (GDI) Engine is known for its economical fuel consumption, improved thermal efficiency and better torque characteristic. Application of GDI technology for small bore engine increases the operating limits of the engine for the light commercial vehicles (LCV) and two wheeler segment; where this percentage of vehicles in Indian roads are higher in meeting the daily commutation. The GDI technology and the usage of Hydrogen as the primary/secondary fuel paves the path towards the lean combustion technology, wherein the real problems associated with the driving condition will be addressed [4]. On roads most of the engines are operated only at the partial load conditions, wherein the actual efficiency of the engine is poor due to the poor load characteristic, throttling effect and traffic conditions (start and stop). Leaning the gasoline by operating the engine under lean conditions leads to other technical issues like overheating engine misfire and unstable combustion [5]. Addition of hydrogen for the lean operating condition of GDI engine provides more stable combustion and significant reduction in the cycle to cycle variations will be attained. After accessing the prior literature, the author aims for hydrogen-gasoline lean burn

combustion for small bore GDI engine; with the performance, emission evaluation. The effect of lean burn combustion with addition of hydrogen in gasoline and the lean limit estimation with stable combustion is also investigated.

EXPERIMENTAL APPARATUS AND METHODS

Experimental Apparatus

The engine used for the present investigation is the 390 cm^3 small bore single cylinder air cooled GDI engine. The layout of the experimental setup is shown in Fig. 1. The engine was originally available as the carburetor engine, Honda make; it was later modified to direct injection gasoline engine. The engine head was modified to support the GDI injector, throttle control was replaced with the electronic actuator and to control the spark and injection timing, an Electronic Control Unit (ECU) was fitted. To make the close-loop system CAM and crankshaft position (CKP) sensors were additionally fitted with fuel rail pressure control. The modification details of the engine were not included since it is beyond the scope of the article. The engine details are listed in the Table 1. The spark plug location in the engine is at the sides with hemispherical type combustion chamber. The piston head was not modified, production type flat piston head was maintained throughout the investigation. The spray guided fuel injector was used and it was fitted near the spark plug. The details of the fuel injector and pump are listed in the Table 2. The water cooled eddy current type dynamometer was used to load engine for operating conditions. To measure the inlet air HFM (Hot Film) Type T-MAF Sensor was employed and the gravimetric type fuel flow measuring system was used to calculate the fuel consumption by the engine. Contact type encoder was coupled with the crankshaft, this was utilized to trigger the data acquisition system to record the various sensor data. Piezoelectric pressure transducer with the resolution of 0.1 crank angle degree (CAD) was employed to record the in-cylinder pressure data. Wideband Lambda sensor (from Bosch) LSU 4.9 was used to monitor the air fuel ratio and the exhaust gas temperature was monitored by K-type thermocouple. Di-gas analyser 444 (from AVL) was used to record the engine out emission.

Experimental Methods

The test condition for the investigation is 3000 rpm with 100% throttle opening, where the maximum brake torque was obtained for the given spark timing. The engine operating conditions are listed in Table 3. The hydrogen flow rates are estimated with the energy balance of not exceeding 50% by hydrogen and the maximum limit was set to 5 LPM. For the equivalence ratio of 1, the hydrogen flow rate was varied from 5 to 1 LPM and similarly the equivalence ratio was increased to 1.1 and 1.2. For the consistent increment in the equivalence ratio the subsequent gasoline leaning will be carried out.

Table 1. Engine Details

Particulars	Details
No. of Cylinders	1
No. of Valves	2
Type of CAM	Single Overhead
Ignition	Spark
Bore*Stroke (mm)	88*64
Displacement (cm^3)	390
Compression Ratio	8.2:1
Induction	Naturally Aspirated
Rated Torque	24 Nm @3000 rpm
Rated Power	8 hp @3600 rpm
Cooling system	Air

Table 3. Engine Operating Conditions

Particulars	Details
Speed (rpm)	3000
Mode	Constant Speed Mode
Throttle position	100%
Fuel Injection Pressure	80 bar

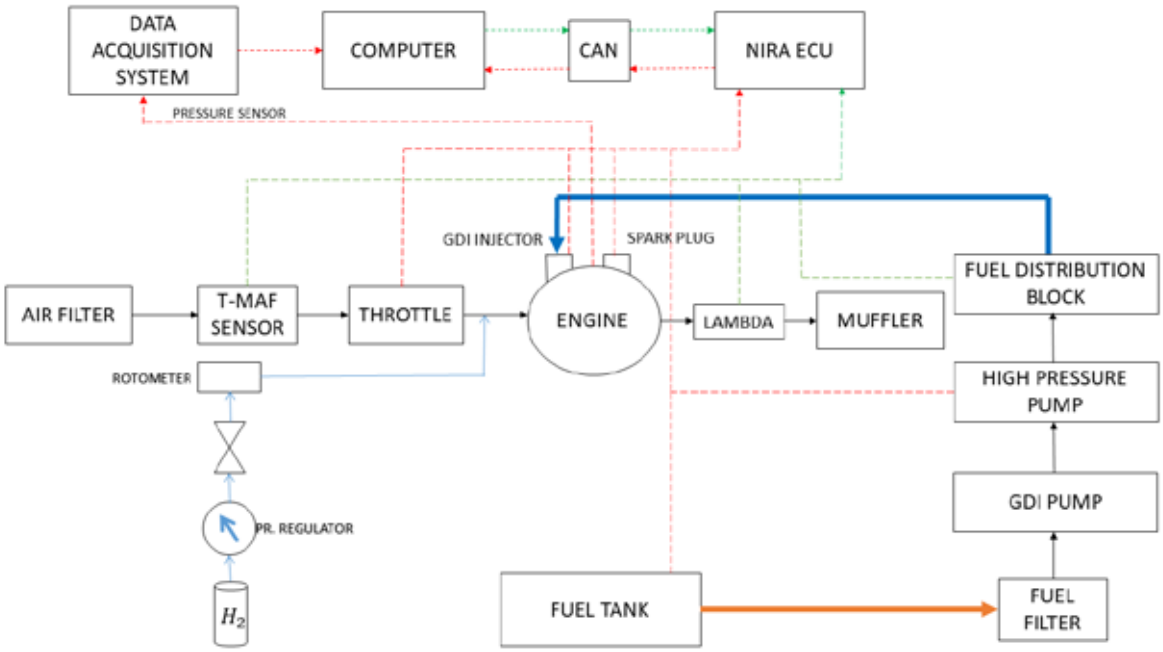

Fig. 1. Experimental Layout

CONCLUSIONS

1. Engine operation with 100% wide open throttle, equivalence ratio of 1, 1.1 & 1.2 and the varied hydrogen fraction of 1 to 5 LPM has the significant effect on the engine performance, combustion and emission characteristic. As the hydrogen fraction increases for the particular equivalence ratio significant increment in thermal efficiency and indicated mean effective pressure. At the equivalence ratio of 1.2 highest thermal efficiency was attained.
2. Engine operation with 100% wide open throttle, equivalence ratio of 1, 1.1 & 1.2 and with the increase in hydrogen fraction the combustion duration was shorten leading to peak pressure attained close to TDC. Keeping the hydrogen fraction constant and increasing the equivalence ratio improves the heat release rate and consistent reduction in the delay period.
3. Engine operation with 100% wide open throttle, equivalence ratio of 1, 1.1 & 1.2 and with the increase in hydrogen fraction CO and HC emissions decreases and increment in NO_x emissions. Keeping the hydrogen fraction constant and increasing the equivalence ratio, CO emission significantly reduces and HC emission reduces initially and increases in the later part. The NO_x emission has the adverse effect with the higher amount of hydrogen fractions.

ABSTRACT

This paper reviews the progress and perspectives in using hydrogen-enriched biogas, produced from agricultural wastes as fuel to power internal combustion engines. There is a direct link between a country's capacity for economic growth and its energy consumption, which in turn, is strongly correlated with its pollutant emissions. In response, many countries aim to exploit and include biofuels in their respective energy matrices to address energy insecurity and environmental concerns, foreign exchange savings, and fomenting growth in the rural sector. One way of realizing this potential is producing biogas through the fermentation or anaerobic digestion of organic, biodegradable waste. However, biogas has limitations when used as a fuel in internal combustion engines. In this context, hydrogen addition is one way of solving the drawbacks associated with biogas. Hydrogen enrichment of biogas has been shown to increase the engine's efficiency, mixture's lean operating limit, improving combustion stability, increase the mixture's laminar speed, and decrease carbon emissions. As a result, biological generation of hydrogen (biohydrogen) from renewable biomass presents the opportunity to simultaneously reduce fossil fuel dependence, decrease carbon dioxide emissions, and recover bioenergy. In addition, in some countries the thermal generation of hydrogen from renewable biomass is a viable option due to the abundance of solar energy.

Keywords: Biogas, Biohydrogen, Hydrogen Enrichment, Waste to Engine, Agriculture,

INTRODUCTION

There is a direct link between a country's capacity for economic growth and its energy consumption, which in turn, is strongly correlated with its pollutant emissions. In the context of a growing interest in finding ways to achieve sustainable economic growth, individual countries are obliged to meet the Nationally Determined Contributions (NDCs) of pollutant emissions agreed upon in the 2016 Paris Agreement. One such way is to replace fossil fuels, responsible for the majority of greenhouse gas (GHG) and carbon dioxide (CO_2) emissions in the energy sector [1,2], with alternatives. However, methane (CH_4) emissions, which were responsible for 20% of total GHG emissions in 2019, have a global warming potential that is 72 times higher than CO_2, and the energy sector is only the second-largest source of methane emissions [3]. The world's largest single source of methane emissions is agriculture, and in 2018, the agriculture and waste sectors accounted for 10% of Europe's and over 50% of New Zealand's GHG emissions [3]. This occurs because biomass such as animal manure and the organic fraction of municipal solid waste can produce methane [4].

Agricultural residues such as wheat straw, rice straw, bagasse, cotton stalk and wheat bran are rich in lignocellulose biomass (LCB) [5], which is the most abundant biomass resource on earth, and widely considered a potential feedstock for biofuels production that is mainly composed of three polymers: cellulose, hemicellulose and lignin, besides ash and extractives [6,7]. Cellulose consists of glucose and cellobiose as the basic coupling unit and is the most abundant polymer in LCB [6]. Hemicellulose is the second main polymer in LCB and is a short and highly branched polymer of pentoses, hexoses and uronic acids [6]. Finally, lignin is a large and complex molecular structure that contains crosslinked aromatic polymers of phenolic monomers and is disadvantageous due to its resistance to biodegradation [8].

In response, many countries aim to promote the use of biofuels in their respective energy matrices, to address energy insecurity and environmental concerns, foreign exchange savings, and fomenting growth in the rural sector [9]. Biofuel refers to a liquid or gaseous fuel that is predominantly produced from biomass. Examples of liquid biofuels include ethanol, methanol, biodiesel, Fischer-Tropsch diesel, while gaseous biofuels include hydrogen and methane [10]. Biofuels are readily available, represent a CO_2 cycle in combustion, are biodegradable, contribute to sustainability, and have a more environmentally friendly potential [11]. One way to explore this potential is by converting biomass to liquid and gaseous fuels, which is mainly done through thermochemical and biological routes [10]. Agricultural wastes are feedstocks that are particularly attractive because it is carbon neutral with low sulfur content and appear to have significant economic potential.

Within the context of the circular economy, one way of realizing this potential is the production of biogas by the fermentation or anaerobic digestion of organic, biodegradable waste [12]. Ref. [13] describes the typical molar composition of biogas as 50–75% CH_4, 25–45% CO_2,0–10% N_2,1–2% H_2, and 0–2% O_2, with a higher heating value of around 25 MJ/Nm^3. Not only composition, but also the production efficiency varies according to the raw material used as shown in Table 1 [14]. Biogas developed today is used mostly for power and heat, and a properly implemented biogas project not only helps to reduce emissions, but also promotes rural development and local job creation [4]. The presence of CO_2 in biogas leads to a narrow range of flammability limit, reduced laminar flame speed, and lower flame temperature, as well as flame quenching due to CO_2's lower reactivity [15]. Overall, direct use of biogas in engines designed for natural gas usually leads to a derating in power due to the lower HHV of biogas compared to natural gas' 39 MJ/m^3 [13].

Table 1. Amount of biogas produced from one kilogram of feedstock. Source: Ref [14]

Raw Material	Biogas Production (m3/kg)
Corn residues	0.563
Wheat straws	0.408–0.483
Rice straws	0.468–0.503
Sugarcane wastes	0.463
Lignocellulose biomass	0.178–0.402
Switch grass	0.208
Pine wood	0.033
Food wastes	0.683–0.725
Nonedible oil seed cakes	0.242
Bagasse	0.330
Dry leaves	0.118
Manure	0.129
Brewer's yeast	0.430
Dry maize	0.397
Cattle slurry	0.370
Maize silage, whole-crop rye silage	0.610

In this context, hydrogen addition is one way of solving the drawbacks associated with biogas use in internal combustion engines (ICE's). Although not a primary fuel, hydrogen is an alternative, odorless fuel with great potential as the energy carrier of the future [16]. It can be used in power generation applications, such as gas turbines, internal combustion engines, and fuel cells. The conversion of hydrogen's chemical energy into thermal energy or electricity is clean and generates only water vapor [17]. Hydrogen's high flame propagation speed and it's low minimum ignition energy facilitates combustion and formation of stable and self-sustaining flame cores, which reduces cyclic variation and accelerates combustion [18]. Also, hydrogen's short quenching distance contributes to reduced heat losses, due to less flame quenching in the vicinity of the combustion chamber walls [19], and its high auto-ignition temperature leads to knock resistance [20]. While it mostly generates non-toxic emissions, its high firing temperatures could increase thermal NO_x production in internal combustion engines [21], and its high diffusivity decreases volumetric efficiency and, depending on injection method, totally developed power due to air displacement [18,21]. Hydrogen enrichment of biogas has been shown to increase the engine's efficiency [14], mixture's lean operating limit [22], improving combustion stability [23], increase the mixture's laminar speed [15], and decrease in carbon emissions [12].

Although naturally occurring hydrogen has been found and reported, its exploration is still in its initial stages [17]. Consequently, the vast majority of hydrogen production worldwide is via extraction from fossil fuels, using methods such as steam reforming, thermal cracking of natural gas, partial oxidation of heavy fuels, and electrolysis of water [17,18,24,25]. In fact, hydrogen production through these processes is only economically viable in areas where electricity is cheap and can also cause significant emissions of CO_2. Alternatively, low-carbon hydrogen, which comprises less than 1% of current total hydrogen production [4], can also be produced from biomass, through thermochemical and biological processes. Thermochemical conversion processes, such as pyrolysis, gasification and steam gasification, are highly energy-intensive [16]. As a result, biological generation of hydrogen (biohydrogen) from renewable biomass presents the opportunity to simultaneously reduce fossil fuel dependence, decrease carbon dioxide emissions, and recover bioenergy [25]. Biohydrogen can be generated by direct or indirect biophotolysis, photo-fermentation, and dark-fermentation, or by a combination of these processes [16]. When by-products are not considered, the efficiencies of these products are lower than steam methane reform (SRM), despite more moderate non-renewable energy use and GHG emissions. However, the efficiencies of these processes increase significantly when by-products are considered. Among these biological processes, anaerobic hydrogen fermentation can yield

higher rates and at lower costs in degrading various organic wastes enriched with carbohydrates. Hydrogen fermentation could also be economical at less than stoichiometric yields by using the same hardware used for methane fermentation [26]. CONCLUSIONS

In conclusion, this paper reviews the potential of recycling agricultural waste and producing biogas and biohydrogen, and then combining these two fuels to improve engine performance of biogas. In summary, it can be concluded that:

- Biogas production from agricultural waste not only helps to reduce emissions, but also promotes rural development and local job creation;
- Biogas performance and emissions in internal combustion engines for waste to engine applications can be improved by hydrogen enrichment;
- Biohydrogen can be produced using the same feedstock used for biogas production;
- This application is a very promising way of offsetting methane and GHG emissions from agriculture and waste

ABSTRACT

Hydrogen can be an alternative fuel to control the environmental affects of the hydrocarbon fuels. Since hydrogen flame temperature and, flame speed is higher than the methane flame it is an important alternative to the hydrocarbon fuels, which can replace hydrocarbon fuels fully or partially in near future. In this study CFD study of a reactive flow of the Hydrogen-Air-Methane mixture is investigated to understand the combustion characteristics of the mixture. 5-20% H_2 is added to the CH_4-Air mixture (16% CH_4) and temperature-specie fields are compared with the CH4-Air mixture combustion. Study conducted with turbulent flow conditions and with Eddy Dissipation Concept. It is found that hydrogen addition to the mixture increases the flame temperature, water production and decreases the CO_2 concentration along the flow in each H_2 percentage increase between 5-20% hydrogen addition.

Keywords: CFD, Methane, Hydrogen, Combustion, OpenFOAM.

INTRODUCTION

Hydrogen utilization is an important research subject that is getting heavy attention over last decades. Hydrogen can be produced locally and can be used in many applications; it is an outstanding research subject. Combustion of the hydrogen is one of the important topics in this sense. Since hydrogen is flammable substance with lower auto ignition temperature (500°C for H2 and 537°C for CH_4), higher flame temperature (2045°C for H2, 1947°C for CH_4, air as oxidant at 1 atm) [1] it is an alternative fuel to the hydrocarbons. Hydrogen can be used to partially or fully replace hydrocarbon fuels in future; therefore, it is important to understand the flow characteristics of the hydrogen included combustion. Many researchers studied CH_4,-Air- H_2 mixtures in the literature [2-5], and, recently researchers studying to develop novel technologies to mix the CH_4 and H_2 [6]. In this study, CFD simulations are conducted to understand the specie production (CH_4, H_2O) and, temperature field of the H2-CH4-Air mixtures.

PROBLEM DEFINITION AND GOVERNING EQUATIONS

2D cyclic replicate of the Sandia Flame-D case is used to model the reactive flow of the CH_4-Air-H2 mixture. OpenSource PDE solver, OpenFOAM [7] is used to calculate the corresponding fields (U, T, p, rho, etc.) with a reactive compressible solver.

Continuity, Momentum, transport equations for species, and energy equation is given in Eq. 1-4 [8]. These equations solved with PISO algorithm and with a pseudo time-step.1e-4 is chosen as convergence criteria for each field. For chemical reactions GRI 3.0 mechanism [9] used. Since the flow is turbulent, $k-\varepsilon$ model is used with EDC (eddy dissipation concept).

$$\frac{\partial \rho}{\partial t} + \rho\left(\nabla . \vec{U}\right) = 0 \quad (1)$$

$$\rho\frac{\partial \vec{U}}{\partial t} + \rho\vec{U}\left(\nabla . \vec{U}\right) = -\nabla \mathrm{P} + \mu\nabla^2\vec{U} + \rho\vec{g} \quad (2)$$

$$\rho\frac{\partial Y_k}{\partial t} + \rho\vec{U}(\nabla . Y_k) = \nabla(\rho D \nabla \mathrm{Y_k}) + \omega_k \quad (3)$$

$$\rho\frac{\partial h}{\partial t} + \rho\vec{U}(\nabla . h) = \nabla\left[\frac{\mu}{\sigma_h}\nabla . h + \mu(\frac{1}{S_{c_k}} - \frac{1}{\sigma_h})\sum h_k \nabla Y_k\right] + \frac{\partial \rho}{\partial t} + S_{rad} \quad (4)$$

Fuel inlet velocity is taken as 49.6 m/s and, pilot inlet velocity is taken as 11.4 m/s. Temperature of the pilot inlet is 1880 K and the fuel inlet temperature is 298 K. Total combustion chamber length is 0.5 m.

RESULTS AND DISCUSSION

Before starting to the simulations, a validation study and, a grid independency study is conducted. Fig. 2 shows the comparison with the Sandia Flame D records [10-12], CH4-Air combustion data and, the grid independence study. Our results shows that this case is grid independent after 46110 number of grids in 2D cyclic domain and, our data is close enough to the experimental values.

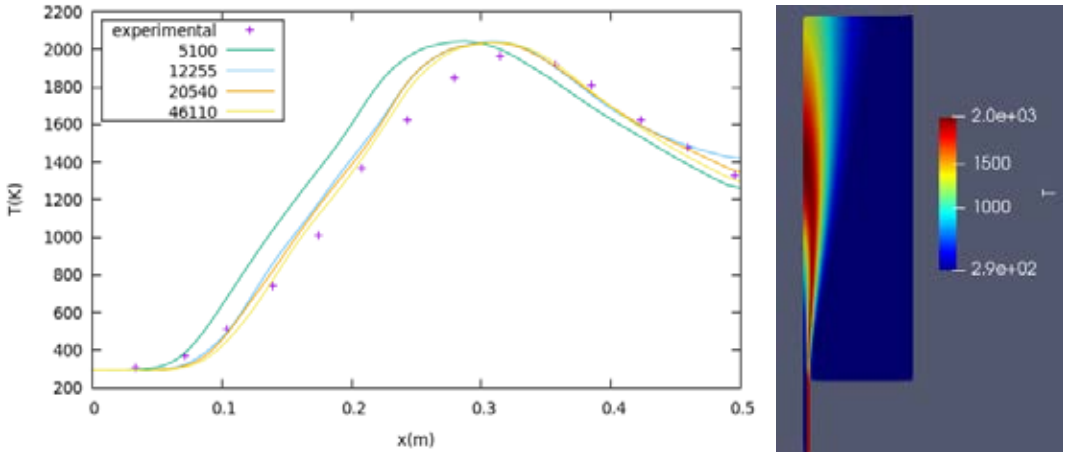

Fig. 2. Grid independency study and the temperature profile

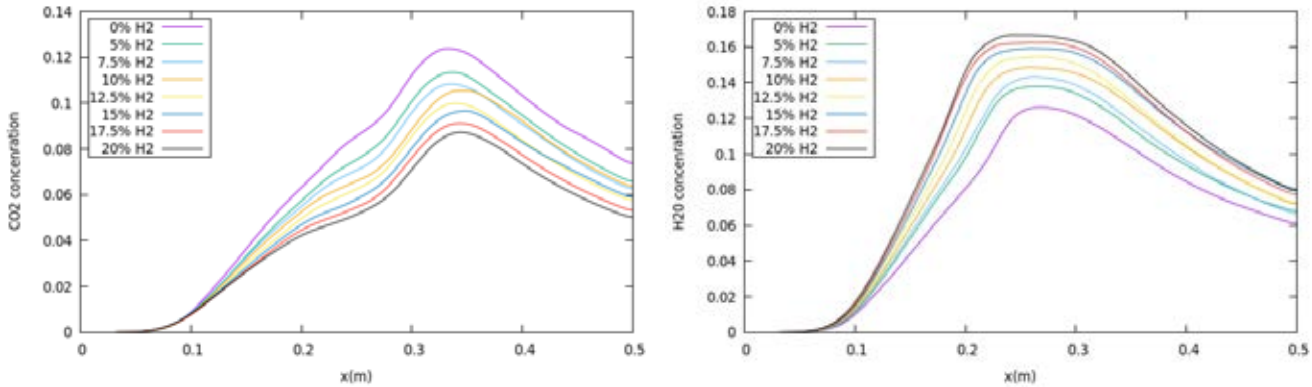
Proceeding with the simulations, 5-20% H_2 addition to the CH_4-Air mixture effects on the computational fields are computed. Fig.3 shows the Temperature profile along the flow direction for different H_2 concentrations in the fuel. It is obvious that H_2 addition decreases the CO_2 concentration in flow path, because hydrocarbon concentration decreases as the fuel composition includes less CH_4. As a result, increase in H_2 concentration decreases the CO_2 concentration. H2O concentration is also influenced from the hydrogen addition. Since the hydrogen oxidation reaction results in H2O production, as the hydrogen fraction in the fuel increases, H2O production also increases. At 20% hydrogen fraction, this increase is around 30%.



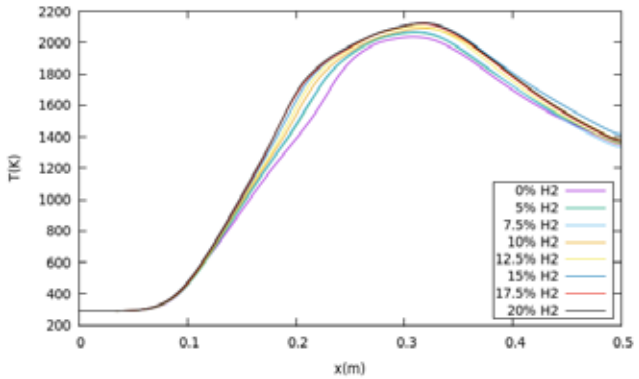


Fig. 3. CO2 and H2O concentration along the flow direction

Fig. 4 shows the temperature profile along the flow direction, as the H_2 addition percent increases, temperature along the flow direction increases. This increase caused by the radical reactions in GRI mechanism [9]. R10, R284, R52 has significant contribution to the heat release during combustion. Hydrogen addition boosts these reactions and the heat release. As result, temperature increases in the flow direction. Maximum temperature increase is 4.3% for 20% hydrogen addition and, position of the maximum temperature also increases with the hydrogen addition.

H2 (%)	T(K)	Position (m)
0	2036	0.308
5	2064	0.308
10	2090	0.318
15	2120	0.318
20	2123	0.318

Fig. 4. Temperature distribution along the flow direction

CONCLUSIONS

In this study hydrogen addition to the CH_4-Air mixture is numerically investigated under atmospheric pressure and, with 5-20% percent hydrogen addition under turbulent flow conditions. Study conducted with pseudo-transient solver, and steady-state solutions are compared. It is found that hydrogen addition increases temperature of the exhaust gas, and H2O production along the flow path and reduces the CO_2 production. This study will be extended to understand the flow behavior in different combustion chambers with transient LES modelling.

ABSTRACT

The transportation sector is a major emitter of carbon dioxide emissions. It is a known fact that carbon dioxide is the cause of global warming which has resulted in extreme weather conditions as well as climate change. In this study a combination of different methods of expediting the CO_2 emission from a single cylinder common rail direct injection (CRDI) engine has been explored. The methods include use of low carbon content biofuels (lemon peel oil (LPO) and camphor oil (CMO), inducing hydrogen in the intake manifold and zeolite based after-treatment system. The emissions were found to reduce even further and at full load condition the lowest CO2 (39.7% reduction) and smoke (49% reduction) emissions were observed with LPO blend and hydrogen induction. The NO emission with hydrogen induction increases for both the blends, however, it was seen that the zeolite-based treatment system was effective in reducing the emission as well. As compared to baseline diesel, the maximum reduction in NO emission was 23% at full load with LPO blend, hydrogen induction and after-treatment system.

Unfortunately, a lot of experimental research in the engineering field takes a long time and costs a lot of money. The number of experimental trials can be minimized by applying predictions using the available experimental data. Machine learning approaches can aid in the development of rapid and reliable data-based models that can supplement a traditional physical model. The goal of this work is to investigate if a data-based model can help to predict engine emission characteristics including CO, NO_X, Smoke, BTE, and HC more accurately.

In machine learning, ensemble methods are strategies for creating numerous models and then combining them to obtain better results. In most cases, ensemble approaches provide more accurate results than a single model. In the present work, ensemble learning algorithms like XGBoost, LightGBM, CatBoost, Random Forest (RF) are used for the prediction of emissions. The brake power and BSEC are the input parameters to these algorithms from which CO, NO_X, Smoke, BTE, and HC are predicted under various combination of additives. The CatBoost model has produced high accuracy predictions which was followed by XGBoost, RF and LightGBM models. The predicted and actual values are compared each other and the performance of the algorithms were analysed using the evaluation metrics like R-Square(R^2), Mean Absolute Error (MAE), Mean Square Error (MSE) and Root Mean Square Error (RMSE).

Keywords: Hydrogen, Low Carbon Biofuel, After Treatment, Machine Learning, Ensemble Learning

MATERIALS AND METHODS

The experimental data generated were used to train the XGBoost, LightGBM, CatBoost, RF models. The dataset was split into two parts for training and testing purposes. 80% of the experimental data are used for training and 20% of data are used for testing the model with unknown data. The independent features that are given as input to the algorithms are brake power and BSEC values, whereas the dependent features that are generated as outputs are the corresponding engine emissions [1,2]. The Machine Learning (ML) model must first be trained with a set of known independent and dependent features. The model is ready to predict the output of any unknown input after it has been trained. Predictions were made for emissions characteristics like HC, NO_X, CO_2, smoke and BTE for diesel engines with different combination of low carbon biofuels and hydrogen with zeolite. The performance of the individual models is analysed with the evaluation metrics like R^2, MAE, MSE and RMSE. The best model was chosen based on the closeness between the predicted and the experimental values.

RESULTS AND DISCUSSION

The variation in CO_2 emission for CMO, LPO, with and without hydrogen along with after-treatment system from no load to full load condition is depicted in Figure 1. Both CMO and LPO blends have lower CO_2 emission than diesel

due to lower carbon content. The carbon dioxide emission at full load with diesel, CMO20 and LPO20 is 7.9%, 6.7% and 6.8%, respectively. The CO_2 emission at full load with hydrogen induction is 5.7% and 5.4%, with CMO20 and LPO20, respectively. Higher reduction in emission with LPO20 is caused by improvement in combustion and higher replacement of the fuel with hydrogen. When the zeolite based after-treatment is placed in the exhaust pipe, further reduction in CO_2 emission is observed. At full load, with LPO20 & hydrogen engine operation and with LPO20 & hydrogen & zeolite engine operation, the CO_2 emission reduced by 20.58% and 39.7%, respectively in comparison to neat LPO20 engine operation.

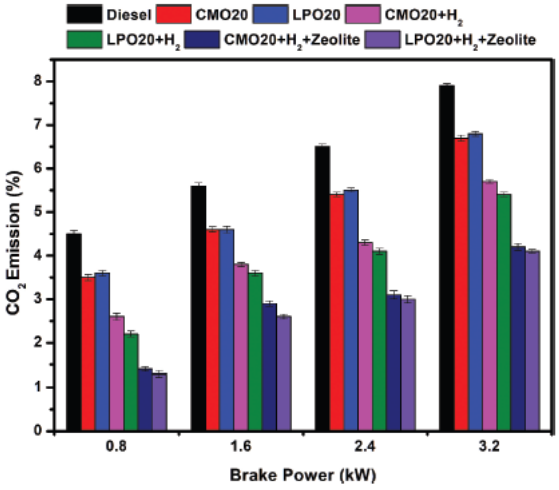

Fig. 1. Variation in CO2 emission with brake power.

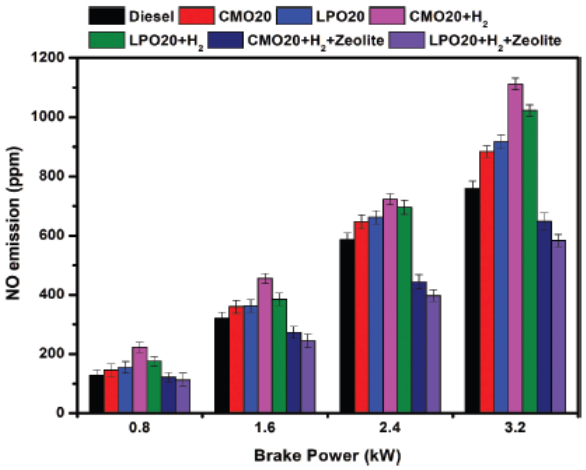

Fig. 2. Variation in NO emission with brake power.

The modulation in NO emission with load for diesel, CMO20, LPO20 and hydrogen and zeolite based after-treatment system is displayed in Figure 2. The NO emission was higher when the engine was operated with low carbon fuels in single fuel mode. At maximum load the NO emission is 759ppm, 884ppm, 917ppm with diesel, CMO20 and LPO20, respectively. With hydrogen induction the NO emission further increases. The NO emission at full load was 1112ppm and 1023ppm with CMO and LPO and hydrogen induction, respectively. The emission with CMO is higher than diesel because of higher substitution of hydrogen with the liquid fuel which increases the combustion temperature. With the after-treatment system in place, the NO emission was found to decrease at all the loads. The zeolite captures and stores the NO molecules in its porous structure, resulting in decrease in the emission.

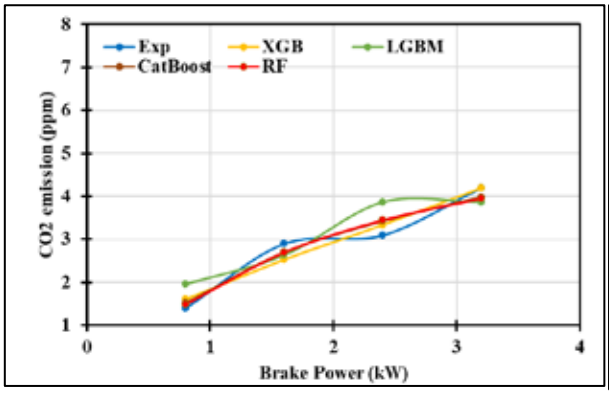

Fig. 3. Experimental and predicted CO2 in CMO20+H_2+Z

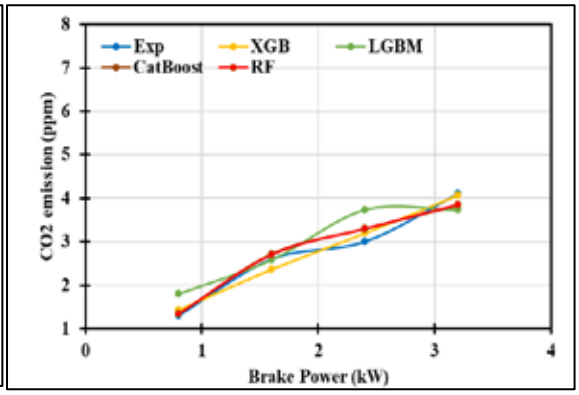

Fig. 4. Experimental and predicted CO2 LPO20+H_2+Z

Figures 3 and 4 illustrate a comparison of experimental findings and machine learning ensemble approaches for various brake power values against HC in the CM20+H+Z and LP20+H+Z, respectively. It is observed that the data-based models except the LGBM have predicted the NOX emission very close to the experimental results.

The comparison of experimental results and data-based models using ensemble techniques is shown in Figures 5 and 6. The various brake powers are represented on the major axis, while NOX emissions are represented on the minor axis. For both CM20+H+Z and LP20+H+Z, the graph depicts the proximity of the experimental data to the

projected data using various algorithms. It can be seen that XGBoost, CatBoost and RF algorithms have done predictions very close to experimental data.

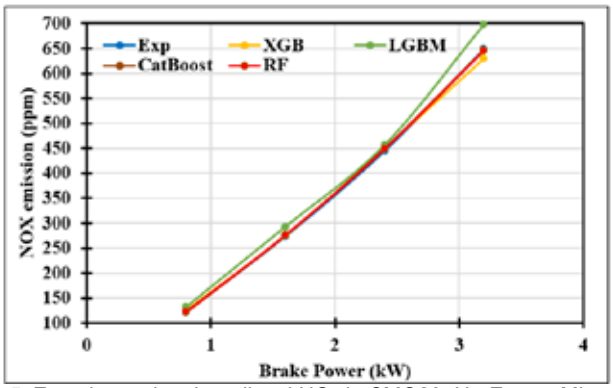

Fig. 5. Experimental and predicted NO_X in CMO20+H_2+Z w.r.t. ML

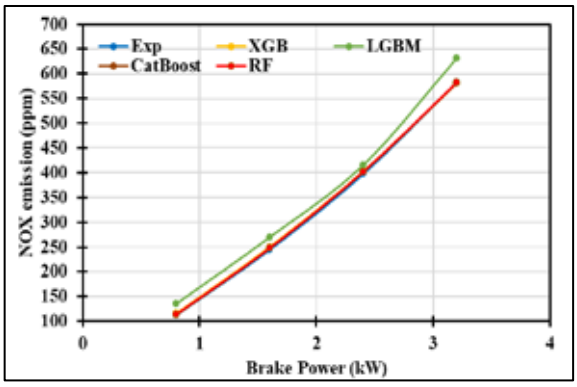

Fig. 6. Experimental and predicted NO_X LPO20+H_2+Z w.r.t. ML

CONCLUSIONS

In this study the CO_2 emission from a diesel engine was reduced by combining various techniques. Then these emissions were predicted using various machine learning algorisms.

- The CO_2 emission with blends of CMO and LPO was 15.19% and 13.94%, respectively, as compared to diesel. With induction of hydrogen the emission reduced by 27.8% and 20.6% for CMO and LPO in comparison to diesel. With the after-treatment system, the maximum reduction in emission was 39.7% for LPO blended fuel and hydrogen.
- The NO emission was found to increase for the blends in comparison to diesel on account of improvement in combustion and the presence of molecular oxygen. Hydrogen induction further improves the combustion thereby increasing the combustion temperature resulting in increase in NO emission. However, with after-treatment system in place the emissions were reduced drastically. The emissions with CMO+H_2 & LPO+H_2 with after-treatment system reduced by 41.72% and 43% as compared to the fuel combinations without after-treatment system.
- Ensemble learning algorithms were used to predict emission characteristics such as NO_X, CO_2, Smoke, BTE, and HC. 80% of the experimental data were used for training, whereas 20% of the data were used for testing purposes. The input parameters were braking power and BSEC, while the output parameters were emission characteristics.
- To predict emission characteristics with varied additive ratios, the XGBoost, LGBM, CatBoost, and RF algorithms were utilized as data-based models. To determine the prediction accuracy, each model was trained with input and output features and tested with unknown data.
- With the exception of LGBM, the other three algorithms have accurately predicted emission characteristics and were extremely closer to the experimental data.
- The percentage of prediction accuracies with respect to the models is analysed by the evaluation metrics R^2, MAE, MSE, and RMSE. It is seen that XGBoost, CatBoost, and RF algorithms have good R^2 value than LGBM. Better the R^2 value results with lesser MAE, MSE, and RMSE values.

ABSTRACT

In this study, the kinetics of Fischer-Tropsch (FT)-to-olefins was thoroughly investigated on activated carbon supported Fe-Cu-K catalyst. Among the evaluated methods, it was observed that the Runge-Kutta method gave better results. In general, the model that pertains to the study of Fernandes introduced fewer errors than Wang et al.'s model. In the simulations based on the Fernandes model, the H_2 values were estimated within error limits between 2% and 8% validated for 7 distinct experiments. CO, on the other hand, was estimated more accurately with the error limits in the ranges of 4-7% for high gas hourly space velocity (GHSV) values. However, error band of the model in the latter case was increased up to 30% for low GHSV values. Regarding hydrocarbon products, an average error value of 30% was obtained for ethylene while the best estimations were obtained for propylene with an error of 0.46% and 13.27%. However, Fernandes model neglects olefin re-adsorption, unlike the Wang's model, so Wang model seems more appropriated to estimate paraffin products. All in all, as per calculations on experimental analysis, both models need improvement in terms of product distribution.

Keywords: Kinetics, Fischer-Tropsch, Advanced optimization, Multi-objective generic algorithm

INTRODUCTION

Extensive kinetic studies on FT reaction, intended for the synthetic fuels, is widely available in literature. Yet in this study, the main interest is for light olefins. In order to implement a modelling study, the heterogeneous catalytic reaction taking place at gas-solid interface should be investigated by considering all steps of reaction, namely external diffusion, internal diffusion, adsorption, desorption along with the main catalytic surface reaction. All these steps should be accurately modeled for a sound computation of kinetics. However, adsorption and desorption are not considered in modeling calculations because they involve a complicated mechanism mostly dependent on the properties of the catalytic surface. Therefore, consideration of external and internal diffusion phenomena as per limitations is more applicable. In a study by Perego and Peratello [1], it has been pointed out that building a mathematical model describing all these limitations is a must to analyse the behaviour of a catalytic reactor. In this study, some assumptions have been made for the simplicity of modelling calculations such as sufficiently smaller size of catalyst diameter in order to omit internal diffusion limitations but would be in size enough with reasonable pressure drop. Since conversion changes with the presence of interphase limitations (external diffusion), operating conditions ensuring the free of external limitations have been determined with flow rate tests [1]. The kinetic experiments were performed under optimum operational conditions. Catalytic bed volume, flow rate and the like all those were selected according to this criterion. Next, a mathematical kinetic model was built fitting the experimental data. Finally, the model was tested with further experimental data that are beyond the ones used for building the model. Deviations from the model were reported with error values and the results were discussed.

EXPERIMENTAL AND MODELING STUDIES

Preliminary catalytic tests were conducted to find out the reaction-limiting conditions where kinetic experiments will be executed. In four consecutive tests, both reactant flow rate and the amount of catalyst were increased while keeping GHSV be constant at 2000 h^{-1}. Since the mass transfer across the boundary layer no longer limits the rate of reaction at sufficiently high velocities, the conversion will be constant at two consecutive flow rates in the reaction limited region. The results of reactant flow rate screening at constant GSHV value of 2000 h^{-1} are given in Figure 1. Reaction conditions were set to T=340℃, P=10 bar and H_2/CO = 0.65. The region where conversion becomes independent of flow rate was noticed for the amounts of catalyst in between 0.3 and 0.4 grams. Thus, the corresponding flow rates were taken as the limits ensuring the absence of external mass transfer limitations. Thereafter, kinetic experiments were executed in the flow rate corresponding to 0.35 gram of catalyst. In the next step, kinetic experiments were carried out in a fixed bed reactor under the reaction limited conditions and the obtained data were used for F-T reaction modelling. Different kinetic models have been evaluated recently by the authors of this manuscript [2]. Based on the previous work, the models that best describe the kinetic data were used in MATLAB R2021a. Driven differential equations were solved with two different methods. The differential equations were

presented in the derivative form of conversion per catalyst weight and Euler method was applied. Alternatively, ode45 function in MATLAB R2021a which uses the Runge-Kutta method was employed.

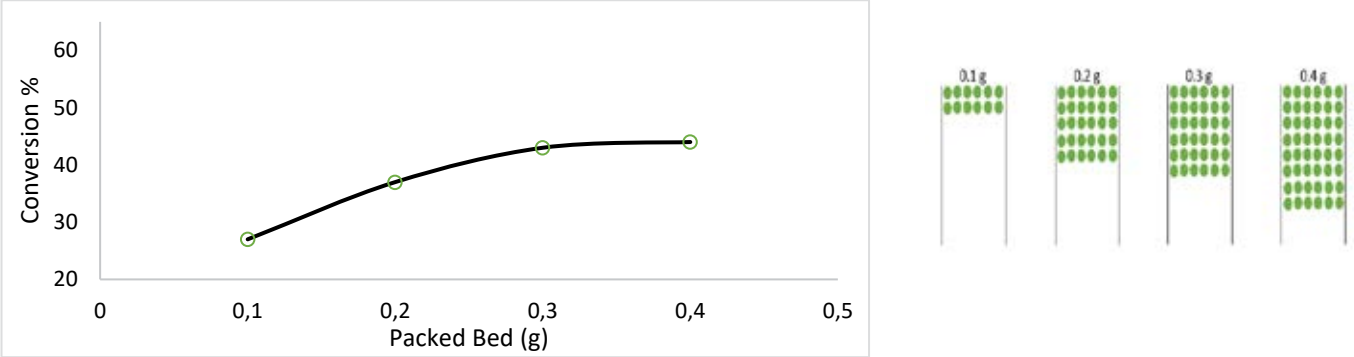

Fig. 1. Conversion versus constant space velocity with different catalyst bed amount

The objective functions for each method were determined as given in Eq. 1 where $N(z,i)_{exp}$ and $N(z,i)_{cal}$ were the experimental and calculated values of the i^{th} species for the z^{th} case. The minimization of these functions with multi-objective optimization led to the determination of kinetic parameters from experimental results. MATLAB multi-objective optimization helped in setting optimum parameters.

$$\mathrm{Fx(z)} = \sum_{i=1}^{n}\left(\left(N(z,i)_{exp} - N(z,i)_{cal}\right)/N(z,i)_{exp}\right)^2 \quad (1)$$

RESULTS AND DISCUSSION

In the experimental design study, an experimental matrix composed of 43 separate experiments was created for three different temperatures, three different pressures, three different GHSVs and two different H_2/CO, and the mathematical kinetic modeling study was carried out based on the experimental results. Experimental conditions and the main results were given in Table 1. Reasonable experimental results were obtained as such that conversion on carbon basis was improved with an increase in temperature and/or pressure and with a decrease in GHSVs and H_2/CO. It should be noted here that the calculated carbon error (%) was within acceptable limits.

The results of kinetic experiments performed on carbon-supported iron catalyst were processed with the models proposed by A.N. Fernandes [3] and Y.N. Wang [4]. In addition, both Euler method, and Runge-Kutta method have been used in an effort to understand the convergence differences among them. The ode45 function was seen to be converged better for the model by A.N. Fernandes [3], therefore the results based on the model Y.N. Wang was calculated with this method. However, only the kinetic data calculated by the model by A.N. Fernandes were reported in Table 2 and Table 3. While activation energies were quite close whatever the method of calculation, rate constants varied considerably according to the method of calculation. Computed kinetic model parameters were validated experimentally. For validation, additional experiments outside the kinetic experimental matrix were conducted. It was seen that the results of models were in good agreement with the experimental results except the Euler method based on the model by A.N. Fernandes.

CONCLUSIONS

Building a kinetic model is quite complex since Fischer-Tropsch reaction mechanism is not fully understood. Two models proposed by A.N. Fernandes and by Y.N. Wang were tested on the experimental data executed for carbon supported iron catalyst. These models were solved both Euler method and ode45 with the experimental results designed for the evaluation of kinetic models. Two of the mathematical kinetic models were observed to be in agreement with regard to hydrogen values. Even though kinetics parameters were akin to that was reported in literature, errors on the values for F-T products were relatively high. In general, whereas the model proposed by Y.N. Wang has been designated more valid to describe F-T mechanism, however, as per our experimental analysis, product distribution is still missing and needs to scrutinize.

ATOME: PURE-PLAY HYDROGEN PRODUCER

Mary-Rose de Valladares
ATOME Energy PLC, Carrwood Park, Selby Road, Leeds, LS15 4LG United Kingdom

Corresponding author e-mail: Mary-Rose.deValladares@atomeplc.com

ABSTRACT

ATOME Energy PLC (ATOME) was created to produce, market and distribute green hydrogen (H2) and ammonia (NH3). A pure-play company, ATOME was incorporated October 2020 in England and Wales and went public year end 2021 as the first green hydrogen and ammonia production company listed on the London Stock Exchange (LSE). ATOME has been awarded the LSE's prestigious Green Economy Mark. ATOME has deep expertise in H2 along with expert, globally experienced management. Shareholders include Trafigura, Schroders and President Energy PLC, its incubator. ATOME has foundation projects in two stable, democratic nations with market-based economies. The foundation projects – one in Paraguay and the other in Iceland -- are strategically situated and locally managed in attractive locations that feature renewable "green" baseload electricity available 24/7. Their combined capacity is conservatively estimated at 350 MW—250 MW Paraguay and 100 MW in Iceland. While an H2 mobility project will launch near-term in Paraguay, the first phase of foundation project production focusses on NH3, a global commodity that is urgently needed to meet market demand for fertilizer. Subsequent phases will expand H2 production. ATOME is laying the groundwork for a sustainable H2 and NH3 that serves the global energy and food systems.

Keywords: Hydrogen, Ammonia, H2, NH3, ATOME, Fertilizer

INTRODUCTION

Since COP 21 in 2015 and IEA release of *The Future of Hydrogen* in 2019, there has been an important global acceleration in adoption of national hydrogen (H2) strategies and dedication of associated national funding. As of July 2021 43 countries had or were about to release H2 strategies. Countries with H2 strategies have committed USD 100 billion to the development and deployment of H2 technologies. Innovative investment incentives are also expected. The cost of renewables and renewable electricity has declined in the recent past as has electrolyser technology, the cornerstone of the H2 value proposition. IRENA notes that electrolysers are poised to benefit from an additional 40% decline in the short term and an 80% decline by 2050.[1]

Heretofore, almost all H2 has been produced from fossil fuels, notably natural gas. However, surging natural gas prices are making green electrolytic H2 economically competitive. Green H2 is already the environmentally favored H2 production method. In response, the private sector has stepped up to participate in the H2 energy future. Included are established companies, some of them household names that are longstanding H2 proponents and others that have pivoted to H2 in recognition of commercial opportunity and climate concerns. Then there are newly formed companies responding to the marketplace and the climate change challenge. ATOME Energy PLC is one of these companies.

COMPANY OVERVIEW

ATOME Energy PLC (ATOME) was created to produce, market and distribute green H2 and ammonia (NH3) in response to the sustainable energy future challenge. A pure-play company, ATOME was incorporated in England and Wales in October 2021 and went public year end as the first green H2 and NH3 production company listed on the London Stock Exchange (LSE). ATOME has been awarded the LSE's prestigious Green Economy Mark. The company has solid Environmental, Social and Governance (ESG) credentials and addresses five (#s 7, 9, 11, 12 and 13) of the 17 United Nations (UN) Sustainable Development Goals. The ATOME team features expert, globally experienced management as well as deep expertise in H2. It holds a 75% Interest in Green Fuel elf in Iceland. Wholly owned subsidiary ATOME Paraguay S.A. operates in Paraguay. There is local management on the ground in both locations. ATOME shareholders include Trafigura, Schroders and President Energy PLC (President). President incubated ATOME and has an impressive track record of investment in Paraguay. ATOME plans to use project finance that combines debt, equity and possibly grants/concessional finance to fund execution of its foundation projects. Final Investment Decision (FID) is expected in late 2022 – early 2023.

MISSION AND MARKET: COMMITMENT TO GREEN HYDROGEN AND AMMONIA

ATOME is focused on green H2 and NH3 for all the reasons the H2 community well knows and appreciates. H2 is a fuel, energy carrier and a chemical base for fertilizers. It is a vital component of the world's toolkit to achieve net zero emissions by 2050. Estimates indicate that low carbon H2 will supply up to 25% of the world's energy by 2050, growing into a USD10 trillion market opportunity equivalent to removal of 20 mm bbl of oil from the market per day.[2]

Current uses of H2 are refining, chemicals, fertilizer, iron & steel and glass. Anticipated future uses include transport (road, rail and shipping), power, heat and renewable energy storage. H2 produced by electrolysis from renewable power is “green” with zero Scope 1 (direct), Scope 2 (indirect purchased) & Scope 3 (indirect all other) emissions.[3]

ATOME is committed to early market entry and fast production in order to scale up H2 and NH3 development in the 100s of MWs. Export markets for H2 and NH3 are expected to grow quickly in the EU and Asia. ATOME is focusing first on production of NH3, a global commodity, and then on production of H2 as its markets mature. ATOME has access to significant domestic and export markets with offtake possibilities through traders such as Trafigura, a shareholder. ATOME plans to produce and sell molecules - not only H2 and NH3 but also oxygen (O2). The shortage of O2 during the pandemic is proof positive of a medical market. As well, ATOME may be eligible to apply, obtain and trade carbon credits on the voluntary market by displacing polluting fuels. Current carbon pricing at approximately $110 per MT suggests that green H2 demand will continue to outstrip supply with a consequent effect on price.

Hydrogen (H2) – The installed global green H2 capacity has increased some 400% from 0.1 GW to .4 GW (March 2022.) However, installed capacity must ramp up to 465 GW by 2050 to meet Net Zero targets. The H2 market is expected to grow from USD755 million in 2020 to USD1.4 billion by 2026. IEA forecasts a sixfold increase in H2 demand (to 530 MT) by 2050.[4]

Ammonia (NH3) The second most widely produced chemical in the world, NH3 has heretofore been made exclusively from fossil fuels. In 2019 the total global NH3 production was 150 MT/ year. The NH3 market is expected to grow to 530 MT/year by 2050.[5] Green NH3 will help decarbonize key industries, include the fertilizer, chemical, refining and shipping fuel industries as well as the power industry. As an H2 carrier, NH3 has three times the energy density of H2 and liquefies at -33.3 C° or -27.27 F° — a much higher temperature than H2. NH3 is thus well suited for H2 storage and a logical choice for green H2 transport from exporting nations to importing nations.

Fertilizer Approximately 70% of all NH3 worldwide is used for fertilizers. In 2021, with the world population at 7.6 billion according to the UN, land use accounts for around 25% of global Greenhouse Gas (GHG) emissions. The UN population forecast is 8.6 billion by 2030 and 9.8 billion by 2050. Consequently, green fertilizer alternatives are imperative. The urgency surrounding fertilizer for food increased exponentially since the onset of the war that has consumed the bread basket of Europe and interrupted the production and export of fertilizer from Russia, the leading producer of urea fertilizer and a top producer of nitrogen fertilizer. This unexpected dynamic is making food and fertilizer for food immediate global priorities.

Marine The International Maritime Organization (IMO), the UN division that regulates shipping, adopted an Initial GHG Strategy in 2018 to reduce — by at least 50% -- GHG emissions from the global shipping sector by 2050 compared to 2008. Every maritime segment — including shipping, fishing, ports – falls within the IMO purview. Maritime transport emits 940 million MT of CO2 annually, equivalent to 2.5% of global GHG emissions. By 2050 the Ammonia Energy Association estimates that NH3 could comprise 25% of all maritime fuel, assuming all new ships operate on NH3 starting in 2044.

ENGINEERING AND TECHNOLOGY

Each project requires a Front End Engineering Design (FEED). The FEED process provides detailed plans and specifications for construction of the projects and their civil works. In order to produce green H2 and NH3 ATOME must procure, integrate and install equipment including electrolysers, air separation units, compressors and NH3 synthesis loops as well as storage. ATOME is agnostic as to technology and seeks to deploy the most efficient, state of the art appropriate and cost-effective technology available. In the early phase(s) ATOME is expected to utilize low temperature electrolysers. Discussions with original equipment manufacturers (OEMs) and engineering, procurement and construction (EPC) companies are well underway.

FOUNDATION PROJECTS

ATOME has foundation projects in two stable, democratic nations with market-based economies. Paraguay belongs to MERCUSOR (Mercado Común del Sur), the Southern Common Market. While not a European Union (EU) Member State, Iceland is part of the EU’s European Economic Area and Schengen Agreements. The foundation projects are strategically situated in attractive locations that feature green electricity available 24/7 as well as low cost water. ATOME’s teams in Iceland and Paraguay have made significant contributions to their respective countries’ H2 and sustainability roadmaps. Combined, the two foundation projects are conservatively sized at 350 MW—250 MW Paraguay and 100 MW in Iceland. Expected output: ~60,000 MT of H2; 333,000 MT NH3; and 476,000 MT of O2.

Paraguay

In Paraguay, hydropower produces renewable electricity. Paraguay’s electricity is sold to Paraguayan consumers at some of the lowest rates in the region. The preponderance of this electricity is produced at the Itaipu Dam, the world’s

second largest dam in terms of installed capacity. The Itaipu Binacional is jointly owned by Paraguay and Brazil which share equally in its hydroelectric output. While Brazil completely consumes its 50% share, Paraguay does not use its entire allocation and exports a substantial amount of hydroelectricity to Brazil or Argentina. Paraguay's energy policy seeks to reduce dependency on hydrocarbons and capitalize on hydroelectric capabilities to produce molecules for domestic consumption. ATOME has already entered into a Memorandum of Understanding (MOU) with ANDE, the national power company of Paraguay, to utilize its hydropower; the Power Purchase Agreement (PPA) is expected to follow shortly. ATOME also has an MOU with the Parque Tecnológico Itaipu (PTI), the Itaipu innovation arm, for a prime site as PTI's exclusive green hydrogen producer. In the first phase(s) ATOME is targeting domestic offtake markets for H2 and NH3 products for agriculture, industry and transport. Notably, agriculture is responsible for 20% of the country's total employment; all fertilizer (a USD470 million market) is currently imported. Paraguay is the world's fourth largest soybean exporter and also boasts the world's third largest fleet of barges, which are used to transport agricultural and industrial production in the absence of a national rail system. Heavy goods vehicles (trucks) are also used for industrial transport. Both road and barge systems need decarbonization. The initial H2, NH3 and O2 production plan for Paraguay comprises two phases and a total of 250 MW: 50 MW in Phase 1 - 2024 and 200 MW Phase 2 – 2025-26.

Iceland

Renewable energy — 75% hydropower and 25% geothermal -- accounts for Iceland's electricity production. This "green" nation, a true H2 pioneer, is in close proximity to Europe and its substantial export market. The maritime industry accounts not only for 25-30% of the country's GDP and 15-20% of its employment but also the majority of its GHG. Iceland's shipping and fishing industries, including vessels and vehicles (related to land transport), are subject to IMO decarbonization guidance. However, as of 2019 Iceland still imported USD605 million in oil so the nation's energy policy targets reduction of fossil fuels for transport and shipping sectors. PPA negotiations for geothermal electricity are underway. The initial identified power capacity is up to 100 MW.

HYDROGEN MOBILITY

In many parts of the world H2 demonstration projects over the past two decades have targeted the crucial transport sector that is responsible for some 20% of all CO2 emissions. While previous demonstrations have typically focused on buses and passenger cars, trucks and marine vessels are nowadays included in the mix. ATOME has created a new mobility division commencing operations in 2023 to produce green H2 for transport – initially road transport only — in Paraguay. Paraguay's *Hacia la Ruta del Verde en Paraguay* examines prospects for H2 road transport and identifies alternative energy possibilities for river transport. Paraguay's 2014 *National Development Plan 2014-2030* enshrines transport decarbonization as the central public policy recommendation, committing to a 60% increase of renewable energy consumption and a 20% reduction of fossil fuel consumption. Imported fuels such as diesel and gasoline cost Paraguay $1.3 billion USD in 2019. Growth is anticipated in the vehicle, motorcycle, truck and bus fleets. The bus fleet is effectively a public-private partnership. Consequently, in Paraguay's unique transport eco-system, which in 2019 introduced electric buses, a demonstration featuring trucks and buses has considerable promise. The mobility division will produce green H2 using a 1 MW electrolyser strategically located on a riverfront site in a prime industrial area.

CONCLUSION

ATOME is a first mover in the green H2 and NH3 production space. In the UK, it is actually the first listed pure-play H2 and NH3 producer. ATOME's foundation projects, beneficiaries of 24/7 baseload renewable power, constitute the groundwork for a sustainable, rewarding business that serves the planet, the global energy and food systems, and all our customers.

ABSTRACT

Environmental concerns such as global warming and air pollution have increased mainly due to the high energy consumption all over the world. In order to reduce the greenhouse gas and pollutant emissions from transportation sector, fuel cell vehicles offer a clean and highly energy-efficient alternative. In fuel cell vehicles, an energy storage unit such as a battery and/or a supercapacitor (SC) is required in high power demands such as accelerating,uphill and start-up conditions. In this study, a mathematical model a fuel cell vehicle including both a supercapacitor and a battery was developed and its drive cycle simulation was conducted to determine the vehicle performance. As a result of the drive cycle simulation, FCEVs equipped with battery and supercapacitor as storage units, energy efficiency has increased according to the developed simulation algorithm.

Keywords: Fuel cell vehicle, drive cycle simulation, battery, supercapacitor

INTRODUCTION

Fuel cell electric vehicles (FCEV) can have various configurations including energy storage components such as supercapacitor, battery, etc. [1]. Due to the slow response time, narrow power generation range, and not being able to store regenerative energy during braking, fuel cells are used together with an energy storage unit in FCEVs [2] Among the energy storage technologies, supercapacitors are alternative to batteries in transportation with their high power density [3]; however, they have low energy densities. For this reason, a supercapacitor and a battery can provide a great advantage if used together in terms of performance and efficiency [4]. Supercapacitors are more useful in the short term power demands due to their high dynamic performance. Additionally, supercapacitors have a longer lifetime than the battery, so they can be used with batteries in vehicles [5]. In the literature, energy management algorithms and optimization studies have been conducted for hybrid vehicles equipped with fuel cells and supercapacitors. For example, a finite state machine strategy has been proposed for the energy management of the hybrid energy system [6] and a comparison between the proposed system and the system including only battery is done [7]. In this study, a simulation algorithm was determined for power outputs of the components and SOC of the battery with the developed algorithm to increase energy efficiency.

POWERTRAIN COMPONENT MODELS AND SIMULATION METHODS

An energy storage system consisting of a battery and a supercapacitor was modeled in Matlab/Simulink environment. The power requirement of the electric motor, which provides the current demand of a small-sized fuel cell electric vehicle, is calculated with the using the principles of vehicle dynamics. To calculate this requirement, as shown in Eq. 1, the vehicle must overcome total motion resistance forces during driving [8]. The motion resistances are F_R rolling resistance, F_L aerodynamic resistance, and F_a positive acceleration resistance for the vehicle. The regenerative braking effect caused by the negative acceleration due to braking is included in the calculation.

$$P_{EM} = \frac{\left(m.g.f_R + \frac{1}{2}.c_W.A.\rho_L.V^2 + m.a + m.a^-.i_{fr}.\eta_{EM}.\eta_M.\eta_B\right)}{\eta_{EM}.\eta_M}.V = \frac{(F_R+F_L+F_a+F_a^-.\eta_{EM}.\eta_M.\eta_B)}{\eta_{EM}.\eta_M}.V \quad (1)$$

In Eq. 1, m is the vehicle weight (500 kg), g is the gravitational acceleration (9.81 m/s^2), f_r is the rolling resistance coefficient (0.0015), C_w is the aerodynamic resistance coefficient (0.4), a is the vehicle projection area (2 m^2), ρ_L is the air density (1.2 kg/m^3), a is the positive acceleration, a^- is the negative acceleration, i_{fr} is the braking ratio, η_{em} is the electric motor efficiency (0.9), η_m *is the* mechanical efficiency (0.9), and η_b is the battery efficiency (0.92). Depending on the vehicle resistance forces, the power requirements of the motor have been calculated for the ECE 15 drive cycle. The speed profile of the drive cycle is given in Fig. 1.

$$SOC(t) = SOC_i - \frac{1}{Q_{bat}} \quad (2)$$

where Q_{bat} is the total capacity (3.3 [kWh]) of the battery, SOC_i is the initial battery charge (0.8).

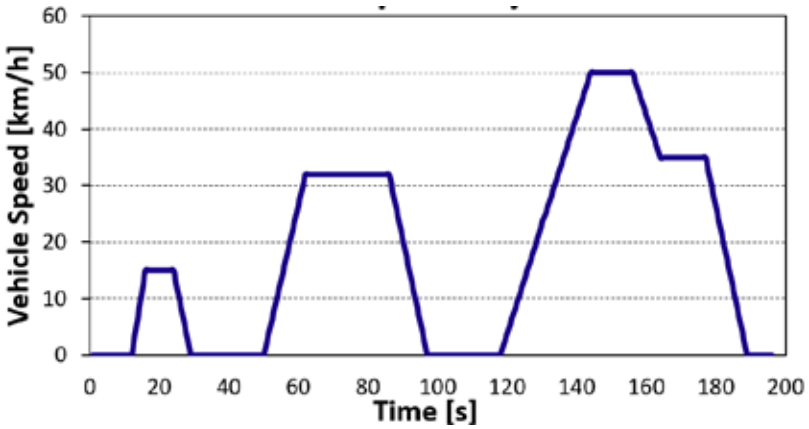

Fig. 1 Speed profile of ECE 15 drive cycle

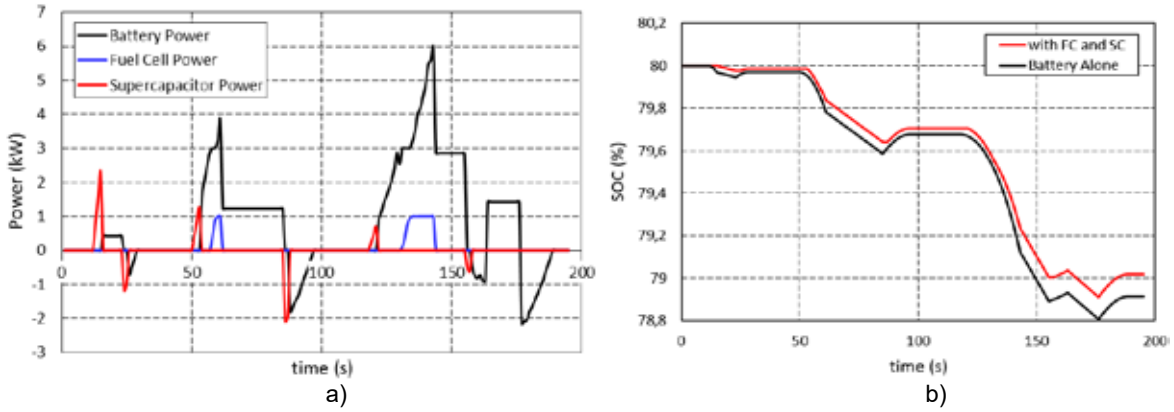
A typical electrochemical zero-dimensional (0D) fuel cell stack model was conducted to simulate stack behavior under different operating and design conditions. It is generally assumed that every cell performs the same in a stack. The fuel cell operating voltage is generally calculated as follows[9],

$$V_{cell} = V_{Nernst} - \eta_{ohm} - \eta_{act} - \eta_{conc} - \eta_{other} \quad (3)$$

Where η_{ohm}, η_{act}, η_{conc} are the Ohmic, activation, and concentration polarizations, respectively; and η_{other} is the other losses.

In this study, a supercapacitor, as a high-power storage device, is added to the hybrid drive system configuration to provide full capacity. A supercapacitor submodel was built in Matlab/Simulink. The output of the model is the time-dependent supercapacitor energy stored in the SC pack. This energy (E_{SC}) is the value of SC relative to the pack voltage (U_{sc}) and is calculated by the following equation [10].



$$E_{sc} = \frac{1}{2} C_{eq} U_{sc}^2 = \frac{1}{2} \frac{N_{p_sc}}{N_{s_sc}} C_{sc} U_{sc}^2 \quad (4)$$

where C_{eq} is the equivalent capacity of the SC's pack, N_{p_sc} and N_{s_sc} are the number of parallel branches and the number of SC's series connections, respectively, and C_{sc} is the SC capacitance.

The battery, fuel cell, and supercapacitor power outputs are calculated according to the simulation algorithm that is developed depending on the vehicle speed, electric motor power, and acceleration time interval.

RESULTS AND DISCUSSION

The speed profile of the drive cycle and vehicle parameters are defined in the Matlab/Simulink model to calculate the power outputs of the fuel cell, supercapacitor, and battery, and the state of charge of the battery. The time-dependent results of the simulations are shown in Fig. 2. As a result of the increase in speed and acceleration due to the driving cycle, the energy required to be supplied to the electric motor also increases. Depending on the simulation algorithm defined for the model, energy is provided from the supercapacitor in regions where the speed increase is sudden, and from the fuel cell and batteries depending on the power requirement in other regions. As can be seen, the maximum battery power requirement of the vehicle is calculated as 6 kW when the fuel cell is also active (Fig 2a).

a) b)

Fig. 2. Simulation results of (a) the battery, fuel cell and supercapacitor power and (b) SOC of the battery

The SOC in the battery, which provides important information about the vehicle range, is calculated for the battery-only and hybrid cases of the vehicle propulsion (Fig. 2b). At the end of the drive cycle time, the SOC of the battery in hybrid configuration differs by 1.25% compared to the case of battery only.

CONCLUSIONS

The powertrain simulation of the fuel cell electric vehicle was carried out to determine the battery, fuel cell, and supercapacitor power with a selected energy management algorithm to investigate the effects of the characteristics of supercapacitor and battery on energy efficiency. The results showed that energy efficiency can be increased with a proper energy management algorithm in fuel cell electric vehicles equipped with battery and supercapacitor as an energy storage unit.

ABSTRACT
This paper presents selected results from the study “Impact of the use of the biomethane and hydrogen potential on trans-European infrastructure” which has been conducted by Trinomics, Ludwig-Bölkow-Systemtechnik GmbH (LBST) and E3Modelling (E3M) for the European Commission. The major objective of the study was to analyse the impact of biomethane and hydrogen on the gas sector in Europe until 2050 from technical, economic and regulatory perspective. In general form the system perspective, the optimal system design strongly depends on the anticipated GHG emission reduction targets. Among the analysed cases the scenario with a strong focus on hydrogen technology appears to be a robust compromise where the advantages of higher system flexibility overcompensate the disadvantages of lower energy efficiency in comparison to the electricity-focused scenario. Based on the study’s results, strategies for fully decarbonized gas system by 2050 should be developed describing cost-effective transition pathways in the medium-term (2030) and towards the long-term (2050) target situation of full decarbonisation.

Keywords: Energy System, Gas Infrastructure, Decarbonization, Modelling

INTRODUCTION

Today the gas sector plays an important role in the existing energy system. It accounts for more than 200,000 km of transmission and 2 million km of distribution grids serving around 150 million customers from different sectors including heating and power sectors as well as industry [1], [2]. The overall natural gas consumption in European Union reached more than 4,800 TWh/a in 2017 out if which ca. 74% was imported mainly from Russia, Norway and Algeria [3]. In this context, natural gas is an important source for primary energy and feedstock for different end-users. It provides also adequate flexibility services to the energy system through the use of gas storage as well as flexible gas power plants. Nevertheless, the gas sector is subject to ambitious plans of the European Commission for deep decarbonization of the economy until 2050 by substituting the fossil natural gas by other green and GHG-free gases such as biomethane or hydrogen [4]. In this context, this paper presents selected results from the study “Impact of the use of the biomethane and hydrogen potential on trans-European infrastructure” which has been recently conducted by Trinomics, Ludwig-Bölkow-Systemtechnik GmbH (LBST) and E3Modelling (E3M) for the European Commission. The major objective of this study was to assess the socio-economic costs and benefits of increased use of biomethane and hydrogen in Europe until 2050 from technical, economic and regulatory perspective.

MODELLING ERUOPEAN ENERGY SYSTEM AND INFRASTRUCTRE

The quantitative analysis is carried out for three scenarios, each focusing on electricity, methane and hydrogen, respectively, as major energy carrier. Although all scenarios are of explorative character the economic value of the use of full potential of biomethane and hydrogen can be derived from comparison of the modelling results between the different scenarios for the time horizons 2030 and 2050. The analysis employs dedicated modelling of the European energy system with the objective to minimize the overall system costs by taking into account technical constraints of all system components. The model is formulated as a linear program and is subdivided into two steps. In the first step the cost-optimal energy supply for the predefined end-user sectors is calculated without any grid constraints. Based on these results in the second step the optimal energy flows and corresponding infrastructure capacities between the Member States for the three energy carries power, methane and hydrogen are analysed.

RESULTS AND DISCUSSION

Under the assumptions of this study the total gas demand in the end user sectors transport, residential, services, industry is expected to decrease from ca. 2,800 TWh/a in 2015 to 2,000-2,500 TWh/a, in 2030. In this context, the strong decline from residential, services, industry sectors due to building insulation and efficiency measures is partially compensated by the increase in gas demand from the transport sectors. Based on comparatively high carbon price of 84 €/t_{CO2} the power sector requires additional 1,000 TWh/a of methane supply (providing 600-730 TWh/a electricity) mainly due to the merit order switch from coal to gas. Hence, gas-fired power plants play an important role for the transition of the future energy system. Natural gas imports along the established routes from East to West

and from North to South are the major supply source in this time step whereas the use of biomethane and hydrogen due to comparatively high costs is limited.

In the long-term until 2050 the gas demand from the end user sectors increases in methane and hydrogen-focused scenarios due to additional gas consumption as fuel in the transport sector. However, since in 2050 gas-fired power plants provide only limited back-up power (25-190 TWh/a with a large capacity of 250-360 GW) to balance out intermittent electricity feed-in the overall gas demand decreases to ca. 2,500 TWh/a (in electricity and hydrogen-focused scenarios) or remains at the same level of approx. 3,500 TWh/a as in 2030 (in methane-focused scenario). Although in electricity and methane-focused scenarios the full potential of biomethane is used to decarbonise the energy system substantial amounts of synthetic methane from Power-to-Gas (200-1,500 TWh/a) are needed to satisfy the gas demand. In the hydrogen-focused scenario large amounts of hydrogen of more than 2,000 TWh/a are produced via water electrolysis which is mainly located in close proximity to renewable power feed-in. Therefore, the gas grid both for methane and hydrogen requires substantial enhancements to transport renewable gas from boundaries of Europe with large renewable energy potentials to demand clusters in Central Europe (Figure 1). The decarbonisation of the energy system and growing renewable power supply require additional flexibility measures to balance out the fluctuating electricity supply and demand. One of the major flexibility measures is represented by electrolysis as a flexible load with an installed capacity of 250-1,200 GW_{el} and utilisation rates of 2,000-3,000 full load hours in 2050.

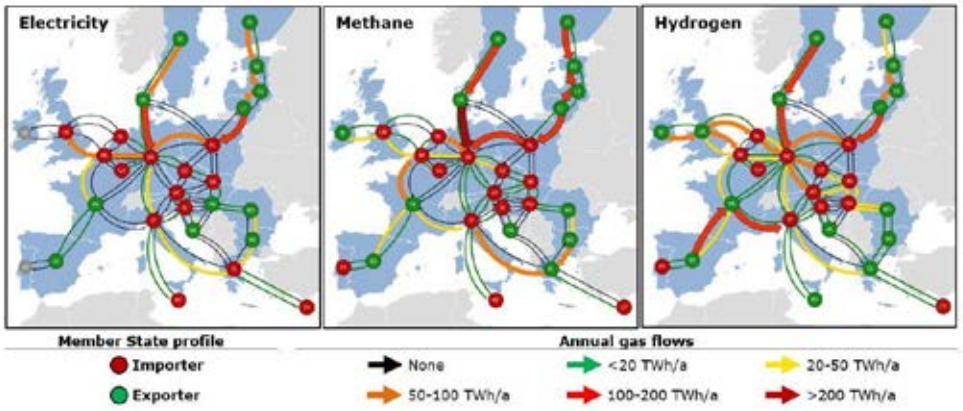

Fig. 1. EU28 cross-border annual gas flows in 2050 for the three scenarios

The comparison of the system costs for the three scenarios until 2030 reveals similar cost structure and magnitude with major contribution from fossil energy imports (Figure 2). In this context, bio methane and hydrogen supply have limited impact on the energy system costs. In the long-term until 2050 the system costs decrease due to cheap renewable power production and increasing sector integration between powers. The lowest system costs are achieved in hydrogen-focused scenario followed by electricity and methane-focused scenarios and can be viewed as a trade-off between renewables, system flexibility and gas supply. The system design with a strong focus on hydrogen technology appears to be a robust compromise where the advantages of higher system flexibility overcompensate the disadvantages of lower energy efficiency in comparison to the electricity-focused scenario. In the methane-focused scenario the lower efficiency of the end user applications makes this option less attractive than both other scenarios. At the interconnector level the gas transport costs are rather similar for all scenarios in 2030 and the electricity and methane-based scenario sin 2050 with approx. 1-2 B€/a. This is due to comparatively cheap existing methane infrastructure and limited investments in new capacities. In the hydrogen-focused scenario in 2050 the investments in new dedicated H2 pipelines as well as its maintenance drive the infrastructure costs at the international level up to 7 B€/a.

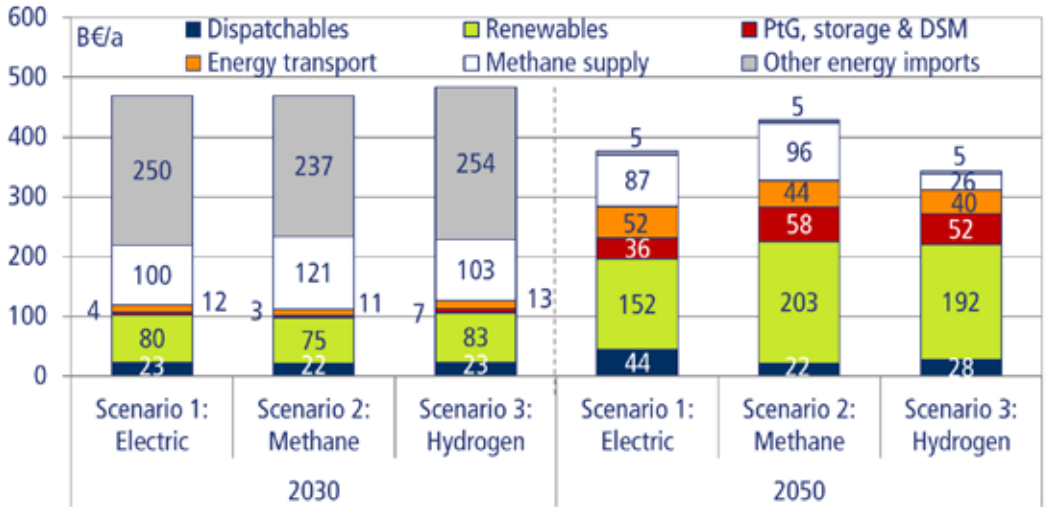

Fig. 2. Annual energy system costs in EU-28

CONCLUSIONS

In general form the system perspective the optimal system design strongly depends on the anticipated GHG emission reduction targets. Therefore, binding targets in particular in the long-term until 2050 are needed for a cost-effective transition of energy supply and transport infrastructures both for gas and power. In this way misinvestments and unfavourable lock-in effects can be avoided. Also, a coordinated development of power and gas infrastructures in line with the build-up of renewable energy and seasonal storage capacities is needed to minimize the system costs. In the context of system stability adequate market mechanism supporting the energy-only market should be considered in order to ensure the competitiveness of flexibility measures with low utilisation rates such as gas-fired power plants or electrolysis as a flexible load. Certification mechanism for renewable gases might help to establish fair competition between different players within the decarbonising gas market. Further analyses from the end user and business perspective would complement modelling exercises from a pure system perspective. Especially for the gas infrastructure the ongoing re-investments in aging assets should be assessed in more detail from the operator perspective to ensure positive business cases when comparing methane and hydrogen infrastructures.

Based on this study's results for 2030 and 2050 as spotlights of gas grid development scenarios, strategies for fully decarbonized gas system by 2050 should be developed describing cost-effective transition pathways in the medium-term (2030) and towards the long-term (2050) target situation of full decarbonisation. Notably for hydrogen, further analysis of possible development strategies and pathways for a stepwise development of 100% hydrogen grid "islands" growing into one large hydrogen grid with methane-based islands in the future is worth exploring for a roadmap for transitioning to a 2050 gas system with separate H_2 and CH_4 grid systems.

ABSTRACT

This work presents the latest advances of hydrogen and fuel cell research and development from Romania.
The presentation focuses more on National Hydrogen and Fuel Cell Centre (NHFCC) researchers' activities as a part of national policy and program issues. This centre is a research and development facility with the mission to implement, develop and disseminate hydrogen-based technologies in Romania, as well as to support national priority policies in the field of energy and environment. It has an exceptional infrastructure for the entire process chain of the new energy revolution (production, storage, transport, and utilization). The researchers are focused on the development of technologies, products and services that contribute to achieve an "economy of hydrogen" in Romania.

Keywords: Romania, National Hydrogen and Fuel Cell Centre

INTRODUCTION

The national hydrogen and fuel cell technology strategies vary considerably from country to country due to different national specific and particular constraints. Two types of policies can be found at EU level: the policies of European Commission, supported by Fuel Cells and Hydrogen 2 Joint Undertaking (FCH2 JU), and the Members States' policies, including both national and regional.

In principle, the hydrogen economy is initiated by hydrogen communities as early adopters (cities, remote locations or islands, self-contained entities as airports, seaports, industrial complexes, etc., or distributed entities as hydrogen highways) of hydrogen and fuel cell technologies for energy proposes. The larger-scale adoption of such technologies within a coherent end-user grouping, is the next step that depend by the success of the initial demonstrative results. The hydrogen communities could be. In this context, it should be mentioned that Romania is a country that traditionally produces hydrogen [1].

In order to ensure Romania's energy security in the next period of time, there is necessary to understand the global perspective and the newest trends in energy. The implementation of new energy solutions depend on the co-operation of numerous public and private stakeholders. In this work authors intend to present and clarify this special situation in Romania. The authors hope that this work will be a useful tool in order to create an accurate picture about national specific situations in Romania.

HYDROGEN ASPECTS IN ROMANIA

National Hydrogen and Fuel Cell Centre

The National Hydrogen and Fuel Cell Centre (Fig. 1) is a research and development facility with the mission to implement, develop and disseminate hydrogen-based technologies in Romania, as well as to support national priority policies in the field of energy and environment. It has an exceptional infrastructure for the entire process chain of the new energy revolution. The human resource is focused on the development of technologies, products and services that contribute to achieve an "economy of hydrogen" in Romania [2].

NHFCC's milestones:

- 2009 – National Center for Hydrogen and Fuel Cells has been developed due to results, knowledge and expertise acquired in the research projects done in the renewable energy field.
- 2009 – the research center becomes a full member of the Joint Technology Initiative – Joint Undertaking on Hydrogen and Fuel Cell, a unique public-private partnership supporting research, technological development and demonstration in the field of fuel cells and hydrogen-based energy technologies in Europe.
- 2012 – the staff of research center leads to the foundation of the Romanian Association for Hydrogen Energy.

• 2012 the entire R&D has been completed both instrumentally and from human resources capabilities by developing two other facilities research: Low Temperature Laboratory - CRYO-HY and Energy Storage Laboratory - ROM-EST (in 2015).

• 2014 - National Center for Hydrogen and Fuel Cells becomes a national interest facility, being a support installation with experimental and testing equipment to address a wide range of research into the use of hydrogen for energy purposes.

• 2017 – NHFCC becomes a member of the Research infrastructure in Energy-Environment-Water-Systems – RENEWS, a Research Integrated Infrastructure active at national level.

The research activity carried out within this facility connects the Romanian research to the international scientific community in field of hydrogen based technologies. The research centre provides adequate scientific, technical and logistical support, being in the same time accessible to other users interested in conducting their own research activities or in collaboration.

Fig. 1. National Center for Hydrogen and Fuel Cell

Hydrogen and fuel cell research in Romania

Some more than 100 scientific articles in the field of fuel cell and hydrogen energy including topics such as: engineering, materials science, chemistry and chemical engineering, energy, environmental science and mathematics, have Romanian authors or affiliates of Romania since 2000.

The Romanian participation in EU co-financed projects is really modest. The National Center for Hydrogen and Fuel Cells has two participations and other four participations is realised by other four research or academic groups.

Here we provide three examples of this types of projects supported by the Fuel Cell and Hydrogen Joint Undertaking. The HyUnder project (FCH JU grant no. 303417) setting out the hydrogen underground storage potential from Romania and where was realised firs this type of study [3]. This project germinated new ideas and other scientific works referring to the hydrogen underground in salt caverns in Romania. The HyLaw (FCH JU grant no. 737977), it is referring to removal of legal barriers to the deployment of fuel cells and hydrogen applications. The results from this project are included in to a common database available on https://www.hylaw.eu/database. The HyLaw database is structured into nine categories with a relevant number of hydrogen applications and different legal and administrative processes. The last project, TeacHy (FCH JU grant no. 779730), strive to deliver a substantially improved teaching of hydrogen and fuel cell content across Europe.

Another important source for financing the projects was the National Plan for Research, Development and Innovation (PNCDI II), lunched by public authorities in period 2007-2013. It was a financing instrument based on competition between research groups. The program financed around 26 hydrogen and fuel cell research projects. The projects was created as a consortium led by research institutes, universities and research centers.

There are need early scientific, technical and business analysis in order to develop a future hydrogen infrastructure, which take years. The scientific studies ad researches are necessary for a better understand the role of hydrogen in Romania's future renewable energy based energy system.

Finally, but not at the end, the hydrogen community, concatenated the efforts and established the Romanian Association for Hydrogen Energy, in order to disseminate knowledge to the peoples and to press the decision makers. The association is a nongovernmental organization formed of individuals and legal entities.

CONCLUSIONS

The worldwide political requirements for reducing GHG-emissions and the EU's commitments and directives for the renewable energy are important aspects for the market penetration of the hydrogen and fuel cell in Romania. It has the opportunity to make the transition from the hydrocarbon power industry to a power sector utilizing hydrogen and renewable energy sources. The replacement of the actual technologies would offer the opportunity to implement hydrogen, fuel cell stacks and hybrid systems.

Above mentioned indices that mainly interest for hydrogen energy is in universities and research centers. This highlights the high level of the universities and research institutes. Unfortunately the industry is not so active and have avoided to participate in this very new sector.

ABSTRACT

Hydrogen energy is among alternative solutions to energy shortage regarding the aspects of being environmentally clean, economic and efficient. In this context, Turkey's energy demand, which cannot be met by our country and will not be able to be met by local resources in the 2020s. Therefore, Turkey should turn to renewable energy sources as soon as possible, especially hydrogen energy to be obtained from the Black Sea, as well as a new type of energy that can be obtained by turning the mucilage crisis in the Sea of Marmara into an opportunity. In addition, the conversion of these organic wastes in the Marmara Sea into hydrogen energy as a renewable energy source will be an innovative and high added value solution method.
Our aim in this study is to bring up the hydrogen energy potential in the Black Sea and Marmara Sea's mucilage crises to investigate the contribution of hydrogen energy to our economy by eliminating the energy deficit.

Keywords: Hydrogen economy, Marmara Sea, Mucilage, H_2S, Black Sea

INTRODUCTION

Hydrogen, as an energy carrier has some advantages with respect to fossil fuels on the environmental and economic bases. The fact that hydrogen fuel can be used in internal combustion engines, that is, in all vehicles such as buses, trucks, automobiles, tractors, and agricultural machinery, replaces petroleum products with limited reserves, and is an environmentally friendly energy, has attracted great interest of companies producing vehicles in recent years.

For instance, in the world's hydrogen energy usage practice as of September 2012, Coradia iLint, the world's first hydrogen powered train developed by Alstom, has passed the tests conducted in France. It was also tested in France at a ceremony in the presence of French Transport Minister Jean-Baptiste Djebarri.

Therefore, German state railways Deutsche Bahn and technology giant Siemens announced last year that they are developing hydrogen-powered trains as part of a plan to reduce emissions to zero by 2050.

On the other hand, the Black Sea is fed by the rivers coming from the countries around it. At the same time, all the polluted wastes of 21 countries in Europe and Asia are transported to the Black Sea. The fact that our Black Sea coasts are rich in hydrogen puts us among the lucky countries in the world in terms of reserves and is Turkey's hydrogen energy center. is mentioned by name.

The outline of the paper is as follows. Section 2 sets up Hydrogen economy and Hydrogen Energy Opportunity in the Black Sea while section 3 deal with as a new topic Marmara Sea's mucilage problem. Finally last section is conclusion.

FUTURE OF THE TURKEY'S HYDROGEN ENERGY POWER IN THE BLACK SEA

Hydrogen is the simplest of atoms. In its normal form in the universe, hydrogen contains an electron and a proton. In its rarer form, called heavy hydrogen, there are three particles. It is this structure of hydrogen that makes it the most active element in the 15-billion-year-old story of our universe (Rigden, 2002).

To achieve low carbon levels, hydrogen is well positioned in countries with a diversity of renewable energy sources, especially in the Middle East region, and some new projects are under development. However, the development of industrial strategies is not sufficient. If hydrogen-rich fuels such as ammonia, as well as critical minerals, gain importance in international energy-related trade, their total share is targeted to increase from 13% to 25% in APS by 2050 (IEA, 2021).

In this context, 90% of the water of the Black Sea is anaerobic and contains hydrogen sulfide (H_2S). 8ml at 1000m depth. The H_2S concentration, which is Lt-1, is 13.5 ml at the base. It reaches the level of Lt-1. There are technological studies on hydrogen production from H_2S using two reactors, such as an electrolysis reactor and an oxidation reactor.

Along the axis of the Black Sea, at a depth of 200 meters, there is a "fuel" layer, about 50 meters thick and yet untouched, between the oxygen-free and oxygenated water layers. The amount of hydrogen sulphate produced from the sediment layers of the sea is estimated to be around 10 thousand tons per day, and this amount is constantly increasing. This means a production potential of approximately 500 tons of hydrogen gas per day.

Producing hydrogen from hydrogen sulfide in the depths of the Black Sea is easier and cheaper than other methods, and R&D studies are also carried out in Russia, Georgia, Romania and Bulgaria in this area. Our Black Sea coasts have more hydrogen sulfide reserves since they are deeper than Russian side 90% of the water of the Black Sea is anaerobic and contains hydrogen sulfide (H_2S). 8ml at 1000m depth. The H_2S concentration, which is Lt-1, is 13.5 ml at the base. It reaches the level of Lt-1.

Another technology development study on this subject is hydrogen production by photocatalytic method using semiconductor particles. It is a scientific research in the literature for the production of hydrogen from the H_2S-containing water of the Black Sea by utilizing solar and wind energy, and Bulgaria is trying to develop a project. However, the presence of a natural hydrogen reservoir at the bottom of the Black Sea is an opportunity for Turkey's future. Hydrogen studies in our country should be developed by considering it consistently and seriously (Ültanır:1998)

In this regard, a PEM electrolyzer unit generates hydrogen from hydrogen sulfide that is available in the Black Sea deep water. The generated hydrogen and sulfur gas from hydrogen sulfide are stored in high-pressure tanks for later use. Hydrogen is blended with natural gas, and the blend is utilized for industrial and residential applications. The investigated system is modeled with the Aspen Plus software, and hydrogen production, blending, and combustion processes are analyzed accordingly (Öztürk, Midilli and Dinçer, 2021).

Therefore, at the international level, producing hydrogen from hydrogen sulfide in the depths of the Black Sea is easier and cheaper than other methods, and R&D studies are also carried out in Russia, Georgia, Romania and Bulgaria in this area. Our Black Sea coasts have more hydrogen sulfide reserves since they are deeper than the Russian side.

On the other hand, in order to activate the hydrogen energy reserves and make the necessary investments, Turkey, Bulgaria, Ukraine, Russia, It can be suggested to encourage the 'Black Sea Energy Cooperation' to be established by regional countries such as Georgia and Romania (Midilli et al., 2005).

Finally, the removal of H_2S from bottom of the Black Sea and separation into components undesirable harmful compound may turn into a useful energy resource. Hydrogen production from H_2S can be achieved by facilitating suitable hydrogen production methods in both the central and coastal regions of the Black Sea (Şeker, 2021).

MUCILAGE IN THE MARMARA SEA AND ITS UNKNOWN ENERGY OPPORTUNITIES

In aquatic environments that are under the influence of many environmental problems such as pollution, overfishing, invasive species, climate change. With the change of trophic conditions, harmful phytoplankton species multiply and become dominant. This harmful phytoplankton overgrowth of species is often referred to as harmful algae growth or algal bloom, and as a result aspect; A high amount of extracellular polymeric organic substance is secreted from the large number of living cells formed. These extracellular organic substances called mucilage; mostly by diatoms and dinoflagellates is produced (Eren, 2021).

Marine mucilage or sea sputum is one of the intense environmental problems that increases with global warming and pollution. Marine mucilage, which occurs especially interior in the waters and gulfs, has increased in recent years, its incidence and density in Turkish seas (Türkistanli, 2021).

Sea of Marmara, it is an important inland sea with traffic around Istanbul and Canakkale which their throats are tied dense sea with numerous industrial zones. In mid-spring of year 2021 appeared in the sea of Marmara The resulting mucilage has become a serious threat over time reachedup to kilometers in length mucilage, with its other names in the literature, “Sea The nature of the phenomenon of "snot" or "sea saliva" as gelatinous aggregates is defined (Kavzoğlu,T et al., 2021).

Another parameter of hydrogen energy is related to carbon dioxide in the atmosphere. It is estimated that the rate of carbon dioxide in the atmosphere will reach 520 ppm in 2050. It is estimated that this amount can be reduced with the widespread use of hydrogen energy (Erdener, 2007).

In sum, we can benefit from Marmara Sea’s mucilage problem as a new renewable energy in using microalgae isolated from marine mucilage. Accordingly, this opportunity should be take into account such as Black Sea’s H_2S hydrogen energy potential.

CONCLUSIONS

Coal is a type of rock formed by the transformation of plants and nature into fossils in swampy environments. Although there is no clear answer to the question of how oil is formed, it is assumed that oil was formed by the decomposition of plant and animal remains that lived millions of years ago.

It is clearly seen that hydrogen, which is an ideal fuel, will be widely used by solving the problems encountered in production, application and economic aspects. On the other hand, H_2S is a colorless, foul-smelling gas, heavier than air and flammable. It is possible to produce hydrogen energy by decomposition of H_2S such as Black Sea deep waters case.

Hydrogen energy from the Black Sea is not a single example in the worldwide .For example, historically, in the socialist period in Romania, former government wanted to build a hydrogen power plant by using the hydrogen sulfur from the deep waters of the Black Sea.

Therefore, if we take into account Marmara Sea's recent mucilage dilemma, hydrogen and photocurrent can be produced using microalgae isolated from marine mucilage. In this context, mucilage should be evaluated in green energy production studies on renewable energy as biological waste.

Consequently, it is suggested that the Black Sea region countries such as Turkey, Bulgaria, Ukraine, Russia, Georgia and Romania should encourage and invest to activate in renewable energy especially „"hydrogen energy" and this energy source can be transported to the European Union countries.

FABRICATION OF PLATINUM-COBALT NANOWIRES BY CENTRIFUGAL ELECTROSPINNING METHOD AS ELECTROCATALYSTS FOR PEMFC

[1]Chen-Yu Wu, [1*] Min-Hsing Chang
[1]Department of Mechanical and Materials Engineering, Tatung University, Taipei, 104, Taiwan

*Corresponding author e-mail: mhchang@gm.ttu.edu.tw

ABSTRACT

The centrifugal electrospinning method is employed to fabricate platinum-cobalt (PtCo) bimetallic nanowires as electrocatalysts for proton exchange membrane fuel cell (PEMFC). The influences of system parameters on the nanowire morphology are explored systematically including the rotating speed of spinneret, applied voltage, and atomic ratio of Pt and Co in the nanowires. The electrochemical performance of the PtCo nanowires is evaluated by performing cyclic voltammetry (CV) tests to characterize the electrochemical active surface area (ECSA). The accelerated degradation tests (ADT) are also conducted to examine the durability of the PtCo nanowires. The membrane electrode assembly (MEA) using PtCo nanowires as cathode electrocatalysts is also made and the fuel cell performance is tested and compared with conventional MEA using Pt/C catalysts. It is found that under the condition of rotating speed 1600 rpm, collecting distance 12 cm, applied voltage 13 kV, and atomic ratio of Pt:Co = 4:1, PtCo nanowires can be produced successfully with good morphology and the mean diameter is 76 nm. The corresponding ECSA is 11.69 $\mathrm{m^2 g^{-1}}$ and the ADT results show the resultant PtCo nanowires exhibit better durability than conventional Pt/C catalysts.

Keywords: Centrifugal electrospinning method, PtCo nanowires, Electrocatalyst, PEMFC

INTRODUCTION

Nowadays, the application of proton exchange membrane fuel cell (PEMFC) is still restricted due to the major barrier of precious platinum (Pt) catalyst. Because the slow reaction kinetics of oxygen reduction reaction (ORR) in the cathode, a high loading of Pt is usually used in the electrode which makes the cost reduction be difficult. In addition, traditional Pt/C catalysts exhibit poor performance in durability which is also a block for commercialization of PEMFC. Numerous studies have focused on the research of novel materials to lower the demand for precious Pt metal. In these efforts, Pt-based alloys have been thought a possible way to remove these barriers. Particularly, one-dimensional (1D) nanostructured Pt-based electrocatalysts have received much attention for their potential application in PEMFCs [1]. Many studies have found that 1D catalysts including nanowires and nanotubes can enhance electron transport performance, improve catalyst utilization efficiency, and increase catalyst activity and durability due to their structure characters. Several kinds of non-precious metals have been used to form Pt-based alloy and test their electrochemical performance. Cobalt is one of them that has been found the PtCo alloy nanowires can present a significant improvement in ORR activity and durability than Pt/C.

Considerable studies have devoted to the investigation of PtCo alloy nanowires in which various methods have been used to fabricate PtCo nanowires. In the work of Higgins et al. [2], they prepared PtCo nanowires by the electrospinning method and obtained an average diameter of 28 nm for the nanowires. They found the specific activity and durability could be enhanced significantly in comparison with commercial Pt/C catalyst. Accordingly, they suggested electrospinning is an attractive approach to prepare PtCo nanowires. While the flow rate of polymer solution was 0.25 ml per hour only, which is quite a low speed and severely restricts the production efficiency of nanowires. Recently, a novel method named centrifugal electrospinning method has been employed successfully to fabricate Pt nanowires [3]. This method takes the advantages of electrospinning and forcespinning together to make nanowires and the production rate can be improved greatly. In the present study, we first attempt to fabricate bimetallic PtCo alloy nanowires by the centrifugal electrospinning method. The morphology of nanowires is examined systematically by adjusting the system parameters including the rotation speed of spinneret, the applied voltage, and the atomic ratio of Pt and Co in the composition. The electrochemical properties of the prepared PtPd nanowires as electrocatalysts are tested by performing cyclic voltammetry (CV), linear sweep voltammetry (LSV), and accelerated degradation tests (ADT). The optimal condition to control the morphology and obtain high electrochemical performance of nanowires would be evaluated. Additionally, membrane electrode assemblies (MEA) using the PtCo nanowires as cathode electrocatalysts are made, and the fuel cell performance is measured and compared with the MEA using commercial Pt/C. The results show that 1D PtCo nanowires can be made efficiently by the centrifugal electrospinning method.

THE EXPERIMENTAL

The schematic of centrifugal electrospinning system can be found in the work [3]. The present study used the same apparatus to fabricate polymer nanofibers. The polymer solution containing precursors of Pt and Co was put inside the spinneret located at the center of the device. The collection distance from the tip of the nozzle to the collector is 12 cm. The rotating speed of spinneret can be controlled by a motor drive and a high voltage can be applied between the nozzle and collector. Once the spinneret rotates, both centrifugal force and electrostatic force exert on the polymer solution simultaneously and the solution would be ejected from the nozzles to form polymer jets. During the flowing process, the solvent would evaporate and the jets would be elongated to form polymer fibers with mean diameter less than one micrometer generally. Finally, the polymer fibers could be collected from the collectors. The polymer solution was prepared by of polyvinyl pyrrolidone (PVP, Mw = 1,300,000), ethanol, DI water, and $H_2PtCl_6 \cdot 6H_2O$ and $Fe(NO_3)_3 \cdot 9H_2O$ as precursors of Pt and Fe, respectively. The collected polymer fibers were calcinated in a high temperature oven. The heat treatment process is the same as the study [3] to burn off the polymer and other elements. The nanowires were then reduced in H_2 at 200 °C for one hour to form PtCo nanowires.

The morphology of the PtCo nanowires was observed by Scanning Electron Microscope (SEM) and the composition was analyzed simultaneously by the equipped energy dispersive X-ray spectroscopy (EDS). The mean diameter of the nanowires was estimated from the SEM image by the ImageJ software. The X-ray diffraction (XRD) patterns were also measured to observe the crystalline phase of nanowires. The measurement of cyclic voltammogram (CV) was conducted by the Autolab potentiostat with a three-electrode system to determine the electrochemical active surface area (ECSA), in which Ag/AgCl (in 3M KCl) was used as the reference electrode. The catalytic slurry of nanowires was prepared and micropipetted onto the polished GC electrode as the working electrode and dried to form a thin film on the GC surface. The tests were performed in N_2 saturated 0.5 M H_2SO_4 solution and scanned between −0.2 V and 1.0 V with a scan rate of 50 mVs^{-1}. The accelerated degradation test (ADT) was also implemented in the same way to evaluate the durability of PtCo nanowires while the potential was scanned repeatedly between 0.4 V and 1V and then the CV pattern was recorded to estimate the degradation of ECSA. Membrane electrode assemblies were also made by using the PtCo nanowires as the cathode electrocatalysts. The catalyst slurry was prepared by mixing PtCo nanowires, Nafion ionomer solution, and isopropanol. The catalyst slurry was brushed on the side of carbon cloth coated with microporous layer until the loading reached 0.5 mg cm^{-2}. The anode electrode was prepared using 20 wt% commercial Pt/C with the Pt loading of 0.5 mg cm^{-2}. A Nafion 115 membrane was sandwiched between the anode and cathode gas diffusion electrodes and then hot pressed to form the MEA with active geometric area of 5 cm^2. The fuel cell performance was measured using fully humidified hydrogen and air as reactants and the cell temperature was held at 70°C during the test.

RESULTS AND DISCUSSION

The effect of rotating speed of spinneret on the morphology of PtCo nanowires is examined as shown in Fig.1 (a)-(d), where the rotating speeds are 1400, 1600, 1800, and 2000 rpm, respectively. The other conditions in the collection of polymer fibers are 13 kV of applied voltage, 10 wt% of PVP concentration, 2 wt% of precursors, and 4:1 of atomic ratio Pt:Co. One can see that the nanowires can be made successfully under these conditions with various rotating speeds of spinneret. The mean diameters with standard deviations (SD) of these cases are 97±21, 76±14, 88±21, and 103±24 nm, respectively. Obviously, the case of 1600 rpm presents the minimum mean diameter with more uniform nanowire morphology. The results indicates that either of insufficient or excessive centrifugal force would result in higher mean diameter and SD. A lower rotating speed cannot provide sufficient centrifugal force to elongate the polymer jet, while a higher rotating speed will shorten the time for the solvent to evaporate during the flowing process since the collection distance is fixed. Hence, an appropriate rotating speed is very important for the evaporation of solvent and elongation of polymer jets during the fiber collection process.

The applied voltage is also a crucial factor that may affect the morphology of nanowires significantly. Two typical SEM images are shown in Fig. 2(a)-(b) for the cases of 12 and 14 kV, respectively, under the rotating speed of 1600 rpm. The mean diameters and SDs are respectively 100±18 nm and 91±24 nm. In comparison with the result of Fig. 1(b), it is observed that the applied voltage also may influence the morphology of the nanowires greatly. A smaller electrostatic force would not fully stretch the polymer jets while a larger electrostatic force may cause a higher flow rate from the Taylor cone at the tip of nozzle and then result in a larger mean diameter. The results of EDS and XRD patterns have shown that the Co can be integrated into the Pt-based alloy structure successfully as shown in Fig. 3 and Fig. 4. The results of CV as shown in Fig. 5 also reveal that PtCo nanowires made by the present method present excellent potential for the application in PEMFCs.

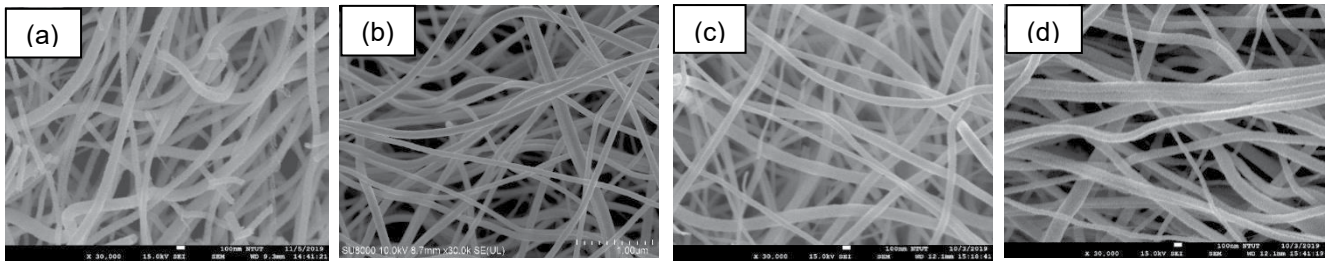

Fig. 1. The SEM images of PtCo nanowires collected at rotating speed of (a) 1400 rpm, (b) 1600 rpm, (c) 1800 rpm, and (d) 2000 rpm. The applied voltage is 13 kV.

CONCLUSIONS

The present results demonstrate that bimetallic PtCo alloy nanowires can be made successfully by the centrifugal electrospinning method. The prepared PtCo nanowires present excellent electrochemical performance which possess great potential to be used as electrocatalysts in PEMFCs. Further studies focusing on how to reduce the nanowire diameters would be helpful in the future.

ABSTRACT

The composite powders consisted of oxygen ion conductive $(La_{0.75}Sr_{0.2}Ba_{0.05})_{0.175}Ce_{0.825}O_{1.891}$ (LSBC) and proton conductive $BaZr_{0.1}Ce_{0.7}Y_{0.2}O_{3-\delta}$ (BZCY) were prepared by solid state reaction and sintered to be a composite membrane. The inter-diffusion was found between LSBC and BZCY. The conductivity of LSBC-BZCY single membrane exhibited slightly non-ohmic behavior in air but obviously non-ohmic diode behavior at 500°C in Ar/H_2. It indicated that the Schottky barrier could be designed at low to intermediate temperatures. The microstructure of sintered LSBC-BZCY surface fluctuated with convex and concave regions. The convex region was hard LSBC and the concave region was soft BZCY by micro-hardness and elemental measurement. The LSBC-30%BZCY let the two phases single membrane possess dual-ions conduction to obtain the power density of 20.51 mW/cm^2. The elemental distribution difference abruptly for Ba, Ce and O occurred at grain boundaries of LSBC/BZCY may correspond to the inter-diffusion and Schottky barrier results. The dual-ions composite membrane was proven single layer fuel cell possibly by this economical design process.

Keywords: Composite membrane, Dual-ions conduction, Schottky barrier, Economical design

INTRODUCTION

The intermediate solid oxide fuel cells (ITSOFCs) are economical and green power sources for large scale distributed power generation [1]. The energy conversion efficiency of sandwich-structured solid oxide fuel cell (SOFC), which consists of anode, electrolyte and cathode, is determined by interface, ohmic and diffusion impedances. Such interface and diffusion impedances result from triple-phase boundaries (TPBs), which are between electrode and electrolyte, and electrode internal structures (porosity, pore geometry and electrocatalytic sites etc.). The ohmic impedance originates from electrolyte and outer conducting interconnection materials [2]. Recently, the composite membrane composed of ionic and semi conductive characteristics is proposed to replace the conventional electrolyte layer to overcome the complex sandwich structure of fuel cells. This concept may avoid the interface polarization loss, lower the operation temperature and simplify the structure of a fuel cell [3,4] to achieve the simple synthesis process and economically in materials utility as well as environment friendly, sustainably.

Ceria-based materials such as Gd-doped ceria (GDC) and Sm-doped ceria (SDC) are well-known oxygen ion conducting electrolytes in ITSOFC [5]. Multiple elements doped ceria ($(La_{0.75}Sr_{0.2}Ba_{0.05})_{0.175}Ce_{0.825}O_{1.891}$ referred to LSBC) can exhibit high ionic conductivity at intermediate temperature (500-750°C) and anti-reduction at low partial oxygen pressure [6,7]. The nanodomain clusters resulted from oxygen vacancies by oxide doping in CeO_2 can be homogeneously distributed by multiple ions doping into CeO_2 structure thus increasing the ionic conductivity effectively [8,9]. To lower the operation temperature below 500°C is expected by using proton conducting electrolytes in SOFC [10]. Perovskite $BaZrO_3$ series materials are promise candidates due to chemically stable in steam and CO_2 atmosphere for proton conduction [11,12]. The yttrium (Y) doped $BaZrO_3$ such as $BaZr_{0.1}Ce_{0.7}Y_{0.2}O_{3-\delta}$ (BZCY) has been proven to be high proton conductivity [13,14].

The aim of this work is to develop economically single composite membrane consisted of LSBC and BZCY to replace the conventional sandwich SOFC structure. Such a LSBC-BZCY composite membrane behaves fuel cell characteristics. The BZCY conducts protons and is used as an electron blocking function for oxygen ion conducting LSBC material. The mixing LSBC-x mol% BZCY composite membranes are studied by dual-ions conduction behavior, Schottky barrier, elemental analyses and power density to characterize the performance of single membrane fuel cell.

MATERIALS AND METHODS

LSBC was prepared by ball milled La_2O_3, $SrCO_3$, $BaCO_3$ and CeO_2 in ethanol for 24 h and calcined at 1000°C/4h.

BZCY was also prepared by ball milled $BaCO_3$, ZrO_2, CeO_2 and Y_2O_3 in ethanol for 24 h and calcined at 1000°C/4h.

The two ball milled and calcined powders were ball-mixed again to obtain the LSBC – xBZCY (x=0, 10, 20, 30, 70,

80, 90 and 100 mol%) mixture and then calcined at 1000~1300°C for 4 h. Such calcined mixtures were pulverized and die-pressed into discs, then were sintered at 1500°C/6h to form composite membranes.

The crystal structures of the calcined powders and sintered bodies were characterized by X-ray diffraction (XRD). A field-emission scanning electron microscope (FESEM) equipped with energy dispersive X-ray spectroscopy (EDS) were used to determine their microstructures, morphologies and elemental analyses. The electric current-voltage (I-V) characteristic and the power density were measured using the Keithley 2400 source meter. Alternating current (AC) impedance analyses of the fuel cells were conducted with an electrochemical instrument (Zahner Zennium, Germany).

RESULTS AND DISCUSSION

The pure phases of LSBC and BZCY are still maintained after mixing LBSC-30BZCY, as shown in Fig. 1(a)(b). It can not detect the existence of secondary phase. The inter-diffusion between LSBC and BZCY is found in Fig. 1(c) by enlarged XRD patterns at 2θ=40°~43°. The diffusion resulted in the lattice distortion due to the diffraction angle shift. The LSBC-10BZCY after measured at 500°C in Ar/H_2 atmosphere by cyclic voltammetry method indicates the non-ohmic I-V behavior, as shown in Fig. 1(d). It revealed a diode behavior that the Schottky barrier may exist in the sample. The electron blocking effect was supposed in the LSBC-10BZCY composite membrane. Then the Schottky barrier may be further manipulated to accommodate the neutralization of proton – oxygen ion at low temperature of 500°C.

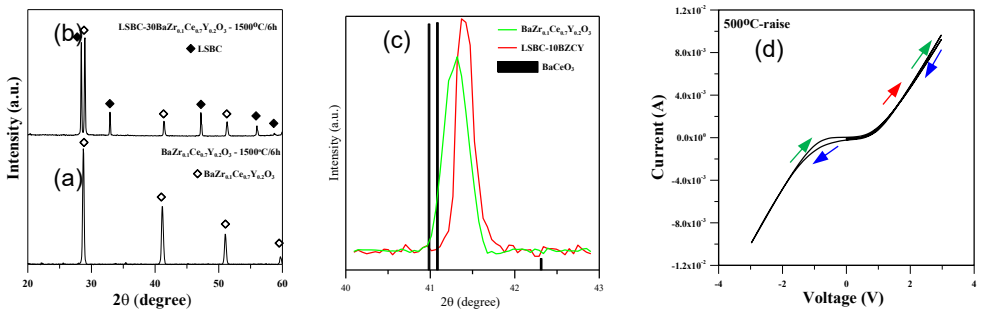

Fig. 1. XRD patterns of 1500°C/6h sintered (a) BZCY, (b) LSBC-30BZCY, and at (c) 2θ=40°~43°, and (d) I-V curve of LSBC-10BZCY measured by cyclic voltammetry in Ar/H_2 atmosphere at 500°C.

The polished LSBC-10BZCY surface fluctuated with convex and concave regions. The convex region was hard LSBC and the concave region was soft BZCY by micro-hardness and elemental analyses, as shown in Fig. 2(a). The EBDS analysis is further proof of the two phases with different hardness in Fig. 2(b). The EDS line scanning analysis presents the Ce, Ba and O elements (red, dark green and grass green color lines) distribution abruptly different at LSBC-BZCY grain boundaries, as shown in Fig. 2(c). The reasons may be originated from inter-diffusion and mechanical polishing stress. Elemental diffusion was more possible reason referred to the XRD results in Figs. 1(a) and 1(b).

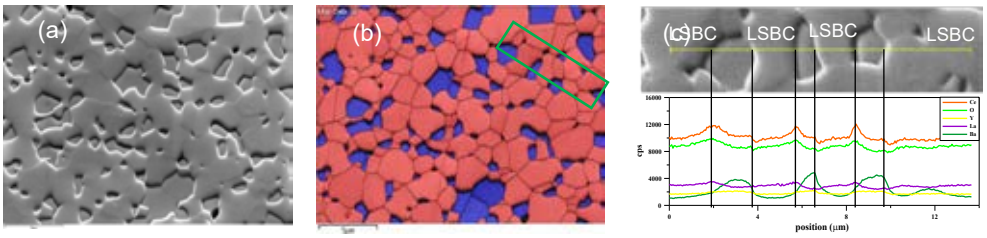

Fig. 2. Polished morphologies of LSBC-10BZCY, (a) FESEM, (b) EBSD, (c) elemental analyses (EDS line scanning) for the green rectangular region in (b).

The LSBC-BZCY composite membrane was realized as fuel cell by Pt||LSBC - xBZCY||Pt structure using H_2 in anode side and air in cathode side. The I-V curve and power density measured at 600 and 700°C are shown in Fig. 3 with different x values. Basically, LSBC-BZCY composite membrane can be used as a fuel cell even the power density is still spaces to improve. From the results, the highest power density is obtained at the LSBC-30BZCY about 20.51 mW/cm^2, as shown in Fig. 3(b). Such results prove the realization of dual-ions conducting single composite membrane as a fuel cell.

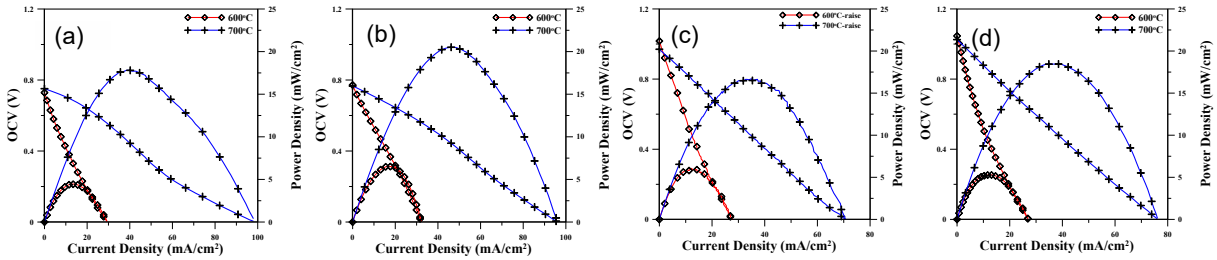

Fig. 3. The I-V and power density of Pt||LSBC - xBZCY||Pt composite membrane cells measured in H_2/air at 600~700°C, (a) x=0, (b) x=30, (c) x=90 and (d) x=100.

CONCLUSIONS

The conductivity of LSBC-BZCY single membrane exhibited slightly non-ohmic behavior in air but obviously non-ohmic diode behavior in Ar/H_2 atmosphere. It indicated that the Schottky barrier could be designed at low to intermediate temperatures. The LSBC-30BZCY let the dual phase single membrane possess dual-ions conduction to obtain the power density of 20.51 mW/cm^2. The dual-ions composite membrane was a single layer fuel cell possibly by this economical design process.

ABSTRACT

In order to achieve carbon neutrality, hydrogen is one of the key technologies to decarbonize the whole energy system. Several countries especially Japan are planning to import low carbon hydrogen using international supply chains setting their hydrogen strategy. There could be a wide variety of combinations among the technology option to make the supply chains. LCOEs using the international hydrogen transport chains are analyzed in this study to consider economic efficiency and to find effective clues for cost reduction in the international hydrogen transport chains. As preliminary results, we have found that the transportation cost that includes liquefaction, storages and international seaborne transport is improved by about 40% considering the advantages of large-scale facilities and that lignite gasification technologies with carbon capture have a competitive edge under the current assumption. For the time being, blue hydrogen could be an affordable option until the cost of green hydrogen decreases to the similar level. (<200 words)

Keywords: Hydrogen carriers, International supply chains, Economic analysis

INTRODUCTION

At COP26 in Glasgow in 2021, it is confirmed that “Reaffirms the Paris Agreement temperature goal of holding the increase in the global average temperature to well below 2 °C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels”[1]. This will accelerate the movement toward greenhouse gas reduction. Japan firstly published their hydrogen strategy [2] and is planning to import low carbon hydrogen using international supply chains. There are already some studies on hydrogen imports from abroad [3-7]. Various hydrogen sources and hydrogen carriers are being studied, however in this research, we conducted an analysis that considers an unprecedented large-scale supply chain for energy applications, and various utilization technologies as well as incorporating the latest technology development.

METHODLOGY FOR ANALYSIS

Fig. 1 shows the scope of analysis in this study. An international hydrogen supply chain to be analyzed consists of a hydrogen production technology using primary energy resources that are low carbon emissions such as fossil fuels with CCS technologies and renewable energies, a storage and transport technology for long distance, and utilization technology in a wide variety of energy demand sectors. Utilization technologies considered are FCV, FC trucks, ships, CHP, hydrogen and ammonia as feedstock especially for chemical industries and power sector.

The procedure of analysis is as follows;

- Define an international supply chain for analysis considering facilities included;
- Set common assumptions such as year, system boundaries, the amount of energy transported, utilization factors, and distance;
- Set specific assumptions of facilities in the defined international supply chain;
- Carry out energy and mass balance analysis to set the capacities of the facilities included, the quantities of utilities used;
- Capital expenditures in the supply chain are estimated using the obtained results above;
- Levelized cost of hydrogen (or electricity) for the supply chain are obtained.

The Levelized cost method shown by the following equation is used to obtain the cost of hydrogen. This is a generic method to calculate the unit cost by dividing the total accumulated cost during the project period by the total hydrogen supply amount during the period. In order to consider the value of cash flow at different times, the cost and fuel supply amount are converted to the present value using the discount rate. This method is one of the standard cost analysis

methods used by the International Energy Agency [8]. As levelized cost of product (LCOP) in the equation is a generic expression, levelized cost of electricity (LCOE) is used as an indicator in this study.

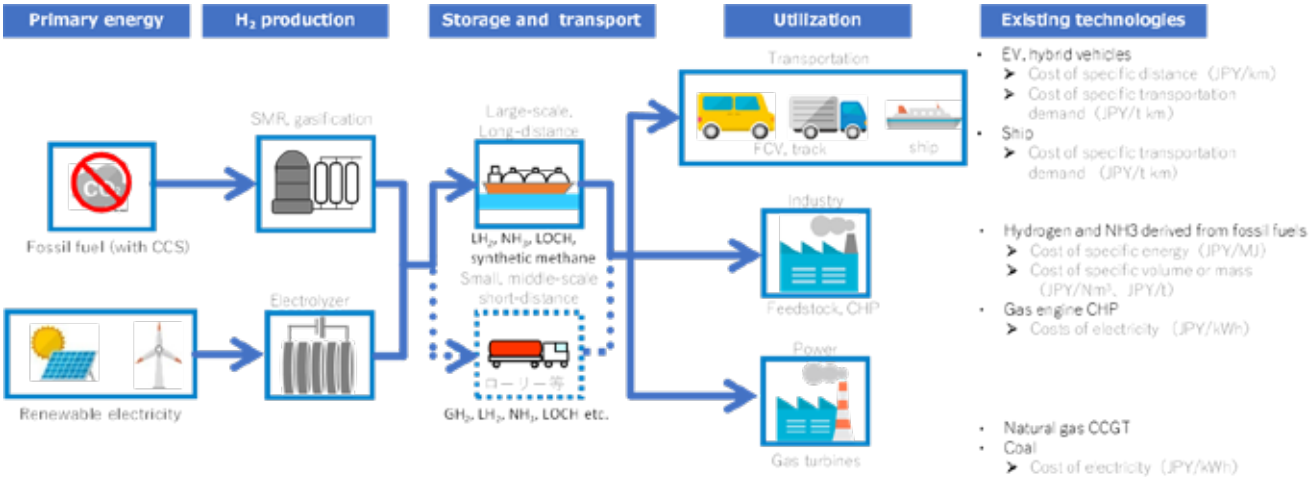

Fig. 1. The scope of analysis in this study

$$\mathrm{LCOP} = \sum_n \frac{\sum_t [(I_{n,t} + M_{n,t})(1+r)^{-t}]}{\sum_t (E_t (1+r)^{-t})} \quad (1)$$

where LCOP (Levelized Cost of Product), In,t: Capital related expenditure at term t and in facility n, Mn,t: operational expenditure, Et: production supply in term r , r: discount rate .

In order to evaluate the economic efficiency of the hydrogen supply chain, we have carried out a preliminary calculation of power generation cost using the imported hydrogen. The data for analysis are mainly based on literature. The capital expenditure of each facility in the supply chain is estimated using the scaling law and corrected by plant cost index and location factor as necessary. As operational and maintenance costs, fuel, electricity, labor, maintenance, insurance and general and administrative costs, are considered.

RESULTS AND DISCUSSION

Fig.2 shows preliminary results of levelized cost of electricity using hydrogen transported via the international liquefied hydrogen supply chain between Australia and Japan. Alkaline water electrolysis and lignite gasification in Australia are considered as hydrogen production technologies. The cost of renewable electricity from wind power for hydrogen production is 6.2 JPY/kWh. The cost of lignite is 12.7 AUD/t [9]. The transport capacity of the chain is 200 kt/year with technologies available in 2030 [10] and 2 Mt/year using advanced technologies in the future.

The most affordable case is lignite gasification with 2 Mt/year chain. The difference in LCOE with the chain of the same transport capacity is due to the cost difference in hydrogen production. The cost of both hydrogen production accounts for a large proportion of LCOE. The hydrogen cost of lignite gasification is about half of water electrolysis under the current assumption.

The transportation cost that includes liquefaction, storages and international seaborne transport is improved by about 40% considering the advantages of large-scale facilities. In this study hydrogen production and power generation did not anticipate economies of scale that changes from 200 kt/year to 2 Mt/year because the maximum unit capacities of these technologies are smaller than the capacity of supply chains. The assumed investment cost of electrolyzer of 200kt/year based on the scaling law is 29,000 JPY / kW which is in a similar range of the 2050 target of IRENA (< 200 USD/kW) considering the current status (500-1000 USD/kW) [11]. The number of lignite gasification reactor is more than one. The amount of hydrogen transport (2 Mt / year) is enough for several units of hydrogen fired gas turbine combined cycle power station. Even if water electrolysis is expected to have a quite good capital cost (the assumption are 29,000 yen / kW and capacity factor 35%), significantly inexpensive renewable energy power (1.6 JPY / kWh) is also required to compete hydrogen from lignite. For the time being, blue hydrogen could be an affordable option until the cost of green hydrogen decreases to the similar level.

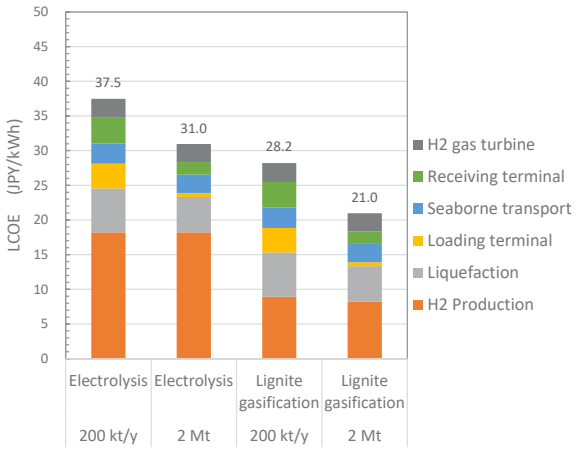

Fig. 2. Preliminary results of levelized cost of electricity using hydrogen transported via the international liquefied hydrogen supply chain between Australia and Japan

CONCLUSIONS

LCOEs using the international hydrogen transport chains are analyzed in this study to consider economic efficiency and to find effective clues for cost reduction in the international hydrogen transport chains. As preliminary results, we have found that the transportation cost that includes liquefaction, storages and international seaborne transport is improved by about 40% considering the advantages of large-scale facilities and that lignite gasification technologies with carbon capture have a competitive edge under the current assumption. For the time being, blue hydrogen could be an affordable option until the cost of green hydrogen decreases to the similar level. In the conference, another combination among hydrogen production, storage and transport (ammonia and liquid organic chemical hydrides) and demand technologies (FCVs, feedstock etc) will be discussed.

ABSTRACT

Increasing electricity generation from variable renewable energy sources, such as wind and solar, has led to interest in additional short-term and long-term storage capacities. The core objective of this paper is to investigate the costs and the future market prospects of different electricity storage options, such as short-term battery storage, and long-term storage as pumped hydro, as well as hydrogen. The method of approach is based on formal economic framework with a dynamic component to derive scenarios up to 2040. The major conclusion is, that the economic prospects of storage are in general not very bright. For all market-based storage technologies it will become hard to compete in the wholesale electricity markets. The core problem of virtually all categories of storage are low full-load hours. However, any new storage capacity should be constructed only in a coordinated way and if there is a clear sign for new excess production, in this case from variable renewables.

Keywords: Storage, Hydrogen, Pumped hydro storage, Battery, Economics

INTRODUCTION

Increasing electricity generation from variable renewable energy sources, such as wind and solar, has led to interest in additional short-term and long-term storage capacities. One of these options is hydrogen. Since many decades hydrogen has been considered as a universal environmentally benign energy carrier. So far high production costs stated a major barrier for a broader market penetration, see e.g. Ajanovic (2008). With the current ambitious targets for increasing the share of renewable energy sources (RES) to 27% by 2030 set by the European Commission new prospects for hydrogen as energy storage for excess electricity from RES emerge. The reason is that an increasing share of these new RES comes from variable sources like wind and solar. This leads to the need for increased balancing activities between supply and demand, as well as flexibility measures in general, see e.g. Lund et al [1], including the demand for long-term electricity storages.

The core objective of this paper is to investigate the costs future market prospects of hydrogen as a storage for excess electricity and its possible more competitive use in the transport sector as a renewable fuel. Of specific relevance is the comparison with other possible storage such as traditional pumped hydro storage or looming new large batteries.

METHOD

Our method of approach on the electricity market side a fundamental approach is used where the intersection of supply and demand at every point-of-time gives the corresponding electricity market price. It is important to note that the quantity of storage has a feedback on the market price for charging storages as well as discharging. The method is based on cost calculation of different electricity storage technologies, see Hiesl [2] and Ajanovic [3]. In the following equation it is described how the storage cost C_{STO} are calculated:

$$C_{STO} = \frac{\frac{IC \cdot C.R.F + C_{OM}}{T} + C_E}{\eta_{STO}} \quad \text{(€/kWh)} \quad (1)$$

With:

C_{STO}… Cost of storing a kWh of electricity in hydrogen, in a pumped hydro storage or a battery (€/kWh)
IC …. Investment costs of a storage (€)
C.R.F. Capital recovery factor (1/year)
C_{OM} … O&M costs (€/year)
T ….. Full-load hours (hours per year)
C_E ….. Costs of electricity on the wholesale market (€/kWh)
η_{STO}… Efficiency of storage

Equation 1 shows the cost of storing one kWh. Whether a market-oriented storage is economically feasible decides the so-called price spread in the electricity market and the number of over-all operating hours, the full-load hours. The importance of full-load hours for the economic feasibility of storage facilities has already been discussed in Hiesl [2], Ajanovic [3] and Schill [4]. Along with the issue of the price spread this is the Alpha and Omega in every discussion on the future prospects of centralized storage as a market-based option from an economic point-of-view. Regarding the costs in the long-term the methodical approach used based on technological learning for the future development of investment costs of the storage technologies investigated, based on expected future quantities of these technologies.

RESULTS AND DISCUSSION

The major results of our investigations are: As shown in Fig. 1 for all types of storage the costs of storage depend very strongly on the yearly fullloadhours. E.g at 500 hours/year the capital costs are four times higher than at 2000 hours/yr. In Fig. 2 the total costs of hydrogen produced in large electrolyzers plants (10 MW) are shown depending on the yearly fullloadhours including also the costs of electricity on the market. E.g hydrogen can be used as storage for electricity from volatile RES, however efficiency of the whole energy supply chain including reelectrification of hydrogen is very low.

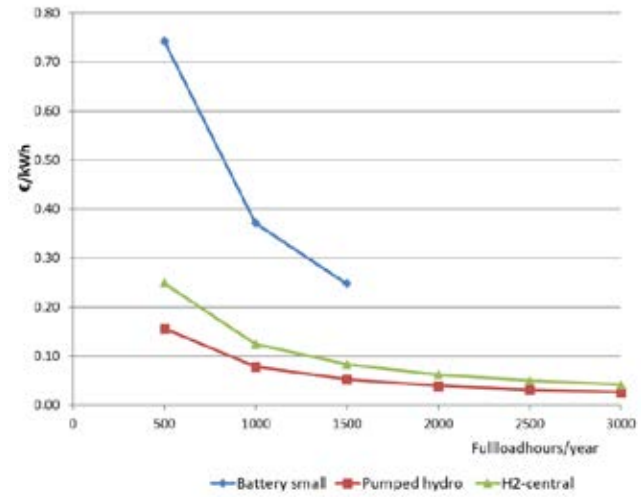

Figure 1. Dependency of the capital costs of various types of storage from the yearly fullloadhours

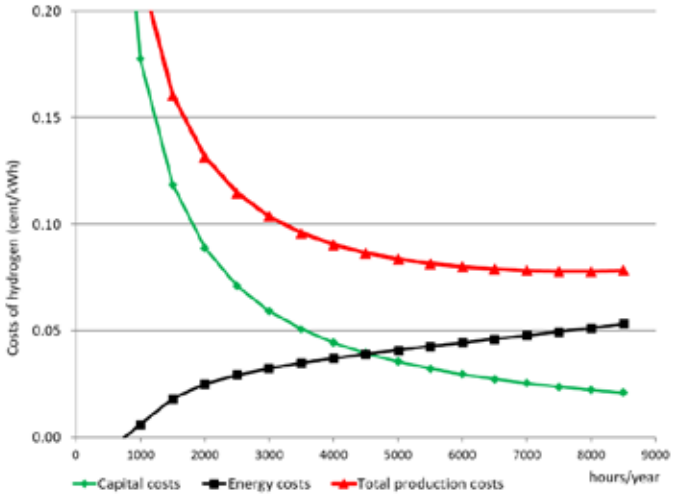

Figure 2. Dependency of the total costs of hydrogen produced in large electrolyzers plants (10 MW) on the yearly fullloadhours

However, over the period up to 2040 decreases in the costs of hydrogen production will take place mainly due to learning effects. In a dynamic market framework the costs of large centralized and smaller decentralized long-term hydrogen storage will finally be too high to become competitive in the electricity sector alone. By 2040 under most favourable learning conditions the investment costs of large electrolyzers will go down to about 1100 EUR/kW from currently about 1600 EUR/kW: The total production costs of hydrogen for 2000 fullloadhours per year will be about 0.09 EUR/kWh, see Fig. 4. For the same fullloadhours the price spread will be at the utmost about 0.08 EUR/kWh. For hydro pumped hydro storages (over a year) further investment costs will rather increase mainly due to a lack of sites with reasonable costs and lack of acceptance, Fig. 3. An additional reason for the unfavorable economic conditions of long-term storages is the self-cannibalism of storages in electricity markets. This means that every additional storage reduces the price spread and, hence, its own economic performance, Ehlers [5]. Other reasons are competition with demand response options, demand –side management, power-to-heat and decentralized storages. The costs of the latter will not decline significantly faster but they will compete on end-user price level which is (and will remain) remarkably higher.
To reduce the relatively high costs of hydrogen cheap surplus electricity from variable RES can be used for electrolysis. The major problem of the economics of all storage options are their low FLH. Currently, a figure of about 2000 hours per year is considered to be the minimum.

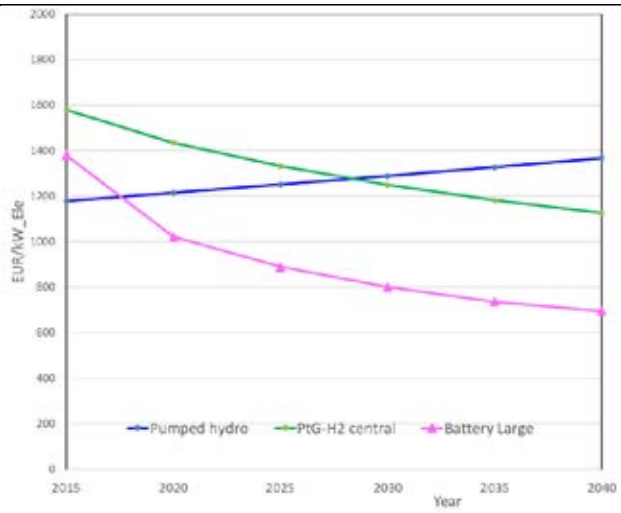

Figure 3. Development of the investment costs of hydrogen (electrolyzers), pumped hydro storage and batteries depending on Technological Learning over time up to 2040

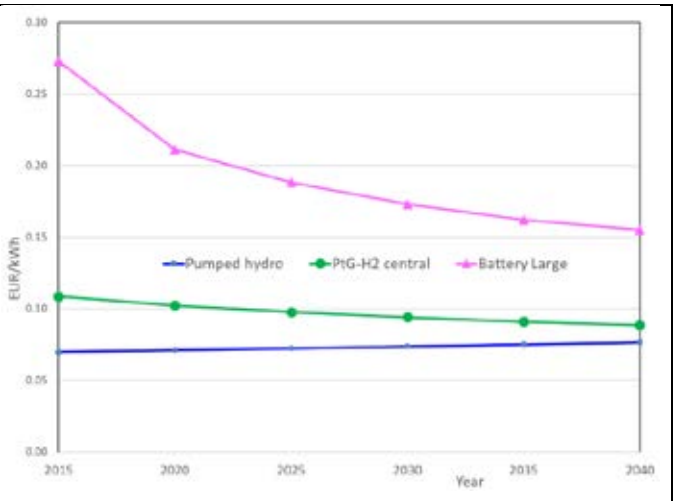

Figure 4. Development of the total storage costs of hydrogen, pumped hydro storage and batteries depending on Technological Learning of the technology over time up to 2040

CONCLUSIONS

The major conclusions are: (i) with respect to all centralized long-term storage technologies the future perspectives will be much less promising than currently indicated in several papers and discussions; (ii) For hydrogen it will also become very hard to compete in the electricity markets by means of re-electrification despite a high technological learning potential.

Finally, it has to be stated that storage is not the only flexibility option. It is in competition with grid extention, load management and other options. In addition, natural gas as storage and natural gas fired turbines for short-term generation are a flexibility alternative, however, not a fully carbon-free one. Hence, from an economic assessments point-of-view of electricity storage the possible competing options has to be considered simultaneously. However, any new storage capacity should be constructed only in a coordinated way and if there is a clear sign for new excess production, in this case from variable renewables. In addition, for hydrogen and methane there could be better economic prospects in the transport sector due to both, higher energy price levels as well as a general lack of low carbon fuel alternatives.

ABSTRACT

Hydrogen plays an important role in the energy transition. The exploitation of hydrogen in gas turbines, as well as in other combustion processes, is promising but it may favor the formation of nitrogen oxides due to its high adiabatic flame temperature. The catalytic combustion of ultra-lean air-hydrogen mixtures solves the issue and improves the stability of the reaction at partial loads. The present work develops a numerical model for the design of catalytic combustors able to process ultra-lean air-hydrogen mixtures. The model simulates the catalytic combustion in a honeycomb monolith. Such tool is useful for the sizing of innovative combustors for micro-gas turbines for power generation. The numerical model solves mass and energy balances in a two-dimensional domain describing a single channel of the monolith. The channel is modelled as a cylinder, while the outer radius describes the catalyst surface. A validation of the numerical model is performed with experimental data obtained on a dedicated test bench at low inlet temperature and pressure. Comparing the simulated results with the experimental measurements, a 0.6% difference in outlet bulk temperature is obtained. Ultimately, useful recommendations are provided for combustor designers, based on the estimations of the numerical model in different operating conditions.

Keywords: Hydrogen, Catalytic combustion, Ultra-lean mixture, Numerical model, Micro-gas turbines

INTRODUCTION

Hydrogen economy is being deeply investigated for the process of decarbonization through the so-called energy transition. Such carrier allows an environmentally sustainable transport, storage, and usage of energy. Therefore, the exploitation of hydrogen for integrated power systems, as within gas turbines or via other combustion processes, is promising thanks to the avoidance of carbon dioxide emissions [1]. However, hydrogen high adiabatic flame temperature poses the issue of the formation nitrogen oxides. In this context, a feasible solution is the catalytic combustion of ultra-lean hydrogen mixtures, allowing for the combustion of hydrogen at low temperature without the production of any pollutant. This technology enables the development carbon and NO_x-free power production systems due to lower operating temperatures. Moreover, it offers an improved stability at partial load, when compared to traditional burners. Furthermore, ultra-lean hydrogen mixtures below the flammability limit are inherently safe.

The objective of the present work is the development and the validation of a tool for the design of the first stage of catalytic hydrogen combustors for micro-gas turbines. Such stage involves the combustion of an air-hydrogen mixture out of flammability limits. The tool allows the estimation of the main operational parameters of a honeycomb monolith catalytic combustor: the fuel conversion, the local maximum temperature, and the outlet bulk temperature. The inputs of the numerical model are the geometry of the catalyst, the inlet stream conditions and the reaction kinetics. Ultimately, inserting the inputs for a case study allowed the experimental validation of the tool.

Catalytic combustors for hydrogen-air mixtures are investigated in literature. Hayes and Kolaczkowski describe the modeling approach for honeycomb monolith catalysts adopting cylindrical coordinates in a book dedicated to the catalytic combustion [2]. The modeling of a single channel monolith honeycomb catalyst is performed also by Groppi et al. for the identification of the simplest representative model [3]. In a more recent work, Mantzaras describes the modeling of catalytic combustion of hydrogen focusing on hetero-homogeneous combustion for power generation applications [4]. The exploitation of hydrogen in micro-gas turbines is investigated in the last years. Devriese et al. developed a compressor and a combustor for a 100-kW hydrogen powered gas turbine [5]. The operation with alternative fuels as hydrogen of such systems is also considered in the review performed by Aslanidou et al. [6].

NUMERICAL MODEL AND EXPERIMENTAL VALIDATION

The current section describes the approach adopted for the numerical model and the setup for its experimental validation in the Laboratory of Energy Conversion and Storage of Politecnico di Milano. The aim is the development of a tool for the design of catalytic burners for ultra-lean air-hydrogen mixtures.

Numerical model methodology

The numerical model solves the mass and energy balances for a single channel of the monolith, eventual non-homogeneity in the feeding conditions should be addressed performing detached simulations for each region of the monolith. The channel of the monolith is described as a cylinder, and the two spatial coordinates indicate the axial and the radial position in the domain, respectively. Moreover, such model is based on simplifying assumptions for the calculation of fluid properties. The flow regime is laminar in the whole domain, neglecting the initial development of the velocity profile. The catalyst is placed on the outer radius of the monolith channel. It is described as a boundary condition of the domain. Such description is performed through a correlation containing the reaction kinetics and the thermal properties of the solid. Ultimately, mass diffusion is described as for a binary mixture for a first approximation of the problem [7]. Such assumption is feasible as more than the 75% of the mixture is nitrogen, on a molar basis.

The domain is discretized adopting finite differences in the axial direction and orthogonal collocations in the radial direction [**Error! Reference source not found.**]. The model is implemented in MATLAB and solved with a built-in solver for non-linear functions. After the solution, the model estimates the design parameters for the monolith catalyst. Among such parameters are included the maximum local temperature, the outlet bulk temperature and the unburnt hydrogen. The latter ones are exploited for the experimental validation of the tool.

Experimental setup for validation

The experimental validation of the estimation of the numerical model is performed on a dedicated test bench at ambient temperature and pressure. It features a monolith catalyst fed with an ultra-lean air-hydrogen mixture. Such mixture has a hydrogen molar fraction of 2.38% and is fed to the catalyst through a long intake duct. Therefore, the stream composition and velocity are uniform at the catalyst inlet for achieving the same feeding conditions on each channel of the monolith. This allows the reproduction of the condition simulated by the numerical model.

The tests are performed in steady state. The apparatus is switched on and the measurements are harvested when the outlet bulk temperature is stable. Such temperature is measured with a Pt1000 thermistor at the outlet of the monolith, close to the axis of the hollow cylinder containing the catalyst. The unburnt hydrogen is measured with a gas chromatograph with Argon as carrier gas. Such instrument analyzes samples gathered at the outlet of the catalyst. The measurements of concentration with the gas chromatograph are repeated three times, for statistical significance. The temperature readings are harvested continuously. Ultimately, the temperature reported in the results is the mean value of the readings in steady state.

RESULTS AND GENERAL RECOMMENDATIONS

The comparison between the estimations of the numerical model and the experimental measurement is reported in table 1. The estimated outlet bulk temperature is 0.6% higher than the experimental measurement. The estimated unburnt hydrogen is comparable with the experimental measurement and close to zero in the tested conditions. Such parameters validate the experimental model at low pressure and temperature. Therefore, the numerical model is exploited as a design tool of a catalytic combustor for micro-gas turbines.

Table 1. Parameters comparison for the validation of the experimental model.

Parameter	Numerical model estimation	Experimental measurement
Outlet bulk temperature [K]	486	483
Unburnt hydrogen [$\%_{mol}$]	0.016	0.022

After the experimental validation, the temperature trend and local hydrogen consumption are investigated for a first stage of combustion in a micro-gas turbine. This leads to some general recommendations for developers of catalytic hydrogen burners operating in ultra-lean conditions. The temperature trend shows an initial peak when the catalyst is operated at low pressure. This local overtemperature must be considered when designing the monolith. Increasing the operational pressure, the local peak is smoothed but not eliminated. The temperature distribution in the monolith channel is reported in figure 1. It shows an overtemperature on the outer radius of the channel. Hydrogen mass fraction is also reported in figure 1. It highlights the very effective diffusion of the component towards the outer radius of the channel.

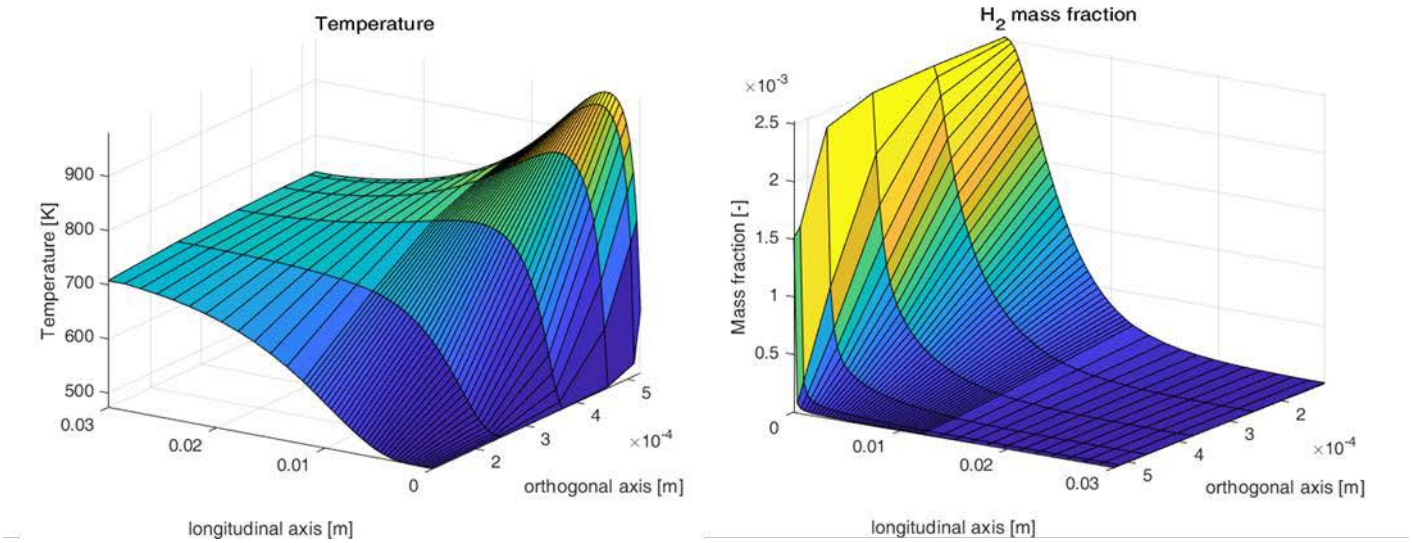

Fig. 1. Temperature and hydrogen distribution in the monolith channel for an inlet condition featuring a temperature of 473 K and an absolute pressure of 400 kPa as typical.

CONCLUSIONS AND FUTURE WORKS

The presented work develops a tool for the simulation of a hydrogen catalytic combustor. The simulation is performed with a numerical model implemented in MATLAB. The results are as follows.

- The numerical model is validated with the simulation of the operating conditions of a case study. The estimated bulk temperature is 0.6% higher than the experimentally measured one.
- The numerical model estimates overtemperatures on the catalyst wall related to the operation with hydrogen in the first 20% of the length of the channel.
- The hydrogen distribution allows an estimation of the unburnt hydrogen and of the fuel conversion. Consequently, the tool is exploitable for the convenient sizing of a catalytic combustor.

Future works will include a more detailed description of the hydrogen mass diffusion and the evaluation of the possible applications of the technology to other hydrogen end uses.

OPTIMIZATION OF A HYDROGEN SUPPLY CHAIN: A CASE STUDY FOR ITALY

[1,2*] *Renato Luise,* [1] *Annabelle Brisse,* [3] *Pietro Quaglia,* [2] *Catherine Azzaro-Pantel*

ABSTRACT

Although hydrogen has been identified as key for a zero-carbon energy system, the design and deployment of the hydrogen supply chain (HSC) is a challenging issue, in particular due to the various ways to produce, condition, store and transport hydrogen. Hydrogen demand is expected to increase rapidly as several new sectors (e.g. mobility, heat and buildings) in addition to the conventional industrial ones realize its applications.

The paper addresses the emerging issue of how to design, organize and size the HSC. The problem involves a single optimization framework, where the total cost of the HSC is minimized, with a multi-period (2020-2040) mixed-integer linear programming (MILP) formulation that is implemented in the General Algebraic Modelling System (GAMS) environment, using CPLEX as a solver. The superstructure used for HSC modelling is split into six echelons, i.e., primary energy source, H_2 production, conditioning and centralized storage, distribution, conditioning and decentralized storage, and finally usage.

A case study for Italy has been developed, leading to a final hydrogen cost of 4.6€/kg in 2045. Various key performance indicators (KPIs) have been identified for the optimal solution obtained: centralization degree of the HSC, form of hydrogen (i.e. liquified, compressed), transport mode (gaseous or liquid H_2 trucks, H_2 pipeline) and economic parameters (i.e. investment, operation and maintenance costs).

Keywords: Hydrogen supply chain, Optimization model, GAMS, Mixed integer programming, Decentralization

INTRODUCTION

Several authors have been tackling the problem of HSC optimization since more than 15 years. The work presented in [1] can be defined as one seminal contribution in HSC modeling which paved the way to other developments (e.g. [2], [3] and [4]). This work is the further development of the model previously developed in [3]. It consists in an optimization tool for the deployment and design the HSC, by minimizing the costs of the whole supply chain.

Hydrogen can be produced in either centralized (i.e. steam methane reforming with carbon capture and storage (SMR w. CCS) plants and large-size electrolysers) or decentralized sites (small size electrolysers) or imported from abroad. The solution includes centralized storage systems, which are linked to conditioning components such as compressors and liquefiers. The hydrogen produced and conditioned can be then transported either on road (i.e. by tankertruck for liquid H_2 by tube trailer for compressed H_2) or via H_2 pipeline. H_2 production must finally satisfy the H_2 demand coming from two different sectors, i.e., industry and mobility.

MODELING

In line with the majority of the works analysed in the literature, this formulation of the HSC design problem is based on a mixed-integer-linear-programming (MILP) approach. The model is developed in the General Algebraic Modelling System (GAMS) environment, using the CPLEX solver in a computer with Intel® Core™ i5-6200U processor with CPU @ 2.30GHz and 16GB RAM. A comprehensive explanation of all the parameters, formulas and constraints can be found in [2], [3], [4]. In this paper, only the new technological bricks and implementation done from [3] will be analysed in detail.

Availability of renewable energy sources (RES)

A parallel study has been carried out on the availability of RES in Italy. The available amount of energy for the production of electrolytic hydrogen has been calculated as the sum of the disincentivized RES electricity from 2020 up to 2045 and the 25% of RES production from the forecasted new installations.

Imported H_2

The model integrated the possibility of importation of hydrogen from abroad and its availability at the centralized storages. Once collected at the centralized storage, the hydrogen is then treated in a similar manner to the hydrogen produced in the system (i.e. conditioned and transported to the final user). Nevertheless, the priority has been given

to the National Italian H_2 production and for this reason the imported hydrogen has been seen only as secondary option and for this reason a high cost has been considered (i.e. 10€/kg).

H_2 transported via pipeline

The pipeline capital cost (PLCC) at each period t is evaluated as the product of the specific unit of pipeline capital cost (UPLCC) by the distance AD between grid g and g'.

$$PLCC_t = \sum_{g,g'} UPLCC \times AD_{g,g'} \times NTUgrid_{g,g',t} \quad ,\forall\, g \tag{1}$$

The pipeline operating cost (PLOC) is split into two parts: the first part is related to the pressure drops along the pipes, with the specific pipeline operating cost UPLOC multiplied by the amount of hydrogen transported via pipeline from g to g'. The second part is linked to maintenance costs, which are a percentage delta of the PLCC.

$$PLOC_t = \sum_{g,g'} UPLOC \times Q_{pipeline,g,g't} + delta \times PLCC(t) \quad ,\forall\, g \tag{2}$$

Overview on the HSC design

The HSC has been designed to satisfy the demand from two different sectors (i.e. mobility, industry) with the production of H_2 through SMR, electrolysis and imported H_2 from abroad. Storage and transport have been implemented in compressed and liquid forms. All the possible paths to satisfy the H_2 demand are shown in Fig. 1.

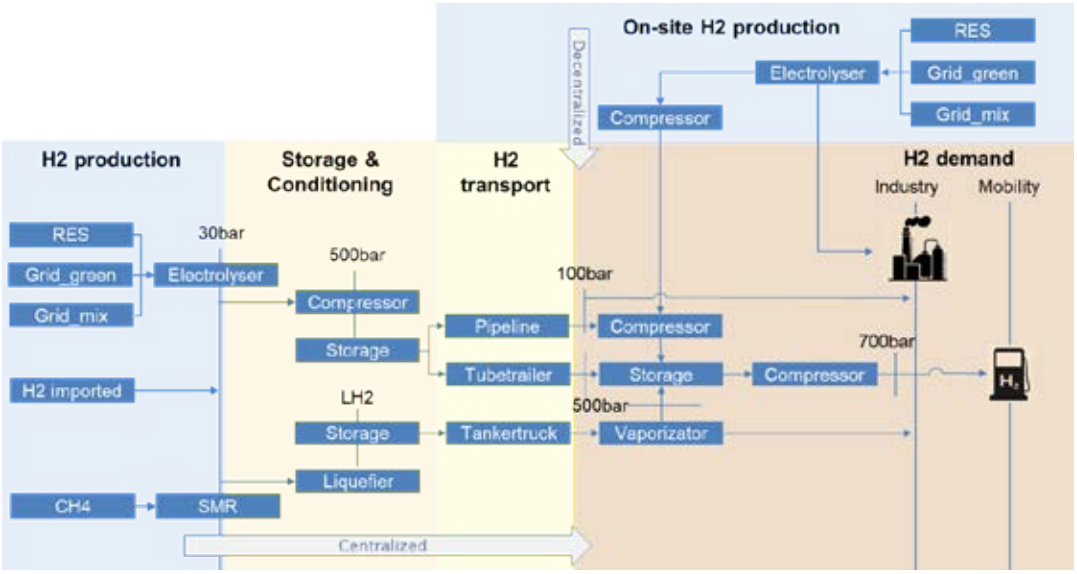

Fig. 1. Technologies and design of the HSC

CASE STUDY

To validate the new implemented model, a case study has been investigated where the system analysed is Italy divided into regions. Each Italian region represents a grid, which is centered in its own regional capital, excluding the islands, which would need different transport modes.

The hydrogen demand for mobility in each grid D_{MOB} has been calculated as the product of the number of vehicles NV registered in each region, the penetration rate PER of hydrogen vehicles, the average distance d traveled by each considered vehicle and the fuel consumption FC of each considered vehicle, as shown in Eq. 3.

$$D_{MOB_{g,t}} = NV_{g,t} \times PER_t \times FC \times d \quad ,\forall\, g,t \tag{3}$$

The hydrogen demand for mobility sector has been indeed calculated as a share of the current hydrogen demand in Italy coming from refinery and ammonia plants, which covers 91% of the Italian H_2 demand. Due to lack of information, the demand of H_2 for refinery has been equally split between the 12 identified plants (i.e. 35,300 ton/plant/year), while the whole H_2 demand for the ammonia sector (i.e. 80,200 ton/year) has been totally satisfied by the unique plant identified.

The resulting demand in average for mobility and industrial sector per each Region ranges from 3,400 ton/year in the first period, up to 11,800 ton/year in the last period.

RESULTS AND DISCUSSION

The optimization has been run to minimize the hydrogen costs along the HSC. Capital, operating and maintenance costs for each energy source and technological brick have been considered. All the economic parameters have been actualized with a discount rate of 2%.

The final cost of hydrogen along the whole analysed period amounts to 5.8€/kg. The costs are strongly influenced by the lack of infrastructures nowadays. Indeed, in the first analysed period (i.e. 2025-2030) the hydrogen has a cost of 9.3€/kg, which falls to 4.6€/kg in the last period (i.e. 2040-2045). Fig. 2 shows the final configuration of the HSC, which refers to the year 2045.

It must be emphasized that the optimization has found a solution with the installation of a steam methane reformer with carbon capture and storage (SMR w. CCS) needed only in the last period when the demand is higher. The H_2 demand in the first periods is indeed exclusively satisfied by electrolytic hydrogen production, with a distribution of 72% centralized rate and 28% decentralized. This ratio remains mainly constant also with the installation of the SMR w. CCS. The solution identified from optimization also includes in the first period only compressed hydrogen. Only in the last period indeed, liquid hydrogen enters the scene with a share of 35% (i.e. 6 liquefaction plants).

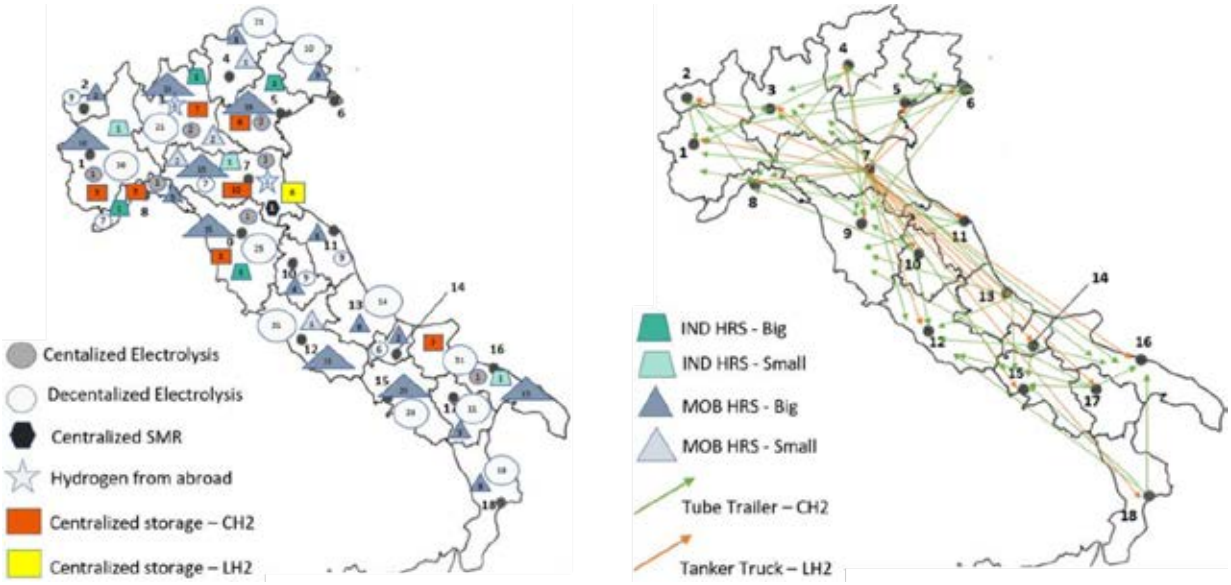

Fig. 2. Italian HSC design in 2045

CONCLUSIONS

When national hydrogen demand is greater than 200,000 tons per year, the model evaluate that the cheapest hydrogen cost for final consumer is achieved with centralised production via SMR w. CCS, the hydrogen being distributed in liquid form. With this H_2 supply chain, the cost for low carbon hydrogen is 5.8 €/kg The H_2 cost of 5.8 €/kg, obtained with this optimization results, is still not competitive with the H_2 produced through SMR at an industrial scale, especially if a margin on the top of the final H_2 cost is considered.

ABSTRACT

A comprehensive literature review on the papers using life cycle costing (LCC) approaches to fuel cell and hydrogen (FCH) related technologies was carried out as one task in the European project SH2E in order to develop an LCC guideline. The papers to be reviewed were extracted from two major literature databases, SCOPUS and Web of Science. The extracted papers were briefly reviewed to decide if the paper is to be reviewed later in detail. The numbers of papers to be reviewed in detail were finally 155. The selected papers were reviewed from the various viewpoints, in particular, the objectives, the scope, the entity of assessment, stakeholder involvement, depth of assessment, mass and energy balances of the systems, the facilities considered, calculation methods, discounting (social vs private) or EoL treatment etc. The overall trend of LCC approaches, methods and indicators will be clarified, in order to establish the LCC guidelines.

Keywords: Life cycle costing, Hydrogen, Fuel cell

INTRODUCTION

Fuel cell and hydrogen (FCH) related technologies are considered as an energy vector connecting low carbon and renewable resources and energy demand sectors for carbon neutrality [1, 2]. Many studies have been performed over the last decade analyzing the costs of FCH systems because costing evaluations are the backbone of all technology development. Companies only invest in new technologies if they see an economic advantage in the future. However, there is no standard methodology for cost calculations. When coming from the life-cycle-thinking perspective the SETAC has published a code of practice in 2011 for life cycle costing (LCC) [3]. Other studies might use the approach of 'Total Cost of Ownership', which also includes the full life cycle of a product from production, over the use phase and its disposal or end-of-life treatment. Regarding FCH systems, LCC is currently of utmost importance, because several FCH are on the edge of commercialization, e.g. water electrolyzers. Thus, in this study a comprehensive literature review was performed on LCC approaches for FCH systems to determine the most important methodological influencing factors and identify best practices.

This study is part of the Fuel Cell and Hydrogen 2 Joint Undertaking (FCH JU) funded SH2E project [4] where eventually guidelines for Lifecycle Sustainability Assessment (LCSA) for FCH technologies are being developed. LSCA consists of three assessment methods that are economy, environment and society and their integration.

This review aims to clarify the overall trend of LCC approaches, methods and indicators (including both conventional life-cycle economic indicators and life-cycle economic indicators based on externalities), identifying their main features and discussing their suitability for the assessment of FCH systems in order to establish LCC guidelines to be subsequently developed in the following task in the SH2E project. The review investigates the objectives, the scope, the entity of assessment, stakeholder involvement, depth of assessment, mass and energy balances of the systems, the facilities considered, calculation methods, discounting (social vs private) or EoL treatment etc.

So far, several review papers about FCH topics have been published. For example, a specific FCH technology is analyzed. Gigoriev et al. [5] are focussing in their paper on water electrolysis. They are mentioning costs, but only in absolute terms regarding the different technologies. Hydrogen supply chains is the technological topic of Fredershausen et al. [6]. On the example of hydrogen supply chains, they discuss already methodological aspects regarding sustainability evaluations. They classify the economic evaluations in four different types, i.e. macroeconomics, microeconomics, long-term competitiveness and innovation capability. However, they do not go further into methodological details, which was carried out in this study.

METHODS AND PRELIMINARY RESUTLS

Fig. 1 shows the procedure of the literature review on LCC papers. We extracted peer-reviewed papers on SCOPUS and Web of Science, dated from January 1st, 2010 to May 21st, 2021 with the search string in their titles, abstracts or

keywords. The number of extracted papers is 317 removing overlaps in both databases. The used search strings are as follows;

- For SCOPUS, PUBYEAR > 2010 AND TITLE-ABS-KEY(((hydrogen OR "fuel cells") AND ("life cycle" OR lifecycle)) AND ("sustainability assessment" OR lcsa OR costing OR lcc OR "economic analysis")
- For Web of Science, (AK=((((hydrogen OR "fuel cells") AND ("life cycle" OR lifecycle)) AND ("sustainability assessment" OR lcsa OR costing OR lcc OR "economic analysis")))) OR TI=(((hydrogen OR "fuel cells") AND ("life cycle" OR lifecycle)) AND ("sustainability assessment" OR lisa OR costing OR lcc OR "economic analysis")) OR AB=(((hydrogen OR "fuel cells") AND ("life cycle" OR lifecycle)) AND ("sustainability assessment" OR lisa OR costing OR lcc OR "economic analysis")) For a timespan from 2011-01-01 to 2021-05-21

Then, the papers were briefly checked based on their abstract, equations, figures, tables, and conclusion using the following criteria to choose the papers to be reviewed in detail;

- Include: Papers with peer review on LCC of FCH related facilities or equipment (production, storage, transport and utilization);
- Exclude: Conference papers, book chapters, review papers, paper that just refers another paper results, papers where hydrogen is minor operating agent, non-English written papers.

The number of the papers to be reviewed was 155. A difference in the scope of the cost items account for was observed in some papers we have reviewed. The overall trend and methodologies, indicators and other important aspects for LCC will be presented in the conference.

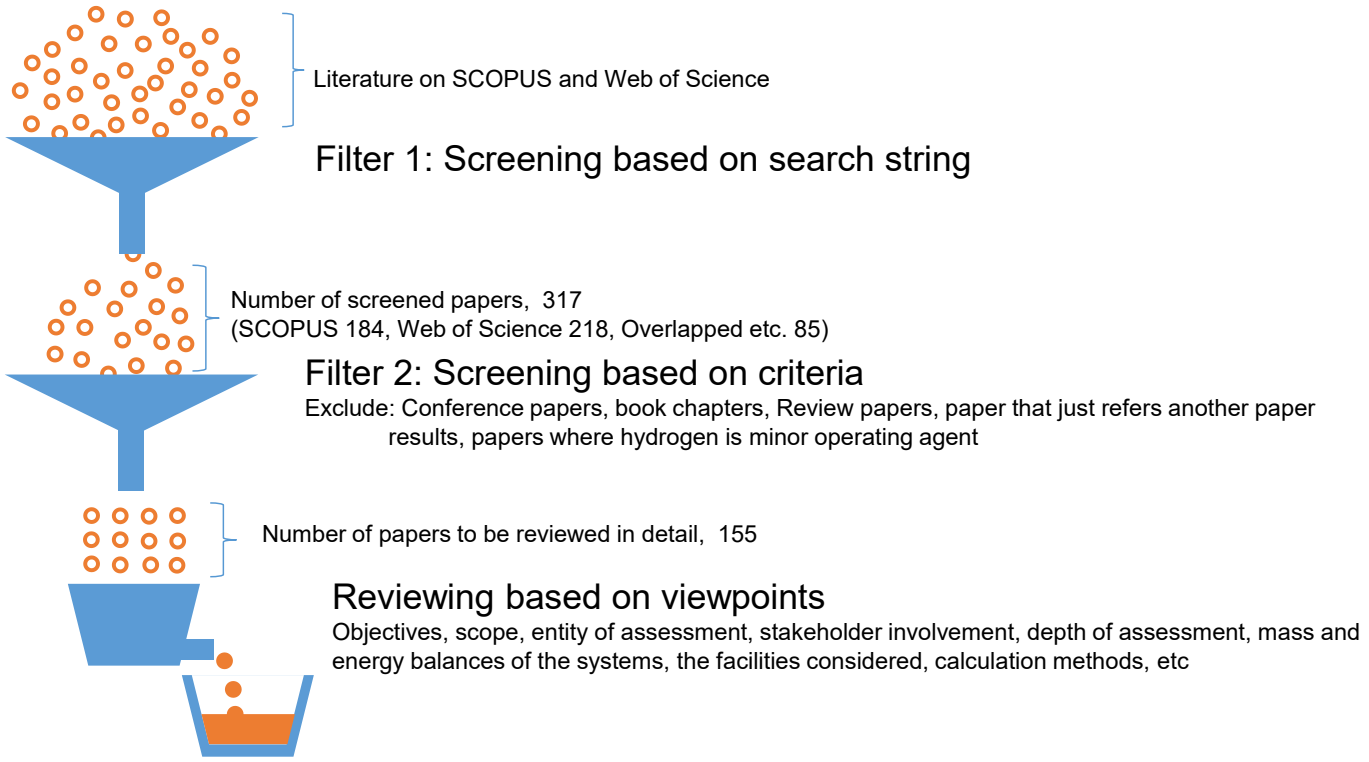

Fig. 1. Procedure of literature review on Life Cycle Costing (LCC) papers

Fig. 2 shows the number of the screened papers by published year. The number of LCC papers about hydrogen and fuel cells increases with time as observed. This could reflect the scientists' interests in these technologies.

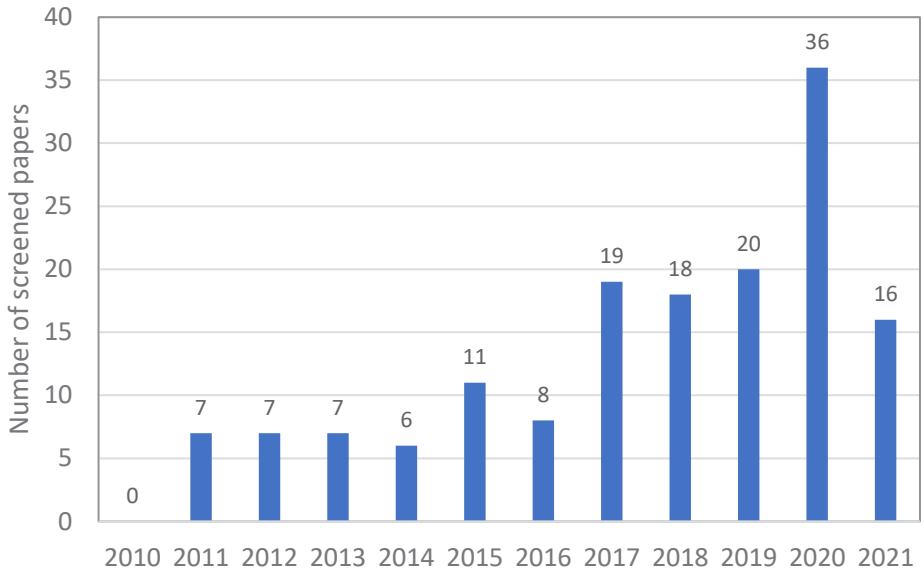

Fig. 2. Number of the screened papers by published year, until May 2021

CONCLUSIONS

A comprehensive literature review on the papers using LCC approaches to FCH related technologies was carried out as one task in the FCH JU funded SH2E project in order to develop an LCC guideline in the subsequent task. A total of 155 papers were extracted to be reviewed in detail. The number of the papers are soaring, which could reflect researchers' interests in this field. The selected papers are reviewed from the various viewpoints, in particular, the objectives, the scope, the entity of assessment, stakeholder involvement, depth of assessment, mass and energy balances of the systems, the facilities considered, calculation methods, discounting (social vs private) or EoL treatment etc. The overall trend of LCC approaches, methods and indicators will be clarified, in order to establish the LCC guidelines.

ABSTRACT

With the significant development of electrolyzer technology, blueprint of economical and long-run hydrogen production adopted by this technology inspires great interest. The economic competence of electrolyzer needs further investigation to answer their current and future viability with technology development of ultimate performance as well as the decisive impactor to affect hydrogen production cost. Economically and technically, this research is originally established with a combination of crucial technology features including current density, overpotential, and ohmic resistance, acquired from the polarization curve to make the techno-economic analysis of anion exchange membrane electrolyzer technology. A cell-stack-system level on materials and fabrication is performed based on the bottom-up study to give an optimal investigation. It reveals the possibility for future hydrogen cost reduction and points out how the internal technical factors act on achieving a more cost-competitive hydrogen production. With consideration of the service lifetime together, this research exhibits the potential economic benefits from multiple dimensions of technological progress.

Keywords: Hydrogen economy, Electrolyzer technology, Hydrogen production

INTRODUCTION

Hydrogen emerges promptly as a promising energy system to revolutionize the traditional power fuels[1]. Currently, H_2 production could be realized by advanced water electrolysis technology, which could be combined with the green renewable electricity[2,3]. Among the various electrolysis technology such as classical alkaline electrolyzer, progressive proton exchange membrane electrolyzer, the anion exchange membrane electrolyzer spurs as a burgeoning newbie which takes the advantage of both alkaline electrolyzer and proton exchange membrane electrolyzer. For instance, the usage of low-cost fabrication materials and high-quality electrolysis current density endow the anion exchange membrane electrolyzer significate competence to satisfy the low-cost hydrogen production demand. With the significant development of the anion exchange membrane electrolyzers technology in a foreseeable future, more economical hydrogen production cost could span the coming hydrogen society rapidly[4-6]. However, there remains critical questions toward the hydrogen production cost by anion exchange membrane electrolyzer technology under techno-economic perspective, including the near-term viability, long-term cost reduction from the key impactor consideration.

Previous hydrogen production cost investigation mainly established on the social market survey regarding capital investment and materials manufacture expansion, a separate economic consideration[7]. However, the greatest hydrogen production cost reduction stems from the technic character of electrolyzer ultimate performance such as electrolysis efficiency and service lifetime. The electrolyzer performance could be attributed by the technic breakoff of critical materials property, especially the catalyst activity, membrane conductivity and mass transfer in gas diffusion layer. Integrally, the special electrolyzer technology factor could be presented as current density and voltage potential, which will decide the electricity consumption. The electricity consumption cost occupies paramount of the final hydrogen production cost regarding to the electrolyzer manufacture costs. These technic impactors are few explored with the relationship of hydrogen production cost, whereas they act as favorable guidelines for the hydrogen production blueprint layout.

Herein, current density and voltage from polarization curve of electrolyzer performance is implemented into the electrochemical calculation and throughout to describe the technical character variation originally. Then, a techno-economic approach is established for the assessment of hydrogen production cost by application of anion exchange membrane electrolyzer technology. Current technology status and future potential of this technology are evaluated form cell-stack-system level.

MODELING

According to Faraday's law and independent efficiency of the anion exchange membrane electrolyzer, the techno-economic model was established for both the stack and system. Starting with the resultant hydrogen production cost, it should be calculated as the total cost divided by hydrogen production mass. Power consumption cost and electrolyzer manufacture contribute simultaneously to the total cost. Detail constructure is exhibited as the following equations and Fig. 1. Notably, the part of Balance of Plant (BoP) is customized rather than mass-produced, and it is viewed as proportion to the cost of the stack according to current Chinese market. Here the BoP is determined as 50% of the stack cost for anion exchange membrane. *C* stands for *Cost* and *P* stands for unit price here. The stack is designed as 1MW scale.

$$C_{stack} = n_{cell} \times \sum_{i=1}^{n} C_{materials,i} \quad (1)$$

$$C_{system} = C_{stack} + \sum_{i=0}^{n} C_{BOP,i} \quad (2)$$

$$C_{electricity} = P_{electricity} \cdot t \cdot n_{cell} \cdot (V_{cell} + R_{ohmic} \cdot i_o) \cdot i_o \cdot S_{cell} \quad (3)$$

$$m_{H_2} = t \times \frac{P_{total} - P_{loss}}{F} \quad (4)$$

$$C_{unit\ hydrogen\ production} = \frac{C_{system} + C_{electricity}}{m_{H_2}} \quad (5)$$

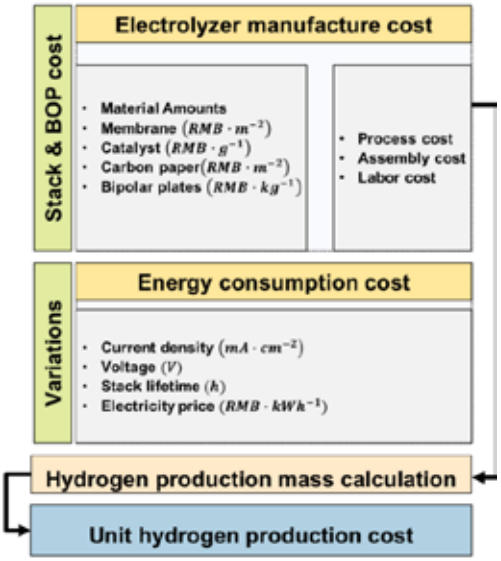

Fig. 1. Flow chart of the techno-economic modelling in which critical parameters are descripted in detail.

RESULTS AND DISCUSSION

Hydrogen production cost division towards anion exchange membrane electrolyzer technology

Generally, the hydrogen production cost decrease from 25.37 $(RMB \cdot kg^{-1})$ to 19.32 $(RMB \cdot kg^{-1})$ when the electrolyzer stack lifetime increases from 2 to 18 years, as shown in Fig. 2(a). To analyze the division of hydrogen production cost, it is mainly divided into manufacture cost and power consumption cost. In detail, the BoP and stack manufacture cost account for less section compared to the whole power consumption cost. And the BoP and stack manufacture cost are greatly diminished as the lifetime of electrolyzer increases. Since the power consumption cost domains, it could be divided into the electricity cost for directly hydrogen production according to Faraday's law, the electricity cost for over potential wastage, the electricity cost for ohmic loss wastage and the electricity cost for BoP support. Despite the electricity cost for directly hydrogen production exceeds largely to the electricity cost for over potential and ohmic loss cost, it should not be ignored that there exists considerable electricity not to be fully utilized.

Influence of voltage ad current density on hydrogen production cost

When the initial voltage starts at 1.43V, the hydrogen production cost decreases equally from 26 $(RMB \cdot kg^{-1})$ to 22 $(RMB \cdot kg^{-1})$ as the current density increases from 400 to 1400 $(mA \cdot cm^{-2})$, shown in Fig. 2(b). When the initial voltage decreases to 1.33V, a 0.1V deduction compared to 1.43V will cause a different change tendency of hydrogen production cost. Under this circumstance, the hydrogen production cost decreases from 25.5 $(RMB \cdot kg^{-1})$ to a minimum value of 21 $(RMB \cdot kg^{-1})$ firstly, whereas increases slightly to 21.5 $(RMB \cdot kg^{-1})$ as the current density increases from 400 to 1400 $(mA \cdot cm^{-2})$. That is to mean there exists an optimal current density point to realize a lowest hydrogen production cost. This current density value is 850 to 1300 $(mA \cdot cm^{-2})$. This

phenomenon could be ascribed to the higher electricity consumption at exorbitant current density. At the same time, the hydrogen production cost reduces rapidly at comparably lower current density of 400 to 600 ($mA \cdot cm^{-2}$), while it decreases slowly at higher current density of 700 to 1400 ($mA \cdot cm^{-2}$).

Sensitivity of hydrogen production cost reduction

As shown in Fig. 2(c), critical impactors including reduction in voltage, ohmic loss and electricity cost, increasement in stack lifetime are given simultaneously to consider the hydrogen production cost reduction degree. Among these factors, electricity cost shows as priority to others as the current density increases. Voltage takes the second place. The prolong of stack lifetime makes a positive reduction in hydrogen production cost at low current density but causes a slight increasement in hydrogen production at extra-high current density.

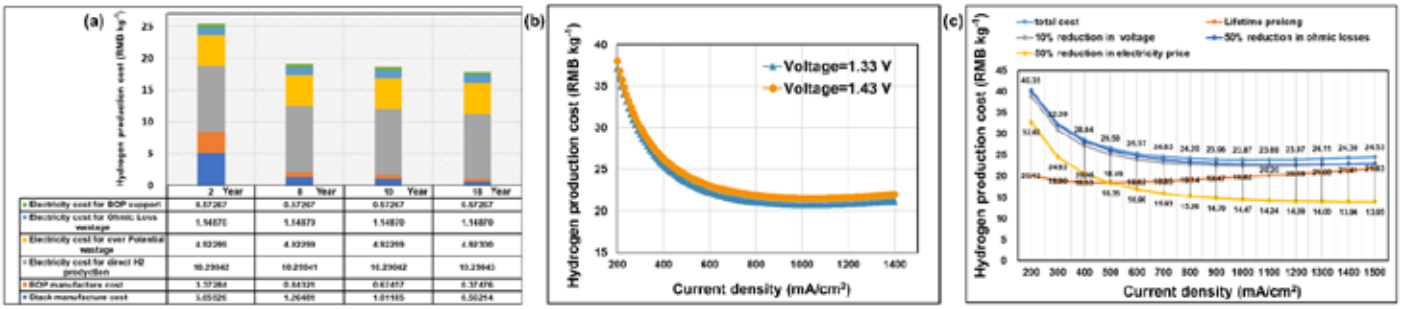

Fig. 2. (a) Hydrogen production cost division; (b) Hydrogen production cost reduction tendency under current density and voltage variation; (c) Sensitivity of hydrogen production cost reduction.

CONCLUSIONS

In summary, a techno-economic analysis of hydrogen production cost is investigated according to the critical technology character of anion exchange membrane at multiple dimensions. The hydrogen production cost division is given firstly to oversee the reduction tendency as electrolyzer lifetime prolongs. Subsequently, the influence of voltage and current density are discussed on hydrogen production cost, showing an optimal current density point for the lowest hydrogen production cost and significant hydrogen production cost triggered by a slight voltage decline. Sensitivity analysis reveals the electricity price as predominated factor and voltage reduction as secondary factor for hydrogen production cost reduction.

ABSTRACT

The catalytic activity of $Ce_{0.6}Mn_{0.3}Fe_{0.1}O_{2-\delta}$ (CMF) for electrode reaction was reasonably high for SOFC anode application. In this study, we investigated the characteristic and electrochemical performance of CMF for solid oxide fuel cell (SOFC) anode in comparison with that of the conventional Ni-based anode. CMF anode powder was prepared by citric acid-EDTA complexing method with a fluorite structure and single phase, which was confirmed by XRD analysis. The average size of primary particle is about 200 nm, which was observed by SEM, and it sintered and aggregated to large secondary particle after calcination at 1000°C. The secondary particle size distribution, which was analysed by Dynamic Light Scattering (DLS), is in the range of 10-95 μm with D_{50} particle size of 27 μm.

Keywords: Solid oxide fuel cells (SOFC), Anode, Sol-Gel Method, Fluorite structure

INTRODUCTION

Solid oxide fuel cells (SOFCs) are the electrochemical conversion devices which generally operated at high temperatures. SOFC is a solid-state electrochemical device that converts the chemical energy into electrical energy. In comparison with other types of fuel cells, SOFC has high efficiency exceeding 80% when included the heat produced as a result of the conversion.
SOFCs includes three major components, i.e., anode and cathode two porous electrodes, and a dense solid oxygen ion conducting electrolyte membrane which separates the fuel and air compartments.
The operating principle of solid oxide fuel (Figure.1. [1])
(a) Cathode: the reduction reaction reduces oxygen to oxygen ions
(b) Electrolyte: transports oxygen ions to the anode
(c) Anode: Oxidizes hydrogen into water and releases electrons to provide electricity for the external circuit
The structure of the anode should exhibit good electronic conductivity and hydrogen catalysis ability, as well as chemical stability under reduction atmosphere.

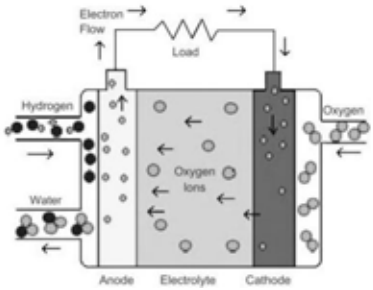

Fig.1. Operating principle of solid oxide fuel cell [1].

Ni-YSZ cermet has been generally used for the anode in SOFCs. However, Ni has the agglomerate problem on long-term operation at high temperatures, resulting in the degradation of anode performance. In order to solve these problems, many kinds of materials have been examined as replacements for Ni-YSZ. Additionally, these metal oxides, it is a mixed ionic-electronic conductor with high tolerance for coke deposition and high catalytic activity in the oxidation of fuels, such as ceria (CeO_2) has been an enhancing choice for anode materials. The catalytic activity of CMF for electrode reaction was reasonably high for SOFC anode application [2]. In this study, we further investigated the performance of CMF for SOFC anode in comparison with the property of the traditional Ni-based anode.

MATERIALS AND METHODS

$Ce_{0.6}Mn_{0.3}Fe_{0.1}O_{2-\delta}$(CMF) powder was prepared by citric acid-EDTA complexing method, $Ce(NO_3)_3 \cdot 6H_2O$, $Mn(NO_3)_2 \cdot 6H_2O$, $Fe(NO_3)_3 \cdot 9H_2O$ nitrate is dissolved in deionized water, EDTA metal chelate is dissolved in ammonia water, then two cups of solution are mixed, and citric acid is added to adjust the pH value to 6. The nitrate solution is under constant stirring, the solution will be configured on the heating stirrer, heated and stirred, and evaporated to dryness to a thick black gel, then put it into a high-temperature furnace and heat treatment at 250 °C for 2 hours to remove nitric acid, ammonia water with moisture. The heat-treated powder was ground in an agate mortar and sieved through a 200 mesh screen, and then calcined at 1100°C for 6 hours. The calcined powder is ground again in an agate mortar and sieved with a 200mesh sieve to obtain CMF powder. CMF powder process is shown in Figure.2.

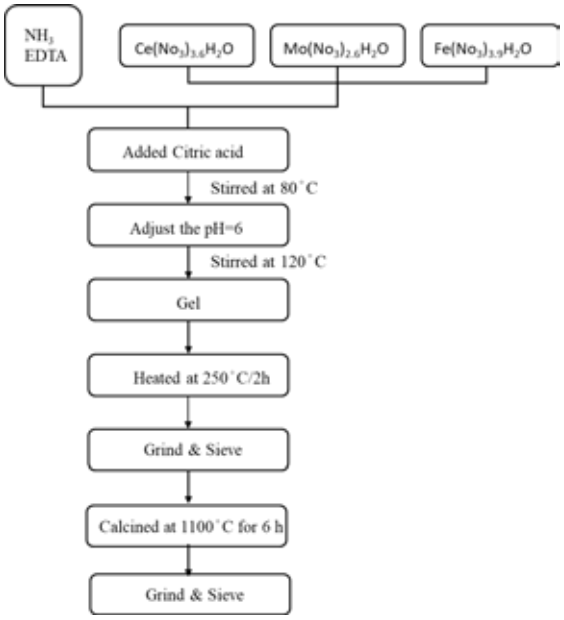

Fig. 2. The experiment procedure of CMF powders synthesis by the citric acid-EDTA complexing method.

RESULTS AND DISCUSSION

The X-ray diffraction (XRD) pattern of the CMF calcined at 1100°C for 6 hours was conducted as shown in Fig. 3. The pattern displays the peaks in agreement with the fluorite structure. There is no second phase was observed. This result indicated that the single phase of CMF powder with fluorite structure was successfully prepared by the citric acid-EDTA complexing method. The surface morphology and particle size of the CMF powder was observed by field-emission scanning electron microscope (FE-SEM) which was shown in Fig. 4. The SEM image shows that the average size of primary particle is about 200 nm, and it sintered and aggregated to large secondary particle after calcination at 1000°C. The secondary particle size distribution was analysed by Dynamic Light Scattering (DLS) which was shown in Fig. 5. The particle size distribution is in the range of 10-95 μm with D_{50} particle size of 27 μm.

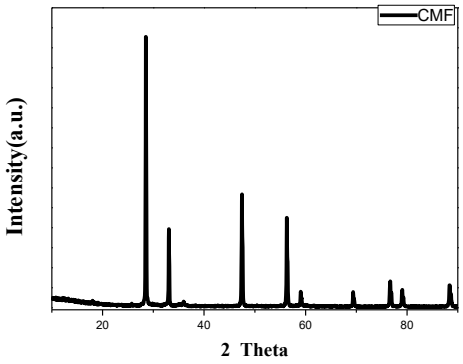

Fig. 3. The X-ray diffraction (XRD) pattern of the CMF powder calcined at 1100°C for 6 hours.

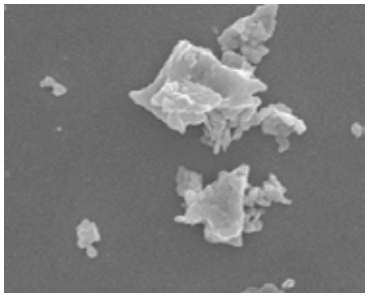

Fig. 4. The SEM image of the CMF powder calcined at 1100°C for 6 hours.

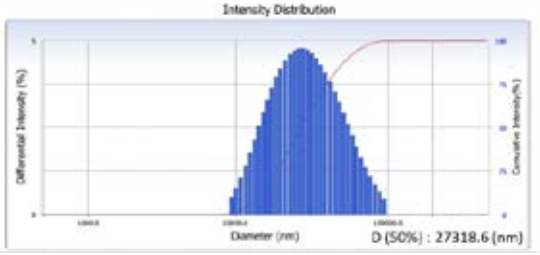

Fig. 5. The secondary particle size distribution of the CMF powder calcined at 1100°C for 6 hours.

CONCLUSIONS

In this experiment, single phase of CMF powder with fluorite structure was successfully prepared by the citric acid-EDTA complexing method. The primary particle is about 200 nm, and aggregated to large secondary particle with D50 particle size of 27 μm after calcination at 1000°C. The electrochemical performance of CMF based on SDC electrolyte will be investigated in the future.

ABSTRACT

In this study, the iron-based oxygen carrier was used for the syngas production via chemical looping dry reforming of methane (CL-DRM). The effect of the content of F_2O_3 supported by Al_2O_3 on the reduction stage during the CL-DRM was examined for various reaction temperatures was experimentally studied. It was found that higher Fe_2O_3 content and reaction temperature were required to obtain high CH_4 and CO_2 conversions and avoid carbon deposition. The experimental results indicated that 100% CH_4 and CO_2 conversion can be obtained from 30wt% Fe_2O_3 oxygen carrier and reaction temperature of 1000°C. At lower Fe_2O_3 contents and temperatures, Fe_2O_3 has low reactivity and high carbon deposition leading to poor CL-DRM performance. The experimental results also indicated that iron-based oxygen carrier was suitable for reducing CO_2 into CO and carbon.

Keywords: Iron-based oxygen carrier, Syngas, Chemical looping dry reforming of methane (CL-DRM), CH_4 and CO_2 conversions

INTRODUCTION

As a new energy conversion technology, chemical looping reforming (CLR) can be used to produce syngas with desired H_2/CO ratio [1]. In CLR, an oxygen carrier is used for oxygen supply instead of air. It consists of an air reactor and a fuel reactor. In the fuel reactor, the oxygen carrier is reduced by the introduced fuel. The reduced oxygen carrier is circulated to the air reactor and re-oxidized with the injected air.

The oxygen carrier is one of the key components in CLR. Iron, nickel, copper, and manganese are the most promising oxygen carriers. As compared with others, the iron-based oxygen carriers are considered to have industrial application potential because of their low price, high reactive, high mechanical strength, and being environmentally-friendly. Many iron ores can be directly used as oxygen carriers after simple treatments. Meanwhile, environmental impact must be considered due to the increasing standards of the environmental protection. Iron has been considered to be a safe material as compared with other materials [2].

In addition to natural iron ore, iron-based oxygen can also be synthesized in the laboratory [3]. In this case, the Fe_2O_3 supported by Al_2O_3 is the most frequently used oxygen carrier. Although CLR using Fe_2O_3/Al_2O_3 as oxygen carriers have been studied extensively, systematic investigation on the weight percentage of Fe_2O_3 on the CLR performance was not reported. This study intended to examine this issue in detail via chemical looping dry reforming of methane (CL-DRM).

EXPERIMENTAL

The CLR was carried out using a conventional packed-bed tubular reactor operated at atmospheric pressure. A quartz tube with an inside diameter of 9 mm was used as the reactor. The oxygen carrier was loaded in the central section with the two ends fixed using quartz wool. The reactor is placed vertically in a temperature controllable electric furnace. A gas mixture of CH_4, CO_2, and N_2 was used as the reactant. The flow rate of each gas species was metered and regulated using mass flow controllers (Brooks 5850E, USA). In the reactant, N_2 was an inert gas and its volume flow rate was used as the basis for evaluating the flow rate of gas species in the product. After removing water using a condenser, the dried gas product was collected and analyzed using gas chromatography (Agilent 7890B, USA).

RESULTS AND DISCUSSION

The reaction temperature, reactant feed rate, reactant composition, oxygen carrier loading, and reaction time are the important factors that affect the CLR performance. In CLR, the chemical reactions involved in the reduction stage are more complicated than those in the oxidation stage. In this study, the reduction stage performance was studied in detail before carrying out the complete cyclic chemical looping processes. The reaction temperature and content of Fe_2O_3 were chosen as the primary parameters to examine the reduction reaction performance under fixed feed conditions and catalyst loading. The total feed rate of the reactant was a mixture of 15 sccm CH_4, 15 sccm CO_2, and 20 sccm N_2. The oxygen carrier loading was 2.5 grams.

Fig. 1 shows the reduction stage performance of CL-DRM using oxygen carriers with various Fe_2O_3 weight percentages for reaction temperature T=800°C. The reaction temperature is initially at room temperature and then gradually increases with the test time. At t=135 minutes, the reaction temperature reaches the designated reaction temperature and then keeps at this temperature beyond 135 minutes. Using 15wt%Fe_2O_3 as an example, the general variation trends of the gas species in the product as a function of test time are described as follows. During the heating period, the CH_4 conversion is almost zero as shown in Fig. 1(a) and negative CO_2 conversion due to CO_2 formation due to CH_4 oxidized by Fe_2O_3 can be found as shown in Fig. 1(b). For t=135 ~ 210 minutes, an abrupt increase in CH_4 and CO_2 conversions can be found indicating that Fe_2O_3 is reduced to Fe_3O_4. For test time is beyond 210 minutes, both CH_4 and CO_2 conversions decrease from maximum values. The decreases in CH_4 and CO_2 conversions may be caused by the deactivation of oxygen carrier due to carbon deposition. From Fig.1, Fe_3O_4 shows low reactivity with CH_4 and high reactivity with CO_2. For T=800°C, Fe_2O_3 content produces an insignificant difference in the reduction stage performance.

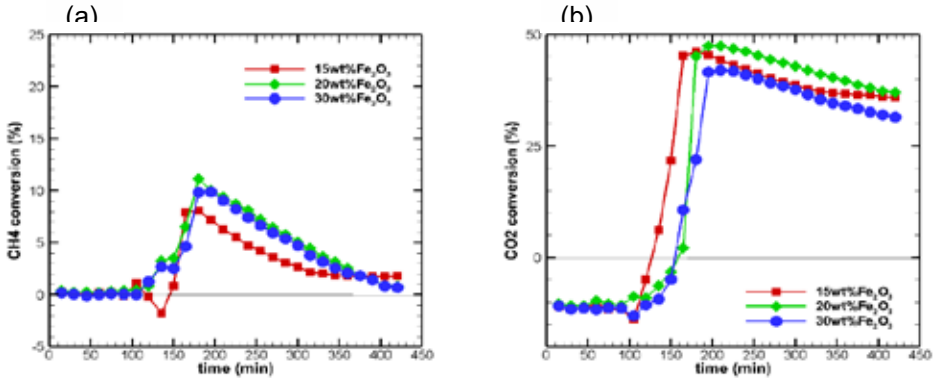

Fig. 1 Performance of reduction stage during CL-DRM for various Fe_2O_3 weight percentages. T=800°C. (a) CH_4 conversion, and (b) CO_2 conversion.

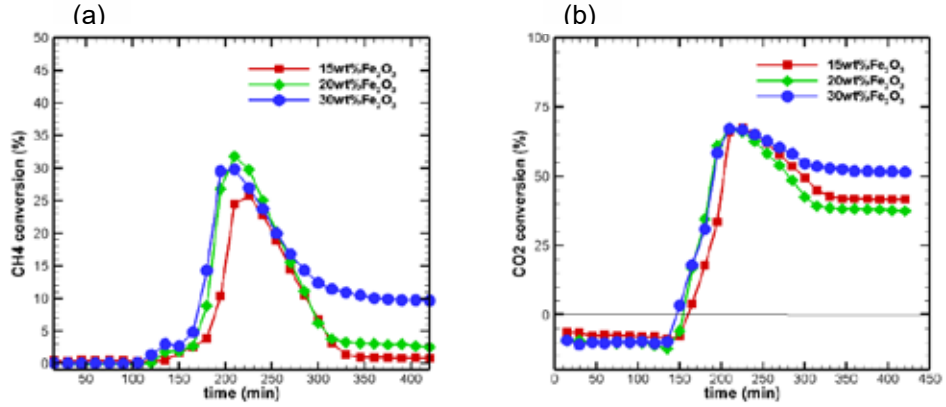

Fig. 2 Performance of reduction stage during CL-DRM for various Fe_2O_3 weight percentages. T=900°C. (a) CH_4 conversion, and (b) CO_2 conversion.

The reduction stage performance during CL-DRM for the T=900°C case is shown in Fig. 2. As compared with the T=800°C case, similar variation trends of CH_4 and CO_2 conversions were found. With increased reaction temperature, catalytic activity was enhanced and higher CH_4 and CO_2 conversions can be obtained. The carbon deposition also causes catalyst activity loss. Because the reactant flow rate has a fixed value, it is then expected that the carbon deposition becomes saturated as the test time increases further. Therefore, stable CH_4 and CO_2 were obtained time is beyond 300 minutes as shown in Fig. 2(a) and 2(b), respectively. Fig. 2 also shows that higher Fe_2O_3 content can enhance the reduction stage performance.

The same experiment was carried out except that reaction temperature is increased to T=1000°C. For the 15wt%Fe_2O_3 and 20wt%Fe_2O_3 cases, Fig. 3(a) and 3(b) show that the variation trends of CH_4 and CO_2 conversions are similar to those for the T=900°C case except that higher conversions can be obtained due to increased reaction temperature. For the 30wt%Fe_2O_3 case, almost 100% CH_4 and CO_2 conversions can be obtained. As a result, the H_2 and CO yields approaching to the theoretical limits were obtained as shown in Fig. 3(c) and 3(d), respectively.

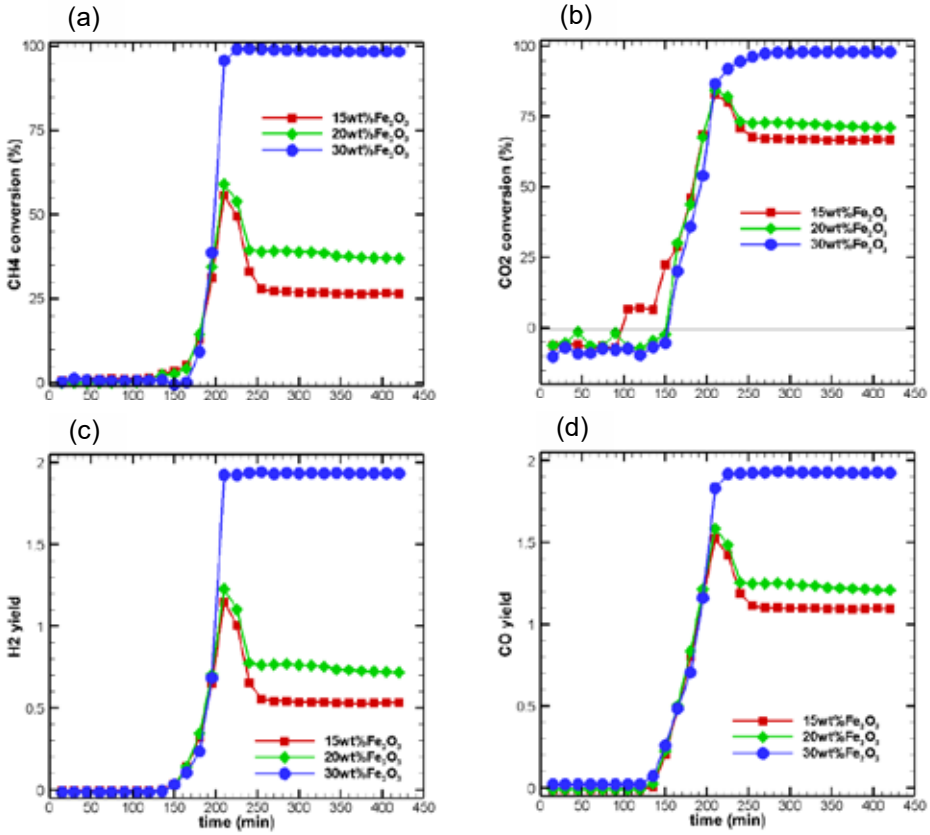

Fig. 3 Performance of reduction stage during CL-DRM for various Fe_2O_3 weight percentages. T=1000°C. (a) CH_4 conversion, (b) CO_2 conversion, (c) H_2 yield, and (d) CO yield.

CONCLUSIONS

As compared with nickel-based oxygen carrier, iron-based oxygen carrier has a lower reactivity for the reduction stage in CL-DRM. A higher reaction temperature is required to obtain the comparable CH_4 and CO_2 conversions. The study indicated that the Fe_2O_3 weight percentage should be high enough to obtain high CH_4 and CO_2 conversions. It was also found that iron-based oxygen carrier is suitable for reducing CO_2 into CO. Future studies on the examining the performance using lowering reaction temperature and higher Fe_2O_3 content are to be carried out.

ABSTRACT

The road transport sector is in need of new technologies to help it emit less greenhouse gases, as the world's emissions should be halved before 2030 and ultimately be part of a net-zero society. To that goal, hydrogen is envisioned to be used as the fuel powering road vehicles, in particular for heavy duty (HD) applications. To achieve the replacement of the current fossil fuel vehicle fleet, a network of hydrogen refueling stations (HRS) should be installed, with the ability to provide safe and rapid fillings to ensure the widest adoption of this clean technology worldwide. The FCH JU project PRHYDE aims to develop a dedicated HD refueling protocol for type III and IV tanks with 350, 500 and 700 bar nominal working pressures (NWP). For this purpose, the SOFIL code, modeling the physical variables in the tanks during filling, is used in the frame of the project. The current paper compares SOFIL to experimental data for HD type IV tanks.

Keywords: Heavy duty, Hydrogen, Refueling, Protocol, Modeling

INTRODUCTION

Greenhouse gas emissions should be lowered in the next decade to help meet the emission targets. This can only be achieved, for the transport sector, with hydrogen as energy carrier, combined with fuel cells. To achieve mass adoption of this new technology, it needs to be safe, affordable and easy-to-use. This is the goal of refueling protocols, standardizing the process across different companies, systems and geographies. Existing LD (Light Duty) refueling protocols, such as the SAE J2601, provide table-based process requirements to ensure a safe filling. The PRHYDE project [1-3] is dedicated to help developing a HD (Heavy Duty) hydrogen refueling protocol. For this purpose, modeling tools, estimating the gas temperature and pressure evolution during fillings, are essential. In particular, SOFIL [4, 5] by Air Liquide and Hyfill by Engie, 0D-gas/1D-wall modeling software, are used in HD protocol development in PRHYDE. This paper is dedicated to their validation in real conditions.
Two different type IV tanks have been used for experimental validation. A first tank, with a volume of 165 L, will be used by Nikola in their vehicles, and was therefore tested in a variety of experimental conditions. The second tank, with a volume of 240 L, has been chosen by Toyota for their vehicles, and was tested by ZBT in different conditions.

RESULTS AND DISCUSSION

The first tank, 165 L type IV tank, was used for experimental testing. A thermocouple tree was placed inside the tank to measure the gas temperature at several locations, denoted as 'TinX' as shown in Figure 1. Thermocouples were also applied to the exterior of the tank, denoted as 'TsX'. The OTV (On Tank Valve) gas temperature is denoted as 'Totv', and the tank pressure 'Ptank' was recorded at the tank. Table 1 shows the different test conditions that have been run with the 165L type IV tank. Figure 2 shows the evolution of gas temperature and pressure in the first test case with the 165 L tank.

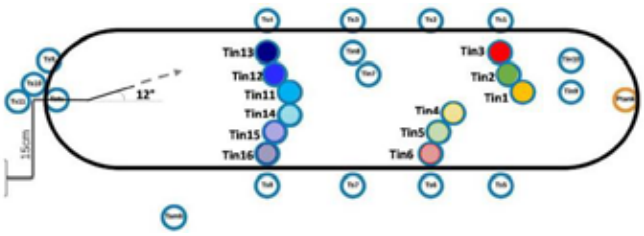

Fig. 1. Locations of thermocouples inside the 165L type IV tank during the testing.

Table 1. List of all tests for the 165L type IV tank.

Test number	Characteristics
#1 (ref)	Initial pressure 2 MPa. Ambient temperature 15 °C. Dispenser temperature -40 °C. Constant pressure ramp rate 8 MPa/min.
#2	Same as #1, but changing ambient temperature to 50 °C.
#3	Same as #1, but changing ambient temperature to 40 °C.
#4	Same as #1, but changing ambient temperature to -30 °C.
#5	Same as #1, but changing ambient temperature to -15 °C.
#6	Same as #1, but changing ambient temperature to 0 °C.
#7	Same as #1, but changing dispenser temperature to -33 °C.
#8	Same as #1, but changing dispenser temperature to -26 °C.
#9	Same as #1, but changing dispenser temperature to -17.5 °C.
#10	Same as #1, but changing initial pressure to 5 MPa.
#11	Same as #1, but changing initial pressure to 25 MPa.
#12	Same as #1, but changing the constant pressure ramp rate to 5 MPa/min.
#13	Same as #1, but changing the constant pressure ramp rate to 16 MPa/min.
#14	Same as #1, but changing the constant pressure ramp rate to 20 MPa/min.
#15	Same as #1, but changing the pressure ramp rate to 20 MPa/min for 3.85 minutes, then 1 MPa/min.
#16	Same as #1, but changing the pressure ramp rate to 20 MPa/min for 3.85 minutes, then 3 MPa/min.
#17	Same as #1, but changing the pressure ramp rate to 20 MPa/min for 3.33 minutes, then 1 MPa/min with pulse of 8 MPa/min for 10 seconds every 30 seconds.
#18	Same as #1, but changing ambient temperature to 40 °C and dispenser temperature to -17.5 °C.

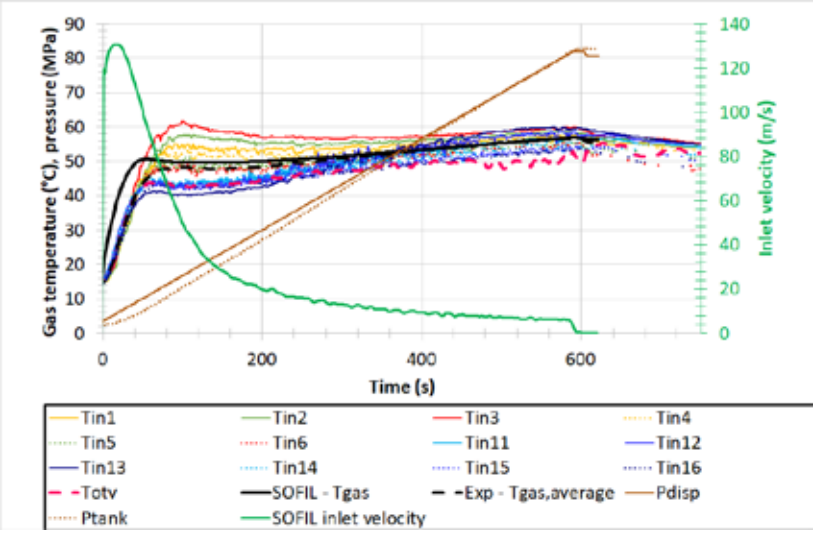

Fig. 2. Comparison of SOFIL model prediction with experimental data from 165 L tank testing. Case #1: Initial pressure 2 MPa, ambient temperature 15 °C, dispenser temperature set point -40 °C, pressure ramp rate 8 MPa/min, with a 165 L type IV tank.

The second tank is also a type IV tank, with a 240 L volume. Another thermocouple tree was placed inside to measure the gas temperature at several locations, as shown in Figure 3. Similar to the first set of tests, for the 240 L tank the tests varied the dispenser temperature (from -40 °C to ambient) and the pressure ramp rate (from 1 MPa/min to 16 MPa/min). Figure 4 shows the evolution of gas temperature and pressure in the reference test case with the 240 L tank.

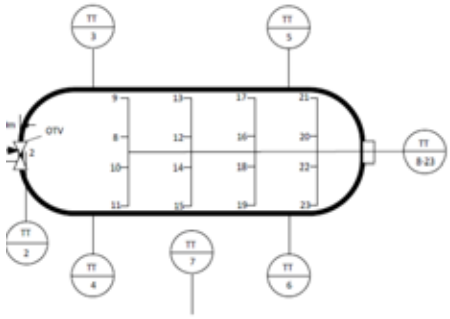

Fig. 3. Locations of thermocouples inside the 240 L type IV tank for testing.

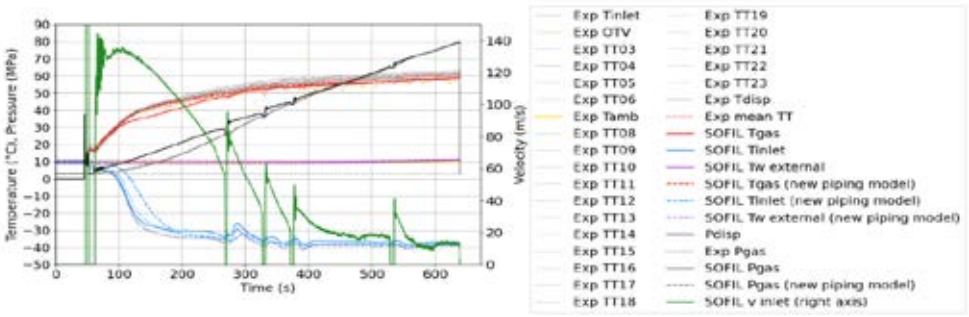

Fig. 4. Comparison of SOFIL model prediction with experimental data from 240 L tank testing. Initial pressure 2 MPa, ambient temperature 10 °C, dispenser temperature set point -40 °C, pressure ramp rate 8 MPa/min, with a 240 L type IV tank.

CONCLUSIONS

The modeling software used in the project is able to correctly estimate the gas temperature during the fillings. The validated software will be used to look into dynamic methods for the HD protocol.

ACKNOWLEDGEMENT

ABSTRACT

During a hydrogen tank filling, high temperatures can be generated inside the vessel with a vertical or/and horizontal thermal stratification that can potentially further increase the temperature of the gas and the tank wall. European funded project PRHYDE study this phenomena as it can have an influence on the choice made during refueling protocol development. CFD tools can help predict this thermal stratification within the tank by providing complete and detailed 3D information on the flow characteristics and temperature distribution. The eddy viscosity turbulence model (Boussinesq hypothesis) approach is most often used since it gives the best compromise between the number of grid cells and equation solving time. This hypothesis is reasonable for turbulent shear flows without big curvature and swirl. These models show their limitations when the anisotropy of the turbulence significantly affects the mean flow. This paper compares several turbulence models (Eddy viscosity and RSM model) for the case of hydrogen tank filling with a turbulent tilted impinging jet and compare simulation results with experimental results generated in the European funded project PRHYDE.

Keywords: Hydrogen storage, Tank filling, Turbulence model, Impinging jet, Stratification

INTRODUCTION

In a context of global awareness of environmental issues, a revolution in production methods is challenging the current operation of the conventional energy system. Hydrogen is widely seen as an energy carrier that could help to overcome issues such as greenhouse gas emission, air pollution and safe energy supply. Compressed hydrogen is the technology of choice for on-board storage in hydrogen vehicles in the automotive industry. Due to the low density of hydrogen at atmospheric conditions, high pressures are required inside the fuel tanks to achieve a range comparable to conventional vehicles. The large pressure increases during refuelling, the gas temperatures inside the tank increase inside the vessel with possible stratification phenomena that can locally increase the high temperature areas. The maximum allowed temperature of 85°C inside the composite tank walls is specified by the international standards.

MATERIALS AND METHODS

In the frame of the FCH JU funded project (PRHYDE), aiming at defining a hydrogen tank filling protocol, a series of experimental tests was performed on several type IV tanks with various filling conditions. The tanks were instrumented with thermocouples trees monitoring the temperature evolution of the gas inside the tank. Some experimental cases presented new physical results, which are difficult to explain, such as horizontal stratification. These cases have been used for the 3D numerical simulation modeling. The 3D computational domain consists of two subdomains: one for the fluid part (hydrogen) and another for the thermal transfer with the solid (tank material). This type of 3D simulation solves Navier-Stokes equations. Real gas model (NIST tables) is essential for the pressure range considered in the experiments. The solved equations are of the form:

$$\frac{\partial}{\partial t}\int_V \rho\Phi dV + \int_A \rho\Phi V dA = \int_A \Gamma_\Phi \nabla\Phi . dA + \int_V S_\Phi dV \qquad (1)$$

instationnaire | Convection | Diffusion | Generation

After decomposing the velocity into mean and instantaneous parts, the transient Navier-Stokes equations can be rewritten as the Reynolds-Averaged Navier-Stokes (RANS) equations with the Reynolds stress tensor as additional unknowns:

$$\left(\rho\frac{\partial \bar{u}_i}{\partial t} + \bar{u}_k\frac{\partial \bar{u}_i}{\partial x_k}\right) = -\frac{\partial \bar{P}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu\frac{\partial \bar{u}_i}{\partial x_j}\right) + \frac{\partial R_{ij}}{\partial x_j} \qquad (2)$$

Reynolds stress tensor

Previous work ([4],[5],[6],[7]) used k-epsilon or k-omega SST and SAS turbulence models (Boussinesq hypothesis). Several publications ([1],[2],[3]) have demonstrated the limitations of models that use Boussinesq hypothesis when anisotropy of turbulence significantly affects the mean flow. This type of limitation can be reached in the case of an impacting jet on concave surfaces, which is the case when the injector is not aligned with the tank.

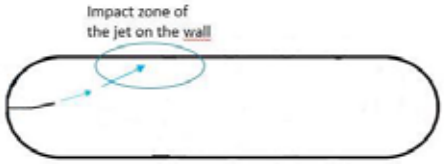

Fig. 1 Illustration of an impinging oblique jet on the tank wall during the filling stage.

To overcome this issue the RSM (Reynolds Stress Model) turbulence model could be used. A crucial step for the application of numerical modelling is the validation of the model against the corresponding experimental measurements. Several numerical simulations were performed to get a qualitative and quantitative comparison of several turbulence models available in ANSYS Fluent and more specifically to compare RSM and Boussinesq turbulence models (like k-epsilon) and SAS. Mass conservation has been verified for all simulations.

RESULTS AND DISCUSSION

Experimental results in the selected cases show horizontal stratification, probably due to a recirculation of the cold jet at the front of the tank and a local overheating at the back due to a limited propagation of the cold jet at the rear of the tank (fig 2).

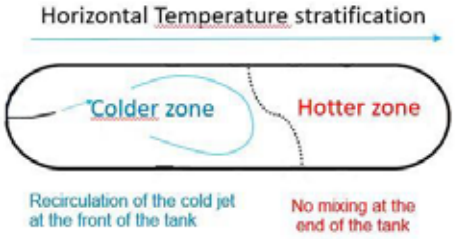

Fig. 2 Diagram of the fluid behaviour observed experimentally

With k-epsilon model, the flow does not behave as in the experiment: no horizontal temperature stratification is numerically observed. As shown on the figure below (fig. 3), the model only predicts vertical temperature stratification.

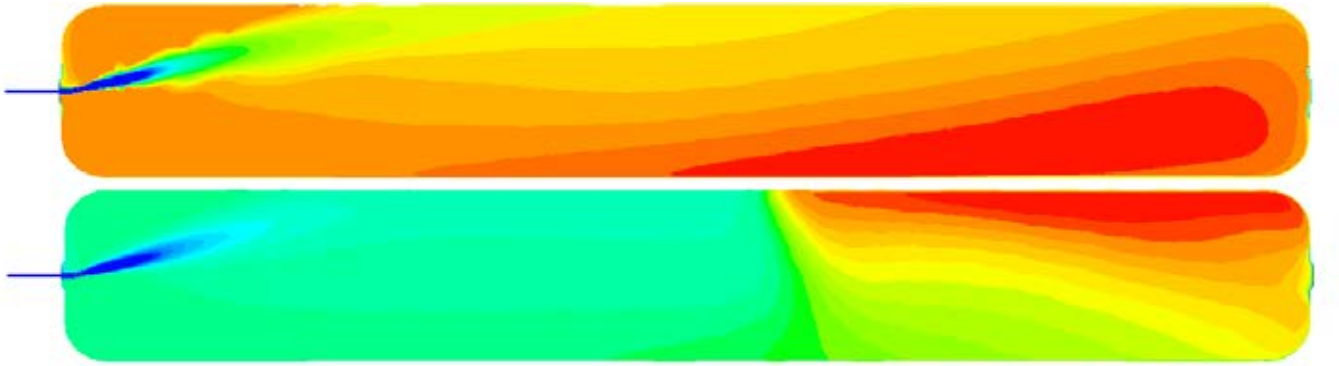

Fig. 3 Temperature field found using k-epsilon model (top frame) and RSM model (bottom frame) for the same time

The results of the two turbulence models show completely different temperature fields. The RSM model clearly demonstrates a horizontal stratification. In order to verify the jet recirculation hypothesis, we have analyzed the

velocity fields of both simulations. Comparisons with experimental measurements have also been performed. They show that the RSM model is better adapted for the impacting jets.

CONCLUSIONS

The impact of the jet on the tank wall is a complicated phenomenon to solve numerically. It shows the limit of Eddy viscosity turbulence models. In order to keep horizontal stratification, RSM turbulence model has been tested and allows highlighting this horizontal thermal stratification.

ABSTRACT

In this study, the formability of the metallic bipolar plates for PEMFCs were studied via DYNAFORM software and LS-DYNA and the performance and the electrochemical impedance the air-breathing PEMFC with the stamped metallic bipolar plates were tested analyzed. The simulation results show that the optimum stamping parameters for the SS316L are the flow channel depth of 0.8 mm, punch and die radius of 0.4 mm, stamping speed of 250 mm/s, blank thickness of 0.2 mm and the binder pressure of 200 kN. The maximum error between the real stamped flow channel depth and the target depth is 12.8%. With the stamped SS316L bipolar plate, which has an active area of 150×54 mm^2, the air-breathing in this work has the maximum power density of 187.19 mW/cm^2 at an operating temperature of 45°C, a torque of 30 kgf-cm, a hydrogen stoichiometric ratio of 1.5 and a relative humidity of 100%.

Keywords: Proton exchange membrane fuel cell, Stainless steel bipolar plate, Stamping fabrication process, Performance test

INTRODUCTION

In recent years, due to the extensive use of fossil energy, the greenhouse effect and air pollution caused by burning the fossil fuels become more and more serious. Thus, the development of non-polluting energy becomes inevitable. The fuel cell is considered an option for the non-polluting energy technology because of its zero pollution. Proton exchange membrane fuel cells have the advantages of rapid start, low operating temperature, low noise, low pollution level and high efficiency. Thus, it is a good candidate for future transportation or portable energy sources and it is one of the most fully developed fuel cell type. To reduce the cost of PEMFCs, developing metallic bipolar plate becomes a trend, because replacing traditional graphite bipolar plate by metallic bipolar plates can significantly reduce the material and fabrication cost the bipolar plates. Among all kinds of metal, stainless steel is the most common material for bipolar plates [1-3]. As a result, the formability of the SS316L bipolar plate is the focal subject. To verify the performance of the PEMFC with metallic bipolar plates, we as well assembled an air-breathing PEMFC with stamped SS316L bipolar plates and tested its performance.

RESEARCH METHODS

In the first part of study, the DYNAFORM software and LS-DYNA are used to study the effects of flow channel geometry and stamping parameter on the formability of the metallic bipolar plate. The forming limit, thinning ratio and springback of the bipolar plates under various conditions are analyzed to obtain the optimum design and process parameters. In addition, the simution results are verified by the measurement of the real forming depth of the flow channel on the stainless steel bipolar plates which are performed via scanning electron microscopy (SEM). In the second part of study, an air-breathing single cell with our stamped stainless steel bipolar plates is assembled and tested. The performance and practicability of the fuel cell is evaluated by the polarization curve and electrochemical impedance spectroscopy.

RESULTS AND DISCUSSION

The research results indicate that the optimal flow channel geometry and stamping parameters for the SS316L bipolar plate are the flow channel depth of 0.8 mm, the radiuses for punch and die of 0.4 mm, the stamping speed of 250 mm/s, the blank thickness of 0.2 mm and the binder force of 200 kN. Through the SEM observation, it is verified that the real sealant groove channel depths and the design sealant groove channel depths are slightly different. The maximal forming error is 13.6%, and the maximal difference of the sealant groove depths is 0.075 mm. In addition, the flow channel depth measurements indicates that the maximal forming error is 12.8%, and the maximal difference of the real and design flow channel depths is 0.103 mm. Moreover, the error between the simulated spring back value

and the experimental value without the binder is 3.67%. The comparison between simulation and experiments presents a good reliability of the simulation. The simulation results as well show that the formability of the bipolar plate is not good as the flow channel depth is too shallow or too deep, and the probability of wrinkle and crack may occur. When the radius of the die and punch is increased, the fluidity of the material increases and this leads to decreasing the thinning ratio and spring back of the bipolar plate (Fig. 1). When the stamping speed is lower than 250 mm/s, the bipolar plate is prone to wrinkle and crack. When the stamping speed increases from 250 mm/s to 10000 mm/s, the amount of spring back increases by about 31.4%. In addition, increasing the thickness of the blank causes a significant increase in the thinning ratio of the blank because the material fluidity becomes lower at elevated thickness. As the thickness is higher than a critical value, cracks may occur. Moreover, increasing the binder force effectively improves the spring back of the bipolar plate.

The air-breathing fuel cell with the stamped SS316L bipolar plates is assembled and tested. The experimental results show that the maximum power density is 187.19 mW/cm^2 with a forced air convection at an operating temperature of 45 ^{o}C, a clamping torque of 30 kgf-cm, a hydrogen stoichiometric ratio of 1.5 and a relative humidity of 100% (Fig. 2). Among all of the operating parameters, the clamping torque, operating temperature and the voltage of fan have greater influence on the performance of the air-breathing fuel cell than other parameters.

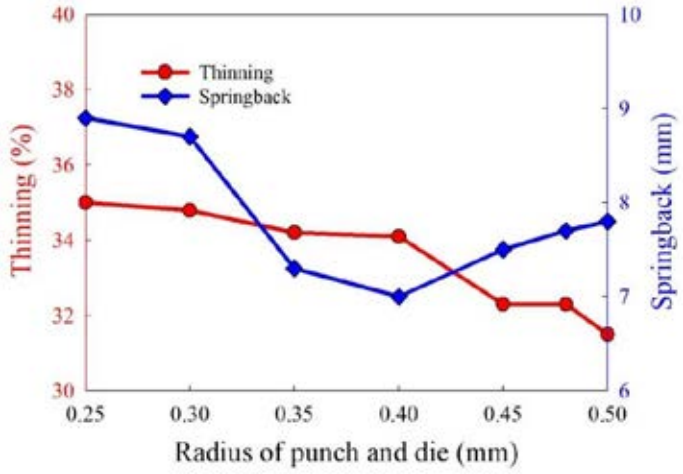

Figure 1 Effects of radius of punch and die on the spring back and thinning of the stamped SS316L bipolar plate

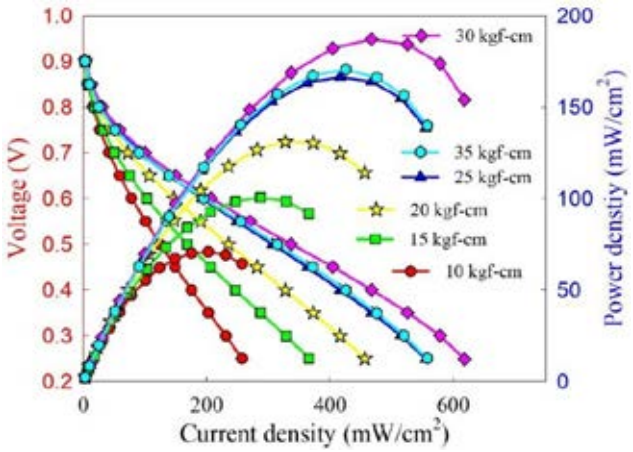

Figure 2 Effects of assembly torque on the PEMFC performance (T_{cell}=45℃，T_{d,H_2}=45℃，St_{H_2}=1.5，V_{fan}=15V)

CONCLUSIONS

An air-breathing single cell with the stamped SS316L bipolar plates of 150×54 mm^2 is successfully developed in this work. In this study, the results can be summarized into the following conclusions:

1. The peak power density of the air-breathing fuel cell with stamped SS316L bipolar plates is 187.19 mW/cm^2 at a cell voltage of 0.4 V with forced air convection at operating temperature of 45℃, torque of 30 kgf-cm, hydrogen stoichiometric ratio of 1.5 and relative humidity of 100%.
2. The simulation results show that when the channel depth increases, then the thinning ratio and springback both increase. When the radiuses of the die and punch increase, the fluidity of the material becomes smoother, leading

to decreasing the thinning ratio and springback of the bipolar plate. When the stamping speed increases, the springback of the bipolar plate increases. When the binder force increases, the springback is also improved effectively.

3. The simulation results show that the optimal flow channel geometry and stamping parameters for the stainless steel 316L bipolar plates are the flow channel depth of 0.8 mm, the radiuses for punch and die of 0.4 mm, the stamping speed of 250 mm/s, the blank thickness of 0.2 mm and the binder force of 200 kN.
4. For the bipolar plate formability, the maximal difference between the design depth of the flow channel and the measured flow depth on the stamped bipolar plate is 0.103 mm, which is equal to 12.8% of the design depth. The error between the simulated springback value and the experimental value without the binder is 3.67%.

ABSTRACT
The electrochemical performances of the solid oxide fuel cells (SOFCs) fabricated with Nd-doped LSCF (NLSCF) perovskite cathodes, thin BCZY electrolytes, and BCZY–Ni anodes by tape casting, spin coating, and co-firing are evaluated at 600–800 ℃. Material analysis, such as SEM, TEM, and XRD, confirmed that no detectable second phase remains in the NLSCF cathode, indicating that the calcined NLSCF nanopowders have good compatibility with the fabrication of anode-supported fuel cells in this study. It can be clearly seen that the NLSCF cathode is highly porous and adhered well to the BCZY electrolyte. Fuel cell testing with the NLSCF cathode exhibits a maximum power density of ~407.6 mW/cm^2 at 800 ℃, which is significantly higher than those of cells with a powder-derived LSCF cathode. The significantly lower polarization resistance elements extracted from electrochemical impedance spectroscopy (EIS) further suggested that the NLSCF cathode has superior catalytic activity for the oxygen reduction reaction and better oxygen ionic transport in the cathode reactions. The performance improvement of NLSCF cathode can be explained in terms of trade-off between electrocatalytic activity, oxygen ionic and electronic conductivity of the NLSCF. This study shows that NLSCF nanopowder would be a promising cathode material for proton-conducting SOFCs.

Keywords: Nd-doped LSCF, Nanopowder, Cathode, Oxygen reduction reaction, P-SOFC

INTRODUCTION

Solid oxide fuel cells (SOFCs) are electrochemical devices that can convert chemical energy directly into electricity and have attracted growing attention in recent years due to their superior efficiency to other energy conversion systems, fuel flexibility, use of non-precious metal/metal oxide catalysts, and low pollutant emissions [1]. All these advantages make SOFCs well suited for clean and distributed power generation [2]. In recent years, extensive efforts have been devoted to developing proton-conducting SOFCs (P-SOFCs) that operate in the low-to-intermediate temperature range (400 - 800 ℃). Compared to the conventional oxygen ion-conducting SOFCs (O-SOFCs) that require high operating temperature, this scheme enables more reliable sealing, use of cheaper materials for interconnect, and a better control of electrode/electrolyte interactions, thus prolonging the operational lifetime of SOFCs. One important factor in achieving high-efficiency P-SOFCs is to develop highly conductive proton-conducting electrolytes with sufficient chemical stability under operation condition. In addition, it is well known that oxygen reduction reaction (ORR) at the cathode is responsible for much of the loss in cell performance, especially when a thin electrolyte is used. The reduction in the cathode kinetics with decreasing fuel cell operation temperature could be more detrimental to the cell performance than the drop in the electrolyte conductivity. Therefore, an adequate material selection and microstructure optimization for the cathode are critical since the polarization resistance of the cathode could dominate the fuel cell performance. For O-SOFCs, relatively low cathode polarization in the intermediate temperature range could be achieved by using mixed ionic and electronic conductors (MIEC) such as LSCF, SSC, and PNO as cathode materials. However, simply applying the well-established cathode materials for O-SOFCs to P-SOFCs is insufficient because the cathode processes involved are not completely the same between O-SOFCs and P-SOFCs. Besides the elementary reaction steps occurring in the O-SOFC cathode, the proton migration and vapor formation also have to be considered in a P-SOFC cathode, both of which make the cathode kinetics more complex and bring about demands on purposely tailored cathode composition and microstructure. Hence, tailoring the cathode composition and microstructure to improve charge carrier transport, oxygen gas diffusion, and water removal is essential to achieving high-performance P-SOFCs [3]. In this research, the NLSCF nanopowder is used as the air electrode for PCFCs. The cell with Nd doped LSCF cathode can effectively promote the performance. The smaller cation radius of Nd^{3+} than that of La^{3+} causes a difference in the average A-site ion radii that has a relationship with lattice strain during oxygen hopping to oxygen vacancy.

MATERIALS AND METHODS

To characterize the electrochemical behavior of the NLSCF cathodes, anode-supported thin-BCZY-electrolyte single cells were fabricated and the process flow is illustrated in Fig. 1. Green cermet anode supports were prepared by tape casting and hydrostatic pressing. The slurry for tape casting was prepared by ball-milling BZCY, NiO, and starch

powders in a mixture of binder (polyvinyl butyral) and dispersant (toluene, alcohol, and menhaden fish oil). The height of the doctor's blade during tape casting was set to give 150-μm-thick green tapes. A stack of three BCZY-NiO-starch green tapes was uniaxially pressed at 5000 psi and then punched to produce 35-mm-diameter discs. The disc anode supports were then pre-sintered to attain sufficient mechanical rigidity required for the subsequent spin coating process. To form a stable colloidal electrolyte slurry for spin coating, BCZY powders were planetary-milled in a mixture of ethanol and polyvinylpyrrolidone (PVP). 50 wt% NiO nanometric powders were additionally added into the slurry for the deposition of anode functional layer (AFL). The AFL slurry and the electrolyte slurry were sequentially spin-coated over the pre-sintered anode support. The spin-coated substrate was then heat-treated at 1000 ℃ for 1 h to remove the organics. The electrolyte-coating processes were repeated twice to achieve the desired electrolyte thickness of ~8 μm. Finally, the half cells consisting of BCZY electrolyte, BCZY-NiO AFL, and BCZY-NiO anode support were co-sintered at 1500 ℃ for 10 h in ambient environment. LSCF, NLSCF, and NSCF nanopowders were separately mixed with the organic vehicle by using a high-speed homogenizer to obtain a homogeneous cathode ink. The ink was then screen-printed through a 200-mesh silk screen of 10 μm thickness. The sample was air-dried to remove bubbles. Afterwards, it was heat-treated at 1100 ℃ for 1h to obtain an NLSCF cathode via evaporation/pyrolysis of the organics and sintering between NLSCF particles.

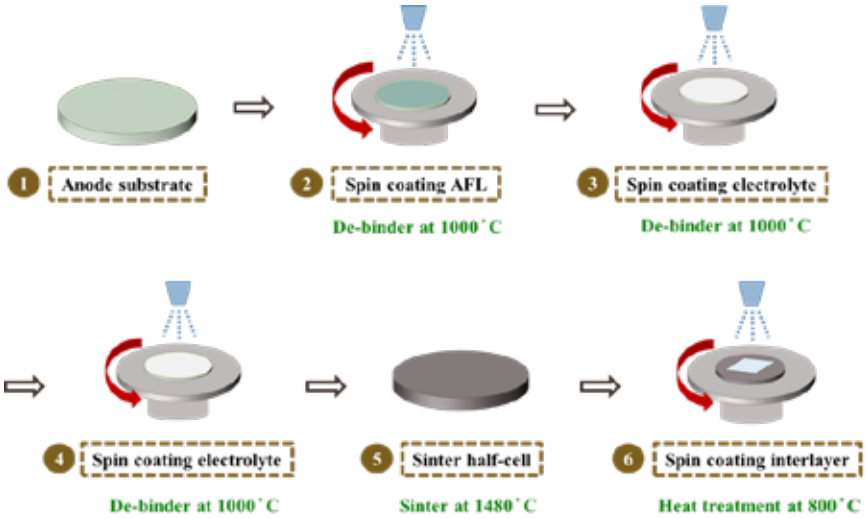

Fig. 1. The process flow anode-supported thin-BCZY-electrolyte single cells.

RESULTS AND DISCUSSION

Fig. 2 show the I-V and power density curves of the fuel cells with LSCF, NLSCF, and NSCF cathodes in the temperature range between 500 ℃ and 800 ℃. ALL cells exhibit open circuit voltages (OCVs) in the range of 0.98 to 1.0 V at 800 ℃, approaching the theoretical Nernst potential and indicating there is no obvious cracks in the thin electrolyte that could cause fuel or current leakage. In addition, no obvious change in the slope of the I-V curves at high current densities is observed, showing that no concentration polarization effect occurs in the electrodes. Furthermore, the cell with NLSCF cathode exhibits a peak power density of 407.6 mW/cm^2 at 800 ℃, which is higher than that of the cell with LSCF and NSCF cathodes. The short-term durability of the cell with NLSCF cathode is also investigated where the current density and power density were monitored as a function of time with a constant voltage of 0.7 V at 800 ℃. The cell power output was considerably stable during the short-term durability test.

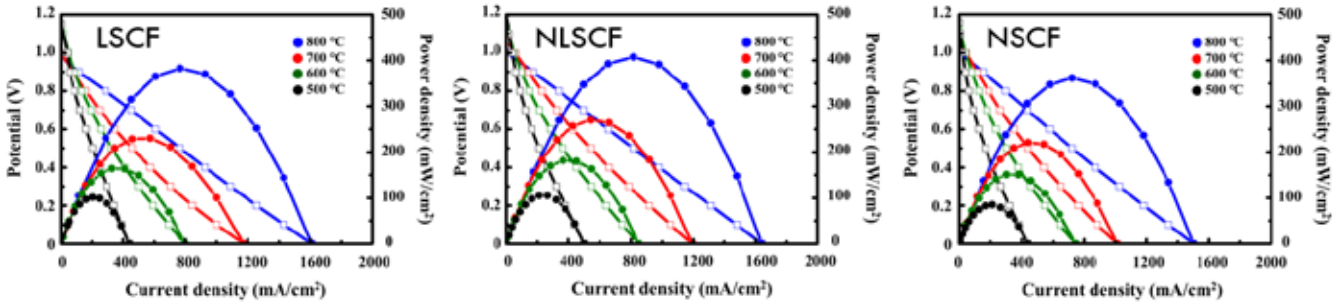

Fig. 2. I-V and power density curves of the fuel cells with LSCF, NLSCF, and NSCF cathodes at 500 - 800 ℃.

To reveal the underlying mechanisms for the greatly enhanced cathode performance and the dependence on added PS amount, electrochemical impedance spectroscopy (EIS) was performed on all these fuel cells at 800 ℃ under open circuit condition, and the results are shown in Fig. 3. The intercept with the real axis at high frequency represents the total ohmic resistance of the cell contributed from protonic resistances in the electrolyte and the anode, transfer of protons to TPBs, and electronic resistances in various fuel cell components. The difference between the high- and low-frequency intercepts on the real axis of impedance spectra gives the electrode polarization resistance. Since these fuel cells use the same BCZY-Ni anode and BCZY electrolyte, the difference in their polarization and ohmic resistances should come from their cathode properties. It is observed that the polarization resistance was improved as the NLSCF cathode was incorporated, which was also comparable to the numbers from similar electrode configurations in other studies. This improvement can be explained in terms of trade-off between electrocatalytic activity, oxygen ionic and electronic conductivity of the NLSCF.

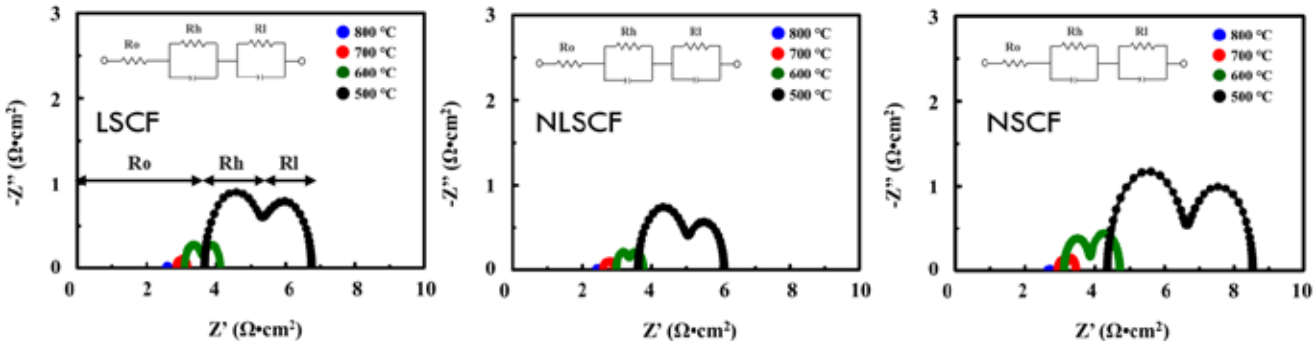

Fig. 3. Impedance spectra of fuel cells using LSCF, NLSCF, and NSCF cathodes at 800 ℃.

CONCLUSIONS

In this study, the NLSCF nanopowders were successfully used as the air electrode for PCFCs. The cell with Nd doped LSCF cathode can effectively improve the performance. The smaller cation radius of Nd^{3+} than that of La^{3+} causes a difference in the average A-site ion radii that has a relationship with lattice strain during oxygen hopping to oxygen vacancy. This improvement can be explained in terms of trade-off between electrocatalytic activity, oxygen ionic and electronic conductivity of the NLSCF.

ABSTRACT

Mobility is supported by transportation infrastructures based on energy networks to meet mobility demands. Transportation electrification enables mobility with more penetration of electric vehicles (EVs) and hydrogen-based fuel cell vehicles (HVs), besides internal combustion vehicles. The charging infrastructures should support mobility based on hybrid transportation technologies. The complex and expensive transition to transportation electrification infrastructures can be alleviated by implementing transactive mobility, which will provide cost management of different layers within the mobility services infrastructures. This paper presents an integrated framework for transactive mobility in view of hybrid charging infrastructures. The interface between transactive energy and charging infrastructures will be modeled and formulated by the transactive mobility model.

Keywords: Transactive mobility (TM), transactive energy (TE), hybrid charging stations (HCSs), hydrogen vehicle (HV), transportation electrification

INTRODUCTION

Transactive energy (TE) offers a marketplace for peer-to-peer energy trading and exchange. It is essential to identify the specified zone or portion of the energy distribution network that will be served [1]. The transactive energy approach will enable consumers and prosumers to benefit from collaboration. Transactive energy can also support the deployment of microgrids with an evaluation of energy costing in view of internal costs within each microgrid [2]. The evaluation of different scenarios and trade parameters and constraints are evaluated with simulation to examine options prior to actual execution [3]. The selection and evaluation of constraints to couple electricity and gas networks are also discussed to show balanced electricity and gas networks in normal and emergencies [4]. Transactive energy is applied to charging infrastructures with different configurations. Transactive energy is applied on charging of EV in buildings with local PV where cost framework is applied considering energy supply from the grid, local PV energy generation, and local energy storage [5]. Transactive energy is applied on PV-based EV charging in parking lots [6]. Scheduling of EV charging can be optimized based on a collaborative cost model using transactive energy [7]. Energy management should incorporate charging schedules based on cost models from the transactive energy framework [8]. There are several applications where energy trade is developed and implemented, such as simultaneous wireless information and power transfer (SWIPT) [9]. The trade mechanism is essential to achieve fair transactive energy, while reducing CO2 emissions in the energy production and supply chain [10]. Energy trade can be implemented across countries. In Europe, energy trade between different countries, such as Turkey, is presented to show negotiation mechanisms to ensure a satisfying energy supply [11]. Energy is coupled with water networks. The trade can be applied to the energy-water nexus, where coupling and value exchange is represented in the trade process [12]. Similar approach is applied on fuel hydrogen vehicles (HVs) with fuel cells [13].

The proposed hybrid transportation and charging infrastructure is shown in Fig. 1. The charging infrastructure includes local hydrogen generation and hydrogen supply infrastructure as integrated with hybrid energy system with renewable and storage energy technologies. The hybrid energy system in the charging station includes PV, wind turbine, fuel cell, nuclear reactor, and hybrid energy storage, including battery, flywheel, and ultra-capacitor. Trade agents are defined to allow bidirectional energy flow between EV/HV, charging station units, renewable energy resources, and the grid. Trade agents will manage negotiation between incoming electric vehicles, hydrogen vehicles, internal combustion vehicles, and the different components within the station and the supply chains. Energy cost models are defined and communicated among trade agents and each component to ensure fair and profitable to each unit and the corresponding investor. The cost model includes cost parameters for energy generation units, storage units, station facilities, and energy supply chains. Key parameters include levelized energy cost, and minimum and maximum price limits for each component and system. The investment model is proposed to allow multiple investors for each component in the charging infrastructure. The bidding process between incoming vehicles and charging units will be managed based on power transfer, energy flow, and cost parameters. Bidding requests will be received and analyzed to ensure profitable mobility with charging infrastructures.

Fig. 1. Hybrid Transportation and Charging Infrastructures for Transactive Mobility

Transactive energy is applied on charging station with local energy resources from renewable energy sources and energy storage. The concept of transactive energy and transactive charging must be coupled to ensure robust strategies for supplying energy from the grid, energy resources, and energy storage. The flow of energy and charging requests are shown in Fig. 1. EV-T is the trade agent for the incoming EV for charging. HV-T is the trade agent for hydrogen vehicle. CU-T is the trade agent for the charging unit for EV. HF-T is the agent for the hydrogen fueling unit. FC-T is the trade agent linked with the trade agent for fuel cell charging and discharging. PV-T is the trade agent for energy supplied by PV.

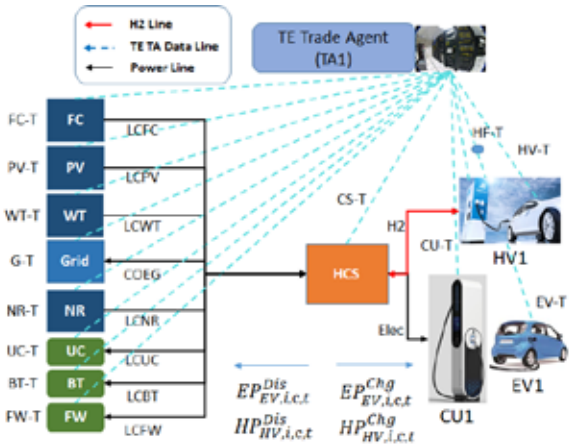

Fig. 2. Transactive Mobility Infrastructure

Similarly, WT-T is wind turbine trade, G-T is grid trade, NR-T is nuclear reactor trade, UC-T is ultra-capacitor trade, BT-T is battery trade, and FW-T is flywheel trade. The levelized energy costs are defined for each component. LCFW is the levelized cost of energy of FW. Similarly, LCBT is the levelized cost of the battery. LCUC is the levelized energy cost of the ultra-capacitor. LCNR is the levelized energy cost of the nuclear reactor. COEG is the cost of energy of the grid. LCWT is the levelized energy cost of wind turbine. LCPV is the levelized energy cost of PV. LCFC is the levelized energy cost of fuel cell.

CONCLUSIONS

This short paper presented a framework for transactive mobility to support hybrid transportation infrastructures with electric vehicles and hydrogen vehicles. Hybrid charging stations are designed based on local hydrogen generation with hybrid energy systems from renewables, small nucleal reactor, and the grid. The station can be implemented in different scales to support electrification of buses, trucks, marine, and railways. Transactive mobility trade agents are defined as supporting the bidding between incoming electric and hydrogen vehicles and the station while considering grid supply and the hydrogen supply chain. Cost models are based on lifecycle cost of each component in the charging station. The proposed transactive mobility model supports multi-investors for components to control profit operation of the charging infrastructures. The proposed transportation infrastructure supports different business models of shared

services, battery swaps, and V2G from EVs and HVs. Detailed research and solution are demonstrated in the extended publication.

ABSTRACT

In this study, different types of hydrogen transportation and delivery options have been evaluated comparatively. Various kinds of hydrogen transportation options including cryogenic tankers, tube trailers, ships, trains, novel transportation options, in addition to existing pipelines have been reviewed. Major findings such as cost-efficiency, technical and logistic challenges and problems, advantages and solutions of each option are outlined along with the further research and development needs.

Keywords: Hydrogen energy, Transportation, Hydrogen infrastructure, Hydrogen pipeline, Hydrogen delivery

INTRODUCTION

Hydrogen (H_2) is an odorless, colorless, light-weight, highly flammable, high permeable, small diatomic gas element that has a high gravimetric density of 120 MJ/kg, and low volumetric density of 0.0107 MJ/L compared to other types of fuels [1-3]. H_2 is the most abundant element in nature yet it cannot be found freely. It is available in different chemical compound for in other materials. H_2 is an emission-less energy carrier, but fossil-based production sources and technologies, and transportation of H_2 are causing high carbon emissions. As it is reported, 900 MT carbon dioxide (CO_2) emitted into the atmosphere to produce 90 MT H_2 solely in 2020 [4]. Luckily, there is a solution for producing clean/green hydrogen with zero emissions instead of grey hydrogen which generating hydrogen from fossil based resources. In green option, H_2 is produced from renewable sources through electrolyzing water molecules to its component H_2 and O_2 [5-7]. Therefore, solar, wind, and hydropower play a crucial role for producing green hydrogen. Nevertheless, this method of production is still at a high cost [2,4,8].

Another vital aspect of hydrogen energy is the transportation and delivery of H_2, and related infrastructure (such as power generation centers, fuel stations), from the production point to the end-use points [3]. Transportation of H_2, building new infrastructures, and installation of new equipment can impose extra costs to the final cost per unit of hydrogen energy for the end-users. Therefore, further research is needed to reduce the cost, increase energy efficiency, safety, and reliability with a focus to reduce environmental impacts in transportating of H_2. On the other hand, the current and future policies of the governments for the energy, economy, and environment are other matters that need attention. Therefore, this paper aims to overview the recent studies on the transportation of hydrogen, current and future policies of governments for hydrogen energy to find out the challenges, possible solutions, and policies in hydrogen transportation and delivery in different parts of the world.

HYDROGEN TRANSPORTATION AND DELIVERY

A variety of hydrogen transportation options can be adopted based onthe service type, demands, and the form of hydrogen to be transferred. Hydrogen either can be transported in gaseous form (at a pressure of 180 bar or even higher) through tube trailers, trains, ships, and pipelines or it can be transported in liquid form (liquefaction temperature -252.8 °C) through cryogenic tankers, ships, and trains. The pipelines are deployed mostly for long-distance, substantial demands (hundreds of tons per day) to remain stable for decades. Liquid cryogenic tankers and tube trailers, on the other hand, are deployed for smaller-scale demands [9]. For example, gaseous form of hydrogen can be delivered in bottles and transported by semi-trailers from 3000 to 6000 m^3 at 200 bar for demands below 50 m^3/h [10].

Based on an estimation by European Hydrogen Backbone (EHB), the pipeline is the most cost-efficient transportation method for importing hydrogen into EU+UK. This study reports that transportation of hydrogen through pipelines costs €0.11–€0.21/kg H_2/1000 km. However, the shipping of hydrogen from Saudi Arabia and North Africa costs 3 to 5 times more expensive than pipeline, around €1/kg of H_2 [11]. It is important to note that the cost of transportation is highly condition-dependent. For example, transporting hydrogen from Australia to the EU and UK is not cost-efficient through the underwater pipeline, due to high-cost infrastructure and safety matters [2] [11]. Figure 1 shows the cost comparison of different hydrogen transportation options at different distances. This is an advantage that the natural gas infrastructures can be repurposed for hydrogen, which makes it more cost-efficient than the new pipeline as is shown

in Figure 1. Also, the recen studies reveal that inland gaseous hydrogen pipeline is preferable to any other methods of transportation for the transportation of bulk amount of pure pressurized hydrogen for a long-distance [12].

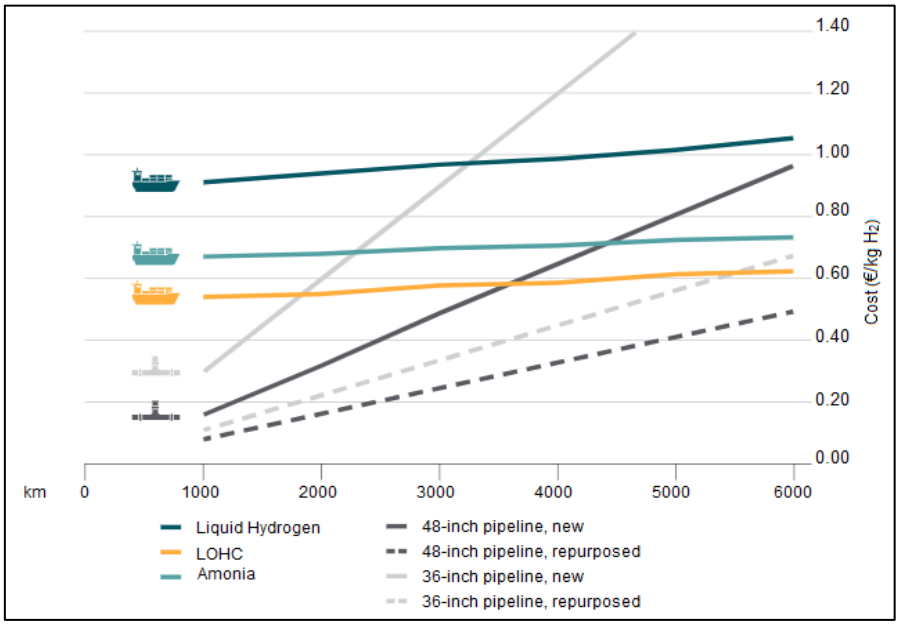

Figure 1. Cost comparison of different hydrogen transportation options at different distances [11]

According to a report by Lebrouhi, *et al*., countries including Australia, Canada, the USA, Morocco, Norway, and Chile are regarded as the top exporter of hydrogen energy while Japan, South Korea, EU are possible major importers based on the policies and projections regarding with hydrogen. China and Saudi Arabia are water-constrained producers of hydrogen. Saudi Arabia has the potential to produce green hydrogen 696 Mt/year which is 24% of the world energy demand in 2050. The report also shows that Spain, Thailand, and Turkey are self-sufficient producers; but India, Russia, Italy, Portugal are infrastructure-constrained producers. Germany, France, the UK, Netherlands, and South Africa are the major importers of hydrogen for their needs to meet NZE scenarios by 2030, and by 2050 [10].

Among the above countries, Turkey has an excellent geographical and geopolitical location that can play a pivotal role in the hydrogen market as it is surrounded by seas and is located close to the EU. Turkey needs to invest around $45 bn investment to produce green hydrogen, installation of electrolyzers, repurpose the current natural gas pipeline for hydrogen transportation, build dedicated hydrogen infrastructures, and so on [13]. Figure 2 shows the key regions for production and transportation of hydrogen.

Material based hydrogen delivery

The idea behind the material-based hydrogen delivery is based on the storage of hydrogen in the form of a solid chemical compound through hydriding a material or chemical compound at the site of hydrogen production, and then dehydriding it at the end-use point or delivery point. Metal-Organic Frameworks (MOFs), complex hydrides such as $NaAlH_4$, NH_3BH_3, and interstitial hydrides such as $LaNi_5H_6$ can be mentioned as a possible material based transportation of hydrogen solutions in the future [14]. This method is in its crawling stage and the studies are mostly concentrated on the storage of hydrogen, no reported projection of transportation yet [9].

Figure. 2. Key regions for the production and export of green hydrogen in Turkey [13].

CONCLUSIONS

Currently, different types of hydrogen transportation infrastructure are commercially available worldwide, and some others are either under investigation or development stages. Undoubtedly, the transportation of hydrogen requires high-cost infrastructure, safety precautions, etc. Nevertheless, the geopolitical stability in the countries along the pipeline, bilateral tensions between countries will also play a critical role in realizing the green hydrogen delivery.

ECONOMIC AND ENVIRONMENTAL EVALUATION OF FUELING OPTIONS FOR HYDROGEN FUEL CELL HEAVY-DUTY VEHICLES

[1*] *Amgad Elgowainy,* [1] *Krishna Reddi*
[1]Argonne National Laboratory, 9700 S Cass Ave, Lemont, IL 60439, USA

*Corresponding author e-mail: aelgowainy@anl.gov

ABSTRACT

Hydrogen fuel cell electric vehicles have the advantage of faster fueling and longer driving range compared to battery electric vehicles, especially for medium and heavy-duty vehicles (M/HDVs). Argonne National laboratory developed cost and energy/emissions estimates of various options for fueling hydrogen fuel cell HDV fleets, considering various hydrogen supply chain (e.g., gaseous vs. liquid). In general, liquid hydrogen sourcing provides a significant cost advantage for large fleets with high fueling rates, compared to gaseous hydrogen supply to fueling stations. However, the hydrogen liquefaction is an energy intensive process that affects life-cycle energy use and greenhouse gas emissions, depending on the electricity generation mix used for liquefaction. The contribution of refueling station to total hydrogen cost at dispenser is between \$2-5/kg_{H2}, depending on daily and hourly fueling demand and speed, but can be reduced to \$1/kg_{H2} when considering large fleets and high production volume of fueling components. The fueling station cost contribution can be further reduced to <\$1/kg_{H2} by considering low-pressure liquid hydrogen storage onboard the fuel cell M/HDVs.

Keywords: Hydrogen, Fuel cell, Refueling cost, Greenhouse gas, Heavy-Duty vehicle

INTRODUCTION

Medium/heavy-duty vehicles (M/HDVs) class is the fastest growing and second largest energy consumer in the U.S. transportation sector, accounting for significant energy use and air emissions in the United States. There are about 11 million M/HDVs, representing only about 4% of the total on road vehicles in the United States. However, NOx emissions of M/HDV fleet are comparable to emissions from the much larger light-duty vehicle (LDV) fleet. Energy consumption share of M/HDVs is expected to increase to represent 30% of total U.S. transportation energy use by 2040. To mitigate the impact of M/HDVs on energy use and air emissions, several states developed plans to gradually increase the share of zero emissions vehicles (ZEV), such as battery electric vehicles (BEVs) and fuel cell electric vehicles (FCEVs) in their efforts to electrify on-road transportation sector. Hydrogen fueling station contributes significantly to the total dispensing cost of hydrogen. Such cost can be mitigated by appropriate choice of hydrogen supply chain (e.g., gaseous vs. liquid). Furthermore, the choice of hydrogen storage onboard the vehicle strongly impacts the fueling station equipment, and therefore the levelized cost of hydrogen dispensing.

MATERIALS AND METHODS

Techno-economic models are needed to estimate hydrogen delivery and refueling costs for various delivery and refueling technology options, considering both near-term and long-term markets. Additionally, techno-economic models can inform infrastructure deployment plans by incorporating important factors such as market demand, capacity utilization in early markets, manufacturing volume of fueling components, and hydrogen sourcing (e.g., delivered vs. onsite production, and liquid vs. gaseous). This study evaluates the cost and life cycle environmental impacts of various hydrogen supply chains for fueling MHDVs. The Heavy-Duty Refueling Station Analysis Model (HDRSAM)[1], shown in Figure 1, is a techno-economic model developed by Argonne National Laboratory (ANL) that was used to evaluate the cost of fueling fuel cell MHDVs.

Environmental life cycle analysis models provide consistent basis to compare the environmental performance of various hydrogen pathways. In particular, the carbon intensity of hydrogen is an important metric to evaluate the greenhouse gas emissions reduction associated with using hydrogen in FCEVs compared to the use of conventional fuels in internal combustion engine vehicles. The Greenhouse gas, Regulated Emissions, and Energy use in Technologies (GREET®)[2], also developed by ANL, was used to evaluate the environment impacts of various hydrogen production, delivery and fueling pathways. The trade-off between cost and environmental performance of various hydrogen pathways is evaluated to inform infrastructure deployment for various vehicle classes and vocations.

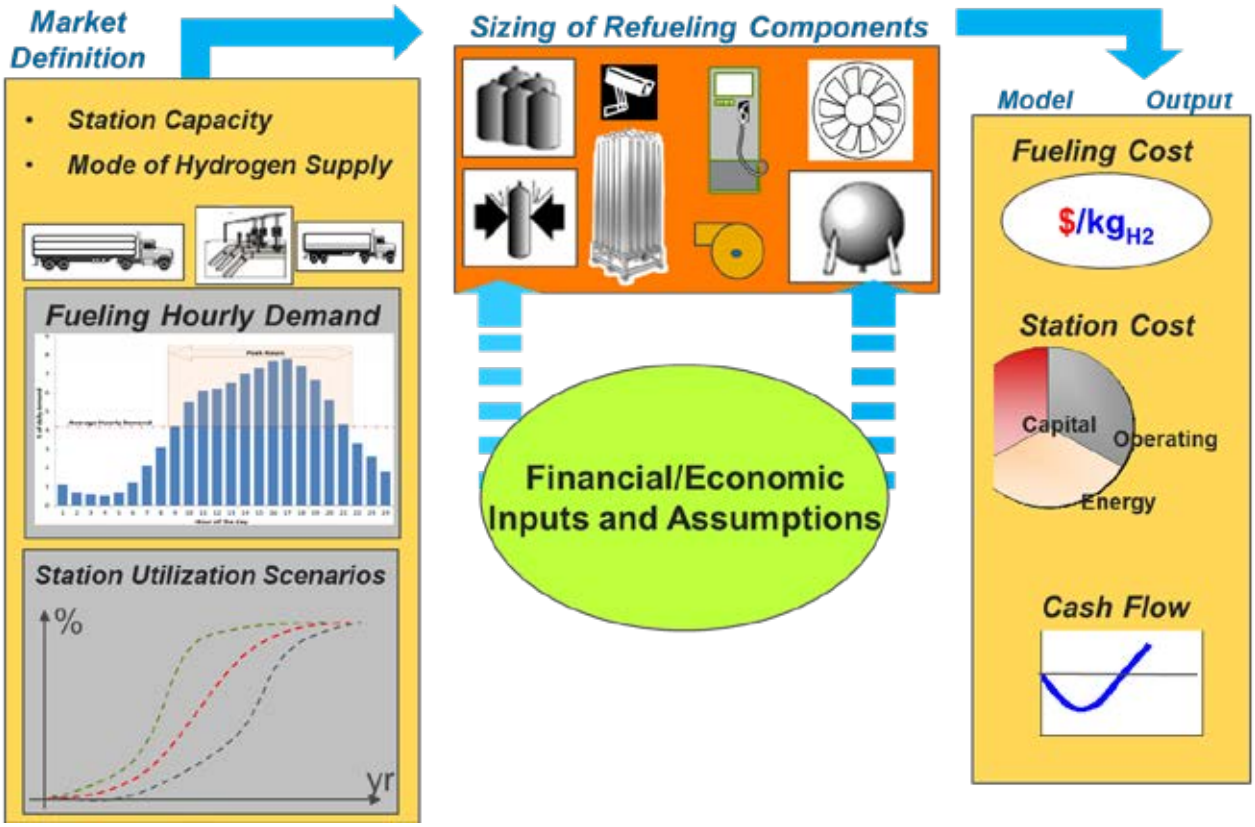

Figure 1. The Heavy-Duty Refueling Station Analysis Model (HDRSAM) framework

RESULTS AND DISCUSSION

ANL conducted a life cycle analysis of hydrogen use in M/HDV to evaluate the economic and environmental impacts of key fueling parameters, including vehicle onboard storage technology, fleet size, fueling amount per vehicle, fueling pressure, fueling rate, precooling requirement, and fleet fueling strategy. In this analysis, ANL presents cost and energy/emissions estimates of various options for fueling hydrogen fuel cell M/HDV fleets, considering various hydrogen sources (e.g., gaseous vs. liquid). In general, liquid hydrogen sourcing provides a significant cost advantage for large fleets with high fueling rates (> 3kg/min), compared to gaseous sources of hydrogen. However, liquefaction of hydrogen is an energy intensive process that affects the dispensing cost of hydrogen and the life-cycle energy use and greenhouse gas emissions, depending on the carbon intensity of the electricity generation mix used for the hydrogen liquefaction process, and its energy efficiency. The contribution of refueling station to total hydrogen cost at dispenser is between \$2-5/kg$_{H2}$ with gaseous hydrogen supply, depending on fueling demand and speed, but can be reduced to ~\$1/kg$_{H2}$ when considering liquid hydrogen supply and high production volume of fueling components (Figure 2). The fueling station cost contribution is also impacted by choice of hydrogen onboard storage option. Compressed hydrogen tanks (350 and 700 bar) require high capital investment in compressors and high-pressure storage to accommodate fast fueling of FCEVs, which impacts the levelized cost of hydrogen at the dispenser. Low-pressure, vacuum jacketed cryogenic hydrogen tanks require less capital investment at fueling station, which may contribute <\$1/kg$_{H2}$ to the hydrogen dispensing cost (Figure 2). However, the carbon intensity of liquid hydrogen supply can be significant if the electricity for liquefaction is sourced from a carbon intensive grid.

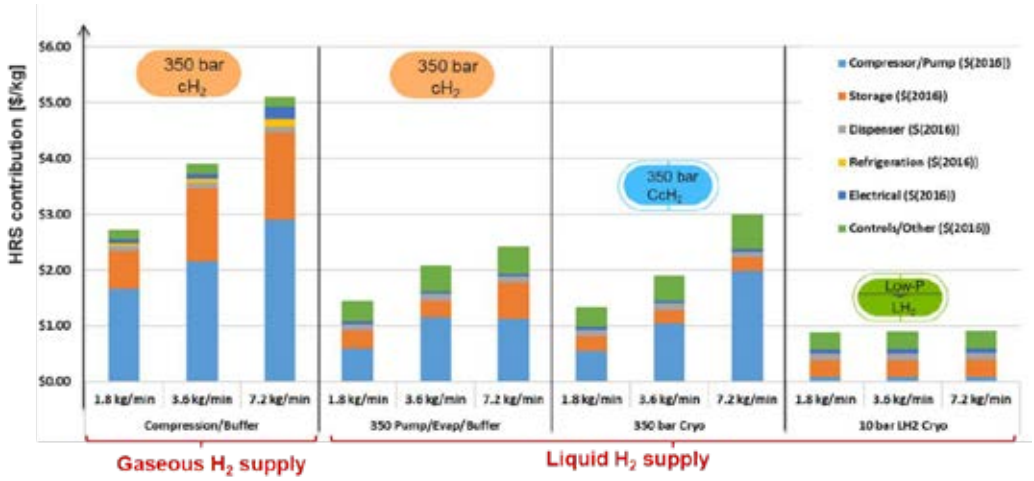

Figure 2. Hydrogen Refueling Station (HRS) contribution to the cost of fueling a fleet of 30 fuel cell buses, with 35 kg fill per bus, for various hydrogen supply modes and onboard storage technologies

CONCLUSIONS

The contribution of refueling station to total hydrogen dispensing cost is between \$2-5/kg_{H2}, depending on daily and hourly fueling demand and speed, but can be reduced to \$1/kg_{H2} when considering large fleets and high production volume of fueling components. The fueling station cost contribution can be reduced further to <\$1/kg_{H2} by considering low-pressure liquid hydrogen storage onboard fuel cell M/HDVs. It is important to use low-carbon electricity for hydrogen liquefaction to realize both the economic and environmental benefits of liquid hydrogen supply for fueling FCEVs.

ABSTRACT

With the growing emphasis on building a green economy with low carbon footprint, UAE is gradually building a hydrogen economy through introducing hydrogen fuel for transport. Although hydrogen sources are abundant in the UAE, the supply-chain model is not in place. Given the cost sensitivity of hydrogen in relation to volumes produced, large consumption is essential to reduce the cost. In this work, we developed a system dynamics model that allow us to design a roadmap for deployment of hydrogen network in the UAE. We examined different policy incentives that inaugurate hydrogen fuel stations at a reasonable price in the UAE market.
Keywords: Hydrogen network, Green transport, System dynamics, Analysis, Demand

INTRODUCTION

Global economies, including UAE, have set strategies to comply with international commitment of reducing emissions by setting targets to develop and implement clean energy technologies [1]. The UAE Vision 2021 National Agenda emphasizes implementing green strategies and increasing reliance on clean energy. The vision is to reach a target of 27% share of clean energy and 15% reduction of CO_2 emissions, while maintaining strong economic growth. Additionally, UAE's 'Energy Strategy 2050' aims to increase the contribution of power generation from renewable energy to 50 percent, while reducing carbon emissions by 70 percent. The roadmap to achieving this ambitious yet realistic target is through diversifying energy sources, shifting from heavy reliance on oil and gas to a mix of 44 per cent clean energy, 38 per cent gas, 12 per cent clean coal, 6 percent nuclear. [2] The global shift to renewables has shed light on the abundance of hydrogen making it a core energy source of the future. Hydrogen energy is clean, storable, transportable and inexhaustible. Due to these attractive qualities, its applications are versatile [3]. With the prominent emphasis on building a green economy with low carbon footprint, UAE is gradually building a hydrogen economy by introducing hydrogen fuel for transport. Although hydrogen sources are abundant in the UAE and the applications are numerous, the supply-chain model is not in place. Given the cost sensitivity of hydrogen in relation to volumes produced, large consumption is essential to reduce the cost. This can be kickstarted through deployment of fuel cell vehicles (FCVs) that will justify the inauguration of hydrogen fuel stations and eventually reduce the price of H_2 fuel to an economically attractive price in the UAE.

Therefore, a roadmap for the development of hydrogen infrastructure is required with clear direction on commencing this transition to hydrogen as fuel for transport. Investors, industry and government need to coordinate to achieve this transition. As with any energy shift, communication is a key especially in the UAE, where it is heavily dependent on oil and gas for energy production. Therefore, it is essential to develop a tool that provides a clear path on fuel cell market penetration and communicate it to authorities and policymakers. Accordingly, a comprehensive vision could be established to reach the emission reduction targets set in the UAE. Deployment of hydrogen FCVs not only results in environmental benefit but also creates a sustainable economic growth through a new market of employment, sales and revenues. This ongoing research aims to analyze potential future demand for hydrogen as a fuel for transport in UAE. This facilitates the development of a roadmap for the utilization of hydrogen as transportation fuel in the UAE, as it provides a forecasting tool for hydrogen demand. This is accomplished through analyzing the incentives and factors that contribute to a successful penetration of hydrogen-powered vehicles in the market and the factors that inhibit its growth. By studying the complex interactions between these dynamic factors, it provides concrete data to commence and establish a hydrogen supply demand network with a site-specific roadmap to employ hydrogen

applications in UAE. This work will contribute to the reduction in carbon emissions and achieving the vision of low carbon economy.

The objectives of the research are to: (1) examine potential market to promote penetration of fuel cell vehicles in the UAE; (2) evaluate factors that would drive hydrogen fuel demand and analyze their effects through causal-loop approach; (3) analyze and quantify the effect of hydrogen fuel cell vehicles on development of hydrogen infrastructure; (4) analyze quantitative models produced to develop reliable hydrogen utilization road-map.

MATERIALS AND METHODS

Several modelling approaches in literature have been used to explore the future of hydrogen market in transportation. Mostly, scenario-based approaches and historical analogy were used to examine hydrogen adoption rate [4]. Key factors

that contribute to the penetration of fuel cell vehicles (FCVs) in the market such as technology economics, political regulations, and consumer behavior should be considered when analysing the demand of hydrogen for transport. Political regulatory interference, in terms of subsidies to support the hydrogen market, taxation on diesel powertrains, and incentives, plays a significant role in the initial diffusion process. Moreover, technology maturity and availability affect the economics, which consequently impact consumer behavior. Given that these factors are dynamic, their interactions and impact on the system as a whole is also dynamic, and hence complex to interpret. In this work, a systems dynamics model is developed to examine the market and study the complex interactions between the factors based on UAE context. The elements that contribute to FCV diffusion are modeled in a causal-loop diagram to analyze the relations between the multivariable system. Following the work done in a German study led by Keles et al (2008) on FCV market penetration, factors affecting the car system can be modeled in four modules: demand and supply, attractiveness, filling stations, and balance of payments [5]. By running different scenarios of policy combinations, the results of the causal-loop diagram demonstrate the real drivers of future hydrogen fuel demand, and the effect of different stakeholders' inputs on the system. Figure 1 demonstrates the main aspects considered in the study. The focus of the model is to estimate hydrogen fuel demand, which translates into fuel cell vehicles deployed annually. Accordingly, it is feasible to quantify the reduction of carbon dioxide emissions from transport achieved by adoption of fuel cell vehicles. Further analysis will be conducted to quantify the approximate governmental funding required and policies necessary for successful market penetration. Based on the results, a reliable hydrogen utilization roadmap will be developed.

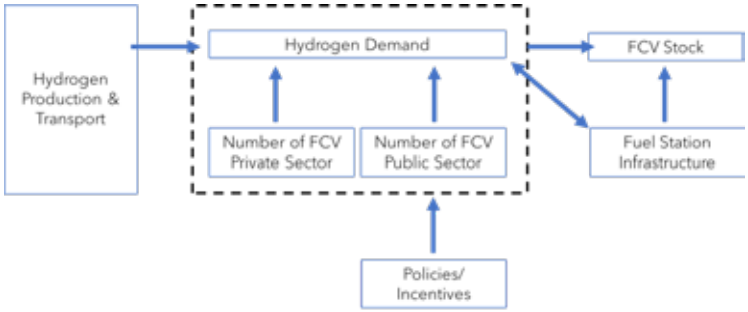

Fig. 1. Linkages between modules of FCV market

RESULTS AND DISCUSSION

The optimum market for preliminary FCV penetration in the UAE transport is through deploying fleets of medium and heavy-duty vehicles. The barriers to entry into medium and heavy-duty markets are easier to overcome relative to passenger FCV markets. Thus, in the near-future, taxi, bus, and truck fleets are more likely to be converted to hydrogen fuel cells. Fleet operators would require long term refueling contracts, as opposed to private users, resulting in consumption of large and predictable quantities of hydrogen fuel. Scaling up hydrogen production to supply the large demand would eventually reduce the cost of hydrogen. Moreover, fleets usually have fixed routes and refuel at base, which translates into fewer refueling stations. Also, the population density centralized in Abu Dhabi and Dubai allows for less infrastructure required to cover nationwide demand. Preliminary penetration of hydrogen in this market paves the way for a wider diffusion into mass market and comprehensive infrastructure. The pilot phase of FCV penetration in

the UAE commenced by importing 55 Toyota Mirais by Al Futtaim Motors, the exclusive distributor of Toyota in UAE. The vehicles refuel at the first hydrogen refueling station in the UAE installed by Air Liquide. Deploying the Mirais is a strategic attempt to demonstrate potential hydrogen market in the UAE, while managing to connect source to application and establishing a hydrogen supply chain. Fuel cells are already gaining momentum in UAE, as Dubai Taxi Corporation is test driving the Mirai for its fleet. Abu Dhabi police announced conversion of entire fleet from fossil fuel powertrain to fuel-cells by 2057. Successful market penetration can be achieved through a combination of FCVs subsidies, sufficient installation of hydrogen fuel stations, and tax-free hydrogen fuel. Subsidies and tax allowances are essential to reach cost parity with diesel vehicles, and hence increasing consumers acceptance to FCVs. Also, financial support from governmental entities is recommended to install hydrogen fueling stations [5].

CONCLUSIONS

A system dynamic model was developed as a tool to forecast the demand of hydrogen as a fuel for transportation in the UAE. The key factors that contribute to the penetration of fuel cell vehicles (FCVs) in the market such as technology economics, political regulations, and consumer behavior were investigated in details in this study using system dynamics approach. We found that the best strategy to close the gap between the demand and economies supply of hydrogen is thorough adoption of large operators such as taxi, bus, and truck fleets

GRID BASED RISK ASSESSMENT OF A HYDROGEN SUPPLY CHAIN

[1*]Ebru Geçici, [1]Mehmet Güray Güler, [1]Ahmet Erdoğan

ABSTRACT

Today's energy recourses are not supposed to be sufficient to fulfill increased energy demand in the near future, thus researchers and governments look forwards to alternative energy sources. Hydrogen energy is one of these alternative energies. To increase the use of hydrogen energy, it is essential to establish a good hydrogen supply chain (HSC), which provides the transmission of hydrogen from production facilities to the users. There are several key issues which must be addressed in establishing a good HSC like capital cost and operating costs, environmental effects like CO_2 emission, and risks. Although minimizing the total costs or total CO_2 emissions can be appropriate for a country, minimizing the cumulative risk may result in an unbalanced risk load between cities or grids of a country. In this study we analyze establishing the HSC of Turkey and showed that minimization of total risk yields low risks in grids with low population and grids with higher populations have to cope with larger risks.

Keywords: Hydrogen Supply Chain, Risk Analysis, Multi-objective Supply Chain

INTRODUCTION

Growing population and developed technology increase the energy consumption day by day. In addition to this, today's main energy sources, which are fossil fuels such as petroleum, natural gas, etc., will not be enough to fulfill energy need. For this reason, researchers seek alternative energy sources. Hydrogen energy is one of these alternative energy sources to meet the increasing energy demand. It is a low pollutant fuel [1, 2], efficient [2], and improves the security of primary energy supply [3]. Through these advantages although it is costly in today's technology, its use has become widespread. However, to retain its expansion in the future, the design of the hydrogen supply chain (HSC) has an essential role. An HSC provides the spread of the hydrogen energy from production facility or storage to the end users by appropriate transportation system. An HSC should be optimally designed to get proper flow from the starting point to the final consumption point with minimum cost in economic, environmental and social terms. Therefore these studies in the literature proposes HSC design by minimizing costs, CO2 emissions and/or environmental risks. One of the first studies in the literature, Almansoori and Shah [3], proposes a mixed integer programming (MIP) model by minimizing the capital and operating cost of the HSC for Great Britain as a single period model. This snap-shot MIP model is later extended to multi-period [4] and multi-objective models [5] by the authors. In the former, the objective function is the minimization of the total daily cost with the same as the main model, whereas, in the latter, the authors consider different objectives as CO2 emission and risk minimization. Carbon emission is directly proportional to the production method (Steam Methane Reforming (SMR), Electrolysis, etc.), the amount of production and the number of transports between the networks. However, in the risk analysis, besides the factors used in the CO2 analysis, it is affected by many different parameters such as the population density of the grid where the production facility will be established, and the route of transportation. For this reason, risk analysis become a significant point of view of the HSC in recent studies.

Almaraz et al. [6] propose a MIP model for the HSC of the Great Britain. Like Almansoori and Shah [5], the authors examine HSC of Great Britain with a multi-objective model (minimization of cost, CO2, and risk). Another multi-objective study is conducted by Bique et al. [7] where the authors examine HSC for Germany in 2030. Han et al. [8], on the other hand, create a multi-objective MIP model for the South Korea. Finally, Geçici et al. [9] propose a MIP model for Turkey's HSC for 2050. In all of the multi-objective studies, the aim is to minimize the total risk together with the total cost and/or the CO2 emission. However, this may result in unbalanced risks in terms of the grids. In another words, trying to minimize the total risk of a country may end up in very high risks in some grids. The subject of this study is minimizing the risk in the HSC on a grid basis rather than the total risk to ensure that all grids share the total risk in a balanced way. In this context, we propose a multi-objective MIP model, which minimize the total risk by taking into account the risk of each individual grid.

MATHEMATICAL MODEL AND CASE STUDY

In this study, we use the HSC model of Almansoori and Shah [5], Almaraz et al. [6], Bique et al. [7] and Geçici et al. [9]. We change the objective function given in (1) and added the constraints given in (2)-(6).

$$\sum_{g \in G} D_g^{risk} \quad (1)$$

$$PR_g \leq \frac{TPR}{NG} + D_g^{risk} \qquad g \in G \quad (2)$$

$$TDC \leq \varepsilon_1 \quad (3)$$

$$TDE \leq \varepsilon_2 \quad (4)$$

$$TR \leq \varepsilon_3 \quad (5)$$

$$D_g^{risk} \geq 0 \qquad g \in G \quad (6)$$

Our aim is to assign the risk to the grids as equally as possible. In order to ensure this, we assign the risk of each grid to the average of the total risk, allow the risk of the grid to deviate from the grid using a deviation variable (D_g^{risk}) and then minimize these deviations in the objective function. Eq. (1) gives the objective function, and it provides the minimization of the risk deviation D_g^{risk}. The constraint in Eq. (2) ensures that production risk of each grid should be smaller than or equal to the average risk as much as possible through the deviation variables. Here, PR_g shows the production risk of grid g. TPR is the total production risk, whereas NG is the number of grids. The constraints in Eq. (3)-(5) keep the other objectives of the model at a certain level, which are total daily cost (TDC), total daily emission (TDE), and total risk (TR), respectively. Keeping the levels at a certain level is a technique used by epsilon constraint method in multi objective problems. The constraint in Eq. (6) is for non-negativity of the decision variable D_g^{risk}.
In this study, the case study of Turkey in Geçici et al. [9] is analyzed. Turkey, which consists of 81 cities, is divided into 33 grids by combining the cities according to the population density. Here, two cases are analyzed: (i) multi-objective model and (ii) minimization of the deviation risk "D_g^{risk}". In the first case (base case), the model is solved as a multi-objective problem (minimization of cost, carbon emission and risk, respectively) by using the ε-constraint method. In the second case, the cost, carbon emission and risk values ($\varepsilon_1, \varepsilon_2, \varepsilon_3$) obtained in the first case are added to the model as constraints, and D_g^{risk}, which is defined to balance the distribution of production risk to the grids, is minimized.

RESULTS AND DISCUSSION

In this part, we examine the effect of the model via the results of two cases. As observed Table 1, in case 1, two different production plants are established in 33 different grids: 286 small-scale, 25 medium-sized electrolysis production plants, and 3 large-scale and 7 medium-sized SMR production plants. According to the open facilities and their effects over production risk distribution of each grid, it is seen that only 3 cities constitute 44% of the total production risk (Table 2).

Table 1. Results

Objectives	Number of production plants			
	Steam Methane Reforming		Electrolysis	
	Medium	Large	Small	Medium
Case 1 (Total)	7	3	286	25
Case 2 (Total)	8	4	274	36
Case 1 (İstanbul)	0	2	16	0
Case 2 (İstanbul)	0	0	2	11

In Case 2 (minimizing the grid-based risk), on the other hand, 274 small-scale, 36 medium-sized electrolysis production plants and 4 large-scale and 8 medium-sized SMR production plants are established (Table 1). The results show slight differences in the total number of established facilities compared to the first case. In both solutions, production facilities are established on all grids. However, while the production risk of 3 cities covers 44%of the total production risk in the first case, it decreases to 34% in the second case, as seen in Table 2. In order to reduce the production risk distribution in this way, 11 medium-sized electrolysis facilities were established in İstanbul instead of 2 large-sized SMR plants and 14 Electrolysis plants. Therefore, as seen in Table 1 although the total number of production plants, total cost, total risk, and total carbon emission values are very close to each other in both cases, there are serious differences in the type, size and number of plants established in some grids such as İstanbul.

Table 2. Distribution of Production Risk

Grid No	Grid Name	Case 1		Case 2	
		Production Risk	Rate	Production Risk	Rate
1	İstanbul	406	26%	273	19%
2	Ankara	150	9%	123	9%
3	İzmir	135	9%	90	6%
Total			**44%**		**34%**

CONCLUSIONS

One must address several objectives like cost, risk and environmental effect when designing efficient HSC. The general approach is to minimize the total of these objective over a particular region. In this study we show that such an approach may lead to unbalanced risks, i.e., very high risks in some parts of the regions. We proposed a model which tries to keep the risk of each grid at the average as much as possible and showed that the results are promising. This model can be improved to get more balanced risk values for each grids.

NOMENCLATURE

g, G	Indice and set of grids
PR_g	Decision variable of the production risk of grid g
D_g^{risk}	Deviation variable of grid g for the risk
HSC	Hydrogen supply chain
MIP	Mixed integer programming
NG	The number of grids
STR	Steam methane reforming
TDC	Total daily cost
TDE	Total daily emission
TPR	The total production risk
TR	Total risk
$\varepsilon_1, \varepsilon_2, \varepsilon_3$	The cost, carbon emission and risk values

ANALYSIS OF A HYDROGEN SUPPLY CHAIN WITH RANDOM DEMAND: A CASE STUDY

[1*] *Busenur Türkali Özbek,* [1] *Mehmet Güray Güler*
[1] Department of Industrial Engineering, Faculty of Mechanical Engineering, Yıldız Technical University, İstanbul, Turkey

ABSTRACT

Today, energy sources that are used intensively especially in vehicles are generally non-renewable energy sources and they are on the verge of depletion with increasing demand. To cope with this, countries have turned to hydrogen, which is seen as a clean and renewable energy source. However, due to the uncertain future demand, it is also difficult to design a good hydrogen supply chain. To overcome this, a stochastic hydrogen supply chain model is proposed in this study and the Marmara region of Turkey is used as a case study.

Keywords: Hydrogen supply chain, Stochastic, Renewable energy source

INTRODUCTION

Fossil fuels have become very popular in the 20th century with the increasing energy need and have been the savior of people for a while. Fossil fuels pioneered the industrial revolution and increased social and economic welfare [1]. But fossil fuels are not renewable and are bound to run out over time. However, the damage they cause to the environment is one of the main causes of global warming threatening the world in recent years.

Since the need for energy has increased with the increase in the world population, renewable energy sources have been preferred considering the depletion of fossil fuels and their damages. The oil crisis in 1973 also plays an important role in this regard [2]. However, although the use of renewable energy sources has become widespread today, the consumption of fossil fuels is still at a very high level.

Along with these, there is another energy source that has become widespread in recent years: hydrogen energy. Hydrogen energy is known as renewable energy, but it differs from renewable energy sources in some aspects. Especially being storable is one of the biggest advantages of hydrogen energy. In addition to this, it is a low pollutant fuel [3, 4], efficient [4], and improves the security of primary energy supply [5].

In recent years, governments of almost all countries have been working on infrastructure for the use and transportation of hydrogen as energy. In Turkey, steps are being taken in this regard. Finally, within the scope of the "Glasgow Agreement for Zero Emission Vehicles" signed by 33 countries, including Turkey, in 2021, it is foreseen that gasoline and diesel engine vehicles will be replaced by zero emission vehicles in the automobile markets until 2035. This means that vehicles working with hydrogen energy will increase.

In order to that countries can plan the hydrogen supply chain (HSC) correctly, various studies are carried out. In 2009, Almansoori and Shah designed a multi-period deterministic HSC model for Great Britain [5], and extended this model to a stochastic model in 2012 [6]. Dayhim et al. developed a stochastic model for New Jersey [7]. Camara et al. have similarly studied for Portugal [8].

In this study, it is aimed to make HSC planning with stochastic modeling within the scope of the Marmara region of Turkey. Under the study, it has been planned in which regions and in which capacities hydrogen production and storage facilities should be opened according to the hydrogen demands in the cities of Marmara region. Stochastic modeling was used to reflect demand uncertainty to the model.

MATERIALS AND METHODS

In this study, hydrogen supply chain planning has been made for the Marmara Region of Turkey for the year 2035, which is considered a milestone in the use of diesel and gasoline vehicles. To model demand uncertainty in the transition to hydrogen vehicles, a two-stage scenario-based stochastic programming framework, in which discrete control variables (here-and-now) are generated first for all generation units, and then the continuous dispatch variables (wait-and-see) are generated using a scenario-based technique is used [9]. In this problem, three different scenarios according to demand is considered. The first stage variables are the number of production and storage facilities to be opened regardless of the scenarios, and the second stage variables are the amount to be produced and stored at each facility and the amount of hydrogen to be transported between cities. In the scenarios, the ratio of hydrogen vehicle use

to the total number of vehicles is assumed to be 35%, 25%, and 15%, and the scenario probabilities are determined as 30%, 50% and 20%, respectively.

The demands in 2035 are given in Table 1 according to the provinces and scenarios in the Marmara Region. While determining the demands, the data of Güler et al.'s [10] study is used. The aim of the model is to determine the locations of the production facilities and warehouses that should be established in each province by minimizing the cost in a way that will meet these demands. It is assumed that the demand in one province can also be met by the production facilities in other provinces, and the flow between these provinces is also determined.

Table 1: Demands of the provinces in scenarios

Code	Name of Region	Demand		
		Scenario 1	Scenario 2	Scenario 3
1	İstanbul	2,176,994	1,554,996	932,998
2	Tekirdağ	469,410	335,293	201,176
3	Çanakkale	34,305	24,504	14,702
4	Balıkesir	376,574	268,982	161,389
5	Bursa	251,852	179,894	107,937
6	Yalova	120,161	85,829	51,498
7	Kocaeli	140,032	100,023	60,014
8	Edirne	83,489	59,635	35,781
9	Kırklareli	69,348	49,534	29,721
10	Sakarya	149,608	106,863	64,118
11	Bilecik	35,835	25,596	15,358

In the model, in order to be compatible with real life, it has been considered that hydrogen can be produced with 3 different methods (steam methane reforming, biomass gasification, electrolysis) and it can be stored with 2 different storage methods (compressed gaseous, liquid gaseous). In addition, three different plant capacities as small, medium and large scales are modeled for production and storage facilities in the model, but for the sake of ease of calculation, the capacities of all of them are considered equally for this study. Minimum capacities of production and storage facilities are considered as 10.000 liter and maximum capacities are considered as 960.000 and 540.000 liter respectively.

RESULTS AND DISCUSSION

In Table 2, the number of production and storage facilities that should be opened in each city to meet the demands in all scenarios and the production and storage rate of these facilities according to the scenarios are given.

Table 2:Results of the Stochastic Model

Code	Name of Region	PF	SF	Scenario 1 (%35)		Scenario 2 (%25)		Scenario 3 (%15)	
				PR (kg)	SR (kg)	PR (kg)	SR (kg)	PR (kg)	SR (kg)
1	İstanbul	1	21	960,000	10,884,972	960,000	7,774,980	932,998	4,664,988

6	Yalova	0	2	0	600,806	0	429,147	51,498	257,488
7	Kocaeli	1	2	960,000	700,161	830,383	500,115	60,014	300,069
8	Edirne	0	1	0	417,443	0	298,174	35,781	178,904
9	Kırklareli	0	1	0	346,739	0	247,671	29,721	148,603
10	Sakarya	0	2	0	748,039	0	534,313	64,118	320,588
11	Bilecik	0	1	0	179,175	0	127,982	15,358	76,789
Total		**5**	**43**	**3,907,608**	**19,538,042**	**2,791,149**	**13,955,744**	**1,674,689**	**8,373,447**

The results show that the construction of only one generation facility in each of the 5 cities is sufficient to meet the demands in all scenarios. According to the scenarios, the production rates of these production facilities change, and all demands are met by transferring from the opened production facilities to other cities. In order to minimize the cost, it is observed that the cities where production facilities are opened are more centrally located compared to other cities. In storage, the situation is different. In each city, storage of hydrogen up to 5 times of its own demand is mandatory in the model. In the results, it is seen that the number of production facilities opened is suitable for this. The total cost for stochastic model is found as $7,456,550,181.

In order to make comparisons, the model was also run deterministically by considering all scenarios and the results are given in Table 3 where PF and SF denote number of production facilities and number of storage facilities respectively, and cost infer the total cost.

Table 3: Deterministic Model Results

Scenario 1			Scenario 2			Scenario 3		
PF	SF	Cost	PF	SF	Cost	PF	SF	Cost
8	43	7,657,653,280	5	31	5,537,647,495	4	21	3,614,969,962

Deterministic model results show that in scenario 1, where the demand is the highest, the number of production facilities opened is higher than the stochastic model. This is due to the fact that demand is certain to be high, and facilities are opened in various cities to reduce transportation costs as well. In the other scenarios, the number of facilities opened and the cost are unsurprisingly lower than in the stochastic model.

CONCLUSIONS

Hydrogen stands out as a clean energy source today. It is envisaged that this energy source will primarily be used as fuel in vehicles, but there is still uncertainty about what the rate of this will be. These uncertainties affect the investments of countries in hydrogen plant. In order to eliminate these uncertainties, a stochastic hydrogen supply chain has been developed for the Marmara region of Turkey. Although not used in this case, three different sizes of production and storage facilities are discussed in the model. In addition, the model has the capacity to be adapted to the whole of Turkey and it is aimed to do this in future studies.

ABSTRACT

The transport of hydrogen will be a key enabler for the widespread use of renewable hydrogen in Europe. To achieve the goals of the European Hydrogen Strategy [1] it is important to understand whether it is cost effective to produce renewable hydrogen where renewable electricity is cheap and then to transport the hydrogen to the customer, or it is better to produce the renewable hydrogen close to the demand location. JRC has performed a comprehensive study regarding the transport of hydrogen, in terms of costs and energy demand. The study reveals that there is no single optimal hydrogen delivery solution across every transport scenario. The most cost effective way to deliver renewable hydrogen depends on distance, amount, final use, and whether there is infrastructure already available. For distances compatible with the European territory, compressed and liquefied hydrogen solutions, and especially compressed hydrogen pipelines, offer lower costs than chemical carriers do. Chemical carriers become more competitive the longer the delivery distance (due to their lower transport costs) and open up import options from suppliers located, for example, in Chile or Australia.

Keywords: Hydrogen delivery, Hydrogen export, Hydrogen import

INTRODUCTION

The European Hydrogen strategy recognises the important role [1] the transport of hydrogen will have in enabling the penetration of renewable hydrogen in Europe in the future, and explicitly mentions the import of hydrogen from outside Europe. JRC is assessing the costs and energy demand of hydrogen transport and distribution for various volumes and distances, allowing for a semi-quantitative ranking of transport options for hydrogen within the chosen set of assumptions [2]. The study considers transport of compressed or liquefied hydrogen, but also by means of liquid hydrogen carriers such as ammonia, methanol or liquid organic hydrogen carriers (LOHC). Each option offers different advantages, for example a good hydrogen storage density (e.g. NH3, MeOH or LOHC) or better round-trip efficiency (e.g. compressed or liquefied gas). The assessment covers the transport of hydrogen to the demand location through various means, the main options being pipelines, ships, trains or trucks.

GOAL AND SCOPE

The goal of this study is to answer the question whether it is more convenient to produce renewable hydrogen close to the demand location or to transport it from a location where renewable hydrogen production is cheaper. A second point we looked into is how long the transport route can be for the cost of hydrogen to still be cost competitive. To provide these answers a comprehensive analysis of the energy demand and costs involved in the delivery chain for the supply of renewable hydrogen has been performed.
A case study (Case A) investigated the cheapest option to transport hydrogen for the delivery of one million tonnes of green hydrogen per year to an industrial plant in Northern Europe. The transport distance considered for shipping is 2,500 km. The end-user site is assumed to be close to the port. A second case study (Case B) assessed a more complex delivery route, involving trucks and rails transport, and a lower amount of hydrogen to be transported (100 000 tH2/a). The delivery is expected to take place in a timeframe of 2030+.

This study considers that the delivery chain comprises the key processes and equipment necessary for the delivery of hydrogen from the production site to the demand/use location(s) (see Figure 1). The delivery chain can be divided in three main segments: i) the “packing”, where hydrogen is prepared for its transport; ii) the transport itself; and iii) the “unpacking”, where hydrogen is prepared for its final use. Across each step of the delivery chain, a storage facility is assumed to enable a smooth transition. Since the focus of this study is the delivery stage, the production of hydrogen and its final use are considered to be outside of the scope.

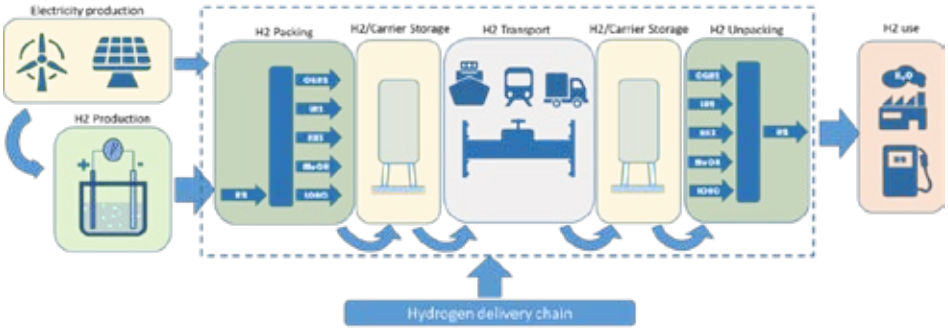

Fig. 1. Delivery chain elements

Figure 1 depicts the delivery chain elements considered in our study. Our analysis refers only to the elements within the dotted line.

The delivery chain options considered for this study are strictly related to the form in which hydrogen is transported (i.e., the 'packaging' mode). Five packaging modes are considered: compressed hydrogen (CGH2), liquefied hydrogen (LH2), ammonia (NH3), methanol (MEOH), with CO2 from Direct Air Capture (DAC), and Liquid Organic Hydrogen Carrier (LOHC) in the form of dibenzyltoluene (DBT). For LOHC, electricity, waste heat and hydrogen for providing the heat for dehydrogenation were assessed.

METHODOLOGY

The starting point of this analysis was gathering information regarding costs and energy demand coming from public literature and in some cases private companies. For several components and technologies of the hydrogen delivery chain, industry experts were consulted to provide information regarding costs and other key parameters.

The figures from literature sources are complemented by assumptions and extrapolations required to model large capacities, or a technology not characterized well enough by the sources collected. Calculations have been performed when the information available in literature was insufficient. One example is pipelines, where literature sources often were in disagreement and provided a wide range of costs.

To assess what difference electricity costs make, two scenarios are explored: (1) Low price (Lo), with a production site electricity cost of EUR 10/MWh and a consumption site electricity cost of EUR 50/MWh; (2) High price (Hi), with a production site electricity cost of EUR 50/MWh and a consumption site electricity cost of EUR 130/MWh. For case A (industrial use of hydrogen), waste heat at 300°C is assumed to be available, at a cost of EUR 20/MWh.

Any hydrogen delivery pathway is broken down into simple constituent individual steps (see Figure 1, i.e. hydrogen storage, hydrogen transport, conversion plants at production and delivery points, purification, compression), and the energy demand and costs assessed for each.

RESULTS

Hydrogen delivery costs obtained for case A (see Figure 2) indicate that transport options based on compressed gas (by ship or by pipeline) are the most cost competitive solution, alongside LOHC by ship if waste heat is available at the assumed price. Liquefied hydrogen transported by ship has a similar cost, within the margin of error. A more distributed delivery scenario involving smaller quantities of hydrogen (case B) leads to different conclusions. Transport and storage costs increase significantly in this scenario, in particular penalising the packaging solutions with lower gravimetric density (i.e. compressed hydrogen). Liquefied hydrogen therefore appears as the cheapest option for the scenario considered here.

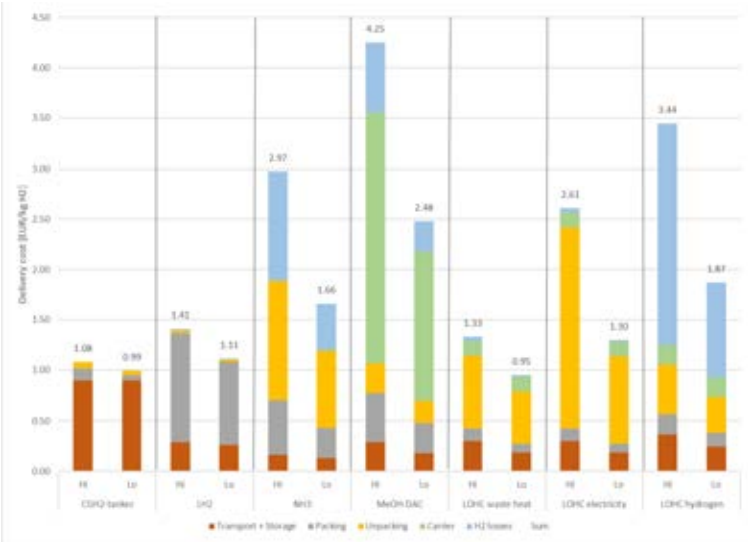

Figure 2 Hydrogen delivery costs. Hi(gh) and Lo(w) electricity prices are shown for each carrier.

CONCLUSIONS

The outcome of the study is that there is no single optimal hydrogen delivery solution across every transport scenario. The most cost effective way to deliver renewable hydrogen depends on distance, amount, final use, and whether there is infrastructure already available.

For distances compatible with the European territory, compressed and liquefied hydrogen solutions, and especially compressed hydrogen pipelines, offer lower costs than chemical carriers do. By contrast, chemical carriers become more competitive the longer the delivery distance (due to their lower transport costs) and open up import options from suppliers located, for example, in Chile or Australia.

Unpacking chemical carriers accounts for a significant share of their total cost, mostly due to the processes' high energy demand and the fact that unpacking plants are likely to be placed in locations with a relatively high electricity price. Optimization of unpacking processes has a key role to play in increasing the competitiveness of the chemical carrier pathways.

ABSTRACT

In this study, two proposed configuration plants were designed and simulated for the production of high-purity hydrogen at a rate of 25 kg_{H2}/day from blue ammonia. In configuration A, hydrogen was generated in a membrane reactor, while in configuration B, NH_3 decomposition and H_2 separation were carried out in an integrated catalytic membrane reactor. The performance of both hydrogen production plants was evaluated under different operating conditions. A pure palladium membrane with a thickness of 20 µm was utilized for pure hydrogen production. Configuration B was more energy efficient than configuration A. The hydrogen flow rate was evident with the increase in feeding pressure from 0.1 MPa to 0.3 MPa. The total H_2 production cost of configuration A was 5.33 €/kg_{H2} and that of configuration B was 5.05 €/kg_{H2}. Since the proposed plant configurations generated hydrogen and nitrogen, the total cost of production was distributed between them. The final H_2 and N_2 separation costs of configuration A was 4.21 €/kg_{H2} and 0.95 €/kg_{H2}, and configuration B was 3.94 €/kg_{H2} and 0.90 €/kg_{H2}. It can be also considered that the ammonia synthesis pathway controlled the ammonia prices and subsequently the hydrogen production cost.

Keywords: Hydrogen separation, Ammonia decomposition, Energy efficiency, Permeation rate

INTRODUCTION

Renewable energy sources combined with traditional ones are garnering interest because of their lower average prices. It is expected that in the upcoming years, renewable energy utilization trend will continue to increase [1]. However, the higher productivity and reliability of the application must be investigated to ensure its stability. Hydrogen can be generated by different technologies, such as water electrolysis and steam reforming [2, 3]. Hydrogen production from water electrolysis offers green products that overcome several compelling issues. Hydrogen is considered to have a unique potential for decarbonising different energy-consuming sectors. Indeed, hydrogen can be seen as a potential renewable energy vector that can be transferred to high demand sites [4]. In this study, a small-scale (25 kgH_2/day) hydrogen production plant using catalytic NH_3 decomposition was evaluated. Two ammonia decomposition systems (pre-catalytic and integrated ammonia decomposition systems) were designed to investigate the best method for hydrogen production at a low cost. The decomposition process of blue ammonia was carried out at low-pressure of 0.3 MPa and maximum temperature of 500°C. Pure hydrogen was separated using palladium membrane and PSA unit was used for nitrogen (N_2) gas separation. NH_3 decomposition processes were simulated using the CHEMCAD program. The effects of operating parameters, such as feeding pressure, NH_3 flow rate, and temperature, were analyzed. Techno-economic evaluation studies were conducted and compared for both systems.

Proposed NH_3 decomposition systems

Two ammonia decomposition system configurations were designed to evaluate small-scale hydrogen production. A good ammonia cracker system should include heat and mass transfer as well as process materials. A detailed blue ammonia cracker design is important for total heat duty calculations, which also results in a more accurate economic assessment. Blue ammonia is decomposed in the catalytic reactor, and the resulting hydrogen is separated using a Pd- membrane foil in another membrane reactor. The palladium and palladium-based alloys membranes have the ability to separate H_2 with high purity.

Configuration A

In this process simulation, the catalytic ammonia and membrane separation reactors were simulated using the CHEMCAD program. Two separate reactors were used for pure hydrogen production in the current ammonia configuration cracker. The process flow layout of the pre-catalytic system, named configuration A, is shown in Figure 3. The first reactor was utilized to decompose ammonia into hydrogen and nitrogen gases, while the second reactor was a membrane reactor used for hydrogen separation. The required heat is generated from the NH_3 combustion reactor (7), and ammonia and hydrogen were utilized as fuel. Combustion air, feeding NH_3, non-reactive ammonia, and hydrogen were mixed before being injected into the combustion reactor. The decomposition process of ammonia was performed at a low temperature and pressure of 500°C and 0.3 MPa, respectively. Heat exchangers were used for preheating the combustion air and ammonia before feeding into the catalytic reactor. In addition, the product

gases from the ammonia decomposition reactor were cooled to 350°C before entering the membrane reactor. The hydrogen permeance of the Pd- membrane thickness of 20 μm was adjusted at 2 × 10^{-6} mol/m²/s/Pa. The operating pressure was 0.3 MPa on the retentate side while the permeate pressure was 100 mbar. The separation process of hydrogen gas from the membrane reactor was operated at a temperature of 350°C and a vacuum pump was used to generate the driving force for the permeation. Nitrogen (N_2) gas was separated using a PSA unit, while the remaining non-reactive ammonia and hydrogen were mixed with ammonia fuel. The reason for decomposing ammonia in a separate reactor is to exploit the total membrane surface area for higher permeability of hydrogen gas. However, the ammonia decomposition and hydrogen separation processes are combined in one reactor, which is expected to lead to a decrease in the hydrogen permeation rate because of the presence of catalytic materials and a high ammonia decomposition temperature.

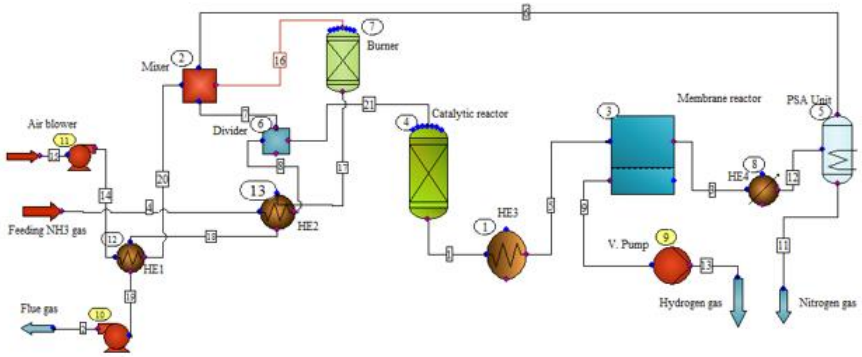

Fig. 1. Configuration A process flow layout.

Configuration B

Figure 2 depicts the integrated NH_3 decomposition system, named configuration B. In this simulation analysis, the decomposition of NH_3 gas was carried out at atmospheric pressure and a temperature of 450°C. The Pd- membrane was designed to be installed in the same ammonia catalytic reactor. Configuration B shows two separate reactors designed to operate under the same conditions as those for the simulation analysis. Indeed, both reactors were combined as integrated reactors that include both reactor functions. The retentate pressure was adjusted to 0.3 MPa, while a vacuum pump was installed at the hydrogen permeation side to generate a pressure of 100 mbar. Hydrogen separation and purification occurred inside the integrated catalytic reactor, while the retentate stream was cooled down and then passed to the PSA unit for nitrogen separation. The outlet gas flow stream from the PSA unit was fed to mix with the NH_3 fuel and then passed into the combustion reactor. The combustion air was preheated by the outlet high-temperature combustion product gases.

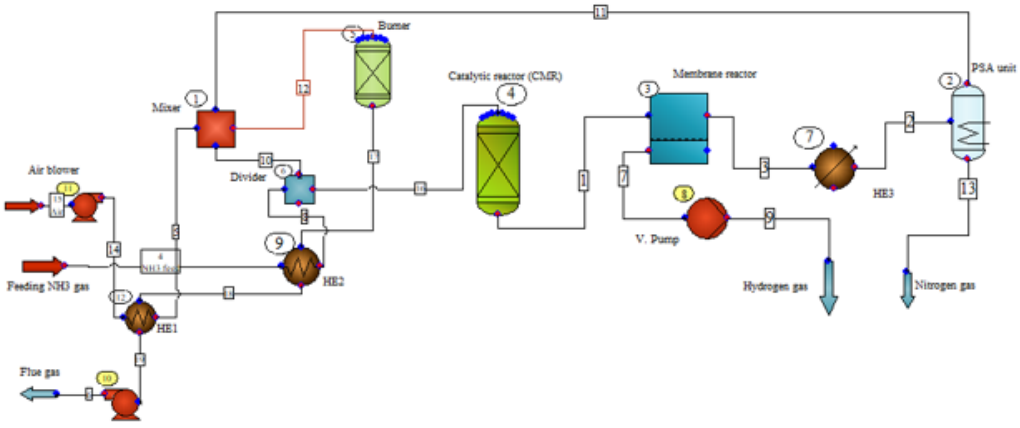

Fig. 2. Configuration B process flow layout.

RESULTS AND DISCUSSION

The hydrogen and nitrogen production costs for both configurations are shown in Figure 3. The results showed that the total hydrogen production cost of configuration A is greater than that of configuration B. Although the energy consumption is an important factor in cost estimation, the total cost of configuration B is high. The cost of blue ammonia as the main feedstock is considered as the main parameter controlling the hydrogen production cost. The total H2

production cost of the proposed hydrogen production system using configuration A was 5.33 €/kgH2, while that of configuration B was 5.05 €/kgH2. The hydrogen production cost using different ammonia types are compared in Figure 4. The results of the H_2 production cost from using gray ammonia as a raw material has lower economic results than the blue and green ammonia. The hydrogen production cost from the advanced NG steam reforming process with CCUS is higher than the NH_3 synthesis without the CCUS because the ammonia price is influenced by NH_3 as raw material cost.

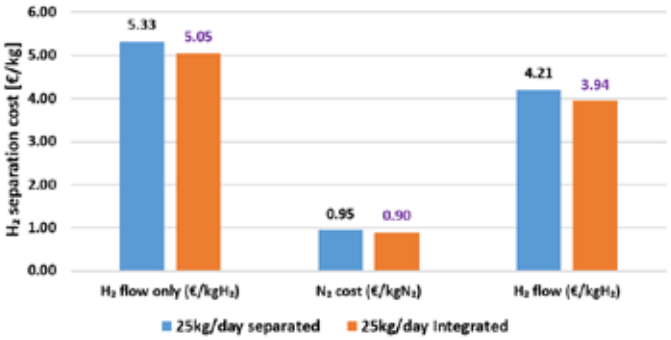

Fig. 3. Comparison of hydrogen separation cost of both systems.

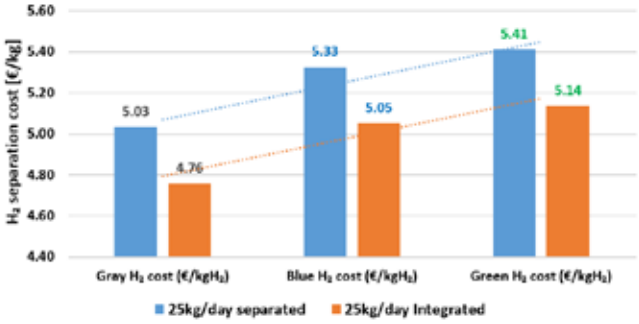

Fig. 4. The 25 kg/day hydrogen production cost from different NH_3 types.

CONCLUSIONS

A techno-economic analysis of pure hydrogen production from green ammonia was performed. Two proposed configuration systems were successfully designed and simulated for small-scale hydrogen production (25 kgH_2/day). It was found that the energy efficiency of the integrated system was higher than that obtained from separated system configuration A. The produced hydrogen flow rate and energy efficiency were enhanced with the increase in pressure from 0.1 to 0.3 MPa. A metal-based membrane was utilized to produce high-purity hydrogen. A techno-economic assessment was carried out for both suggested small-scale hydrogen production from blue ammonia. It was found that the total H_2 production cost of the proposed hydrogen production system using configuration A was 5.33 €/kgH_2, and that of configuration B was 5.05 €/kgH_2. The proposed plant configurations generated hydrogen and nitrogen; therefore, the total cost was distributed for hydrogen and nitrogen production. The H_2 and N_2 costs of configurations A and configuration B are 4.21€/kgH_2 and 0.95€/kgH_2, and 3.94€/kgH_2 and 0.90€/kgH_2, respectively.

TECHNO-ECONOMIC ANALYSIS OF 350 BAR LOHC-SUPPLIED HYDROGEN REFUELING STATIONS FOR HEAVY DUTY VEHICLE FLEETS

[1*] *Stefan Aschbrenner,* [2] *Tobias Eissler,* [3] *Marius Schneider,* [4] *Christopher Voglstätter*
[1,2,3,4] Fraunhofer Institute for Solar Energy Systems ISE, Heidenhofstrasse 2, 79110 Freiburg, Germany

ABSTRACT

The cost of hydrogen at a refueling station depends mostly on two factors, the hydrogen production itself and the hydrogen supply chain. For both there are different options with LOHC that are in the focus of several scientific discussions. The aim of this work is to contribute to this discussion a techno-economic comparison of a 350 bar Liquid Organic Hydrogen Carrier (LOHC)-supplied hydrogen refueling station (HRS) with a standard HRS. The analysis was focused on supplying hydrogen for a fleet of busses or trains with a total daily hydrogen demand of around 1.2 t/d. A dehydrator required to release the hydrogen from the LOHC as well as other standard components of an HRS were dynamically modelled and optimised depending on various demand profiles of the vehicle fleets using the inhouse simulation software H2ProSim. The results show specific refueling costs (HRS only) of between 2.1 €/kg and 3.3 €/kg for the LOHC-HRS scenarios investigated and a minimum of 0.89 €/kg can be obtained for a standard HRS. This cost difference is mainly caused by the high energy cost of the dehydrator and the added CAPEX. Furthermore, a smart demand management on the vehicle side can lead to significant cost reductions for the HRS infrastructure.

Keywords: Hydrogen Refueling Station, LOHC, Compressed Hydrogen, Refueling Cost

INTRODUCTION

To the present day more than 90% of the energy used in the mobility sector in germany is fossil based [1]. Solutions for the conversion of this sector to low-or zero carbon energy carriers need to be provided promptly to meet the ambitious CO_2 reduction targets for vehicle fleets. Electric batteries, hydrogen and synthetic fuels take up the challenge to replace fossil fuels in transportation. Hydrogen offers a compromise in terms of energy density and tank-to-wheel efficiency. Adding a given predictability in fuel demand especially Heavy Duty Vehicles (HDV), such as regional fuel-cell buses and trains are promising first applications [2]. For these applications, hydrogen refueling stations are required. With almost one hundred stations up and running in Germany alone, the most common HRS design is based on the supply of CGH2 for passenger cars, and consequently with small capacities (kg/d) [3]. To supply HDV fleets an upscaling of the HRS in terms of capacity is crucial. In this context, hydrogen transport via CGH2 trailer is facing capacity limitations. The use of Liquid Organic Hydrogen Carriers (LOHC) is analysed to be economically advantageous, regardless of distance, especially for the transport and storage of quantities of up to 10 tH2/d [4]. In this context the objectives of this publication are to provide novel insights into cost structures of a LOHC-HRS, identifying cost drivers and technical limitations, evaluating economical feasibility and analyse the footprint of such HRS infrastructures – all analysis in comparison to CGH2-HRS as the current standard approach to hydrogen refueling. The work was carried out as part of the Kopernikus P2X project, which aims to create a synergy between industry, academia and civil society on the subject of energy transition, whereby the subproject P2X includes research on the conversion of renewable electricity into gaseous or liquid energy carriers, plastics and chemicals.

MODELING APPROACH

First of all, a basic design of a LOHC-supplied hydrogen refueling station for a fleet of buses or trains with a tank pressure of 350 bar and a daily demand of 1200 kg_{H2} was created. A process flow schematic of the design is displayed in Figure 1.

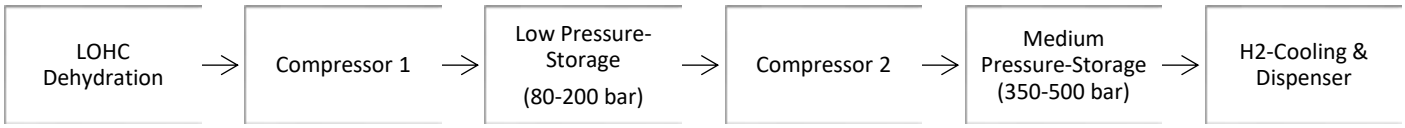

Figure 1. Process flow schematic of the basic LOHC-HRS design

According to this basic design, a dehydrator required to release the hydrogen from the LOHC as well as other HRS components, such as compressors, storage tanks and dispensers were modelled using the inhouse simulation software H2ProSim. Additionally, several refueling profile scenarios of the vehicle fleets were created (Table 1).

Table 1. Overview of the refueling profile scenarios

	Busses 1	Busses 2	Trains	Trains & Busses	Busses 3	Busses 4
H2 demand [kg/d]	1200	1200	1320	1210	~853	~494
Refueling profile	20x busses backtoback, two time slots / day	2x busses backtoback / 72 min	1x train / 8 h	1xTrain / 12 h + 1xBus / 2 h	Real dynamic profile, 7 days	Real dynamic profile, 28 days

Following a bottom-up cost approach depending on the optimized design parameters of the HRS components, the CAPEX and OPEX are determined via a cost model based on own cost data and functions, which is based on quotations from manufacturers. The technological part of the model is based on a dynamic thermodynamical simulation of the main components. (see Figure 1); for each demand scenario rated compression capacity of the compressors and volume of the storage tanks were optimized via a genetic algorithm with the optimisation objective minimum specific refueling cost for the whole HRS model. The calculation of the hydrogen refueling costs is carried out using the annuity method. The gas price was assumed at 0.045 €/kWh and the electricity price at 0.178 €/kWh. For one of the scenarios, rough footprints of the LOHC-HRS and a classic HRS design were calculated by a foot printanalysis tool of H2ProSim by utilizing footprint data of the individual components including German regulations concerning hazard zones and fire safety measures.

RESULTS AND DISCUSSION

The results in Figure 2 show specific refueling cost for the 350 bar CGH_2 trailer supplied HRS of 0.89 €/kg_{H2} and significantly higher cost of 2.39 €/kg_{H2} for the LOHC based solution, both for the same vehicle fleet and demand profile. For the LOHC-supplied HRS (left), OPEXs are dominated by energy costs (approx. 85-90 %), followed by maintenance costs of the dehydration system (approx. 5-10 %). As a result, energy supply costs also account for almost 50 % of the specific refueling costs. Thereby, half of the energy supply cost comes from heating the dehydrator and the other half is from the required electrical energy for the compression. Two other cost drivers are the LOHC dehydrator and compressor CAPEX (both 18% share). The high share of the H2 storage costs in the 350 bar trailer supplied HRS reflects the need for large storage volumes to supply the demand of the vehicle fleet at all time, which is chosen by the optimization algorithm due to the low part load capability of the dehydrator and its high costs.

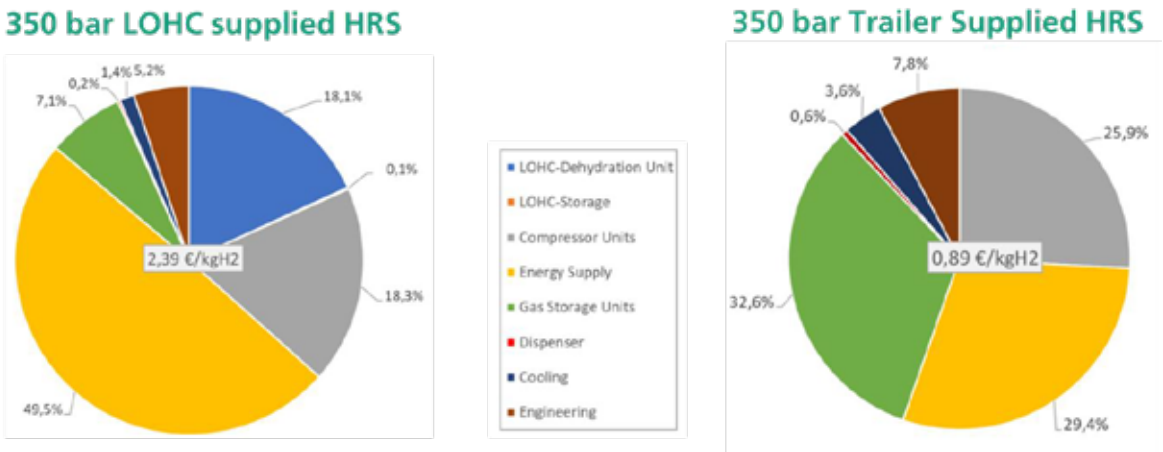

Figure 2. Comparison of the specific refueling cost [€/kgH2] and cost structure of LOHC supplied HRS (left) and conventional supply by CGH2 trailer (right), 1200 kg_{H2}/d

A total footprint of 738 – 1005 m² depending on the placement of fire protection walls for the 350 bar LOHC refueling station and data from literature states a footprint of 734 – 894 m² for the CH2 trailer supplied HRS [5]. From both values it could be deduced that the benefit of placing LOHC-storage tanks underground could be reduced or nullifiedby the space requirements for the dehydrator system. However, it must be mentioned that the footprint calculations represent a rough estimation and is not based on a detailed installation plan. Figure 3 displays the results of a sensitivity analysis of different refueling profiles, based on the investigated vehicle fleets, for the LOHC-HRS.
Figure 3 shows the impact of different refuelling profiles on hydrogen refuelling costs for the LOHC based refuelling stations. A more evenly distribution of the refuelling processes over time instead of concentrating the refuelings in two time slots results in lower CAPEX, since the HRS components can be dimensioned smaller, their utilization can be increased and thus the coupling with the rather continuous H_2 release from the LOHC dehydration process

improved. This CAPEX advantage reflects in the specific refuelling costs and can reach a difference of up to 0.5 €/kg_{H2} between scenarios with the same daily H_2 demand. The train scenario or a combination of trains and bus fleet offers slight cost advantages compared to the bus fleet scenarios due to better utilization of the LOHC-HRS components and smaller compressors required. It also causes higher costs for 500bar storage due to the large tank sizes (up to 2 x 94kg) compared to busses (roughly 34 kg) which required large storage for refueling in the required time.

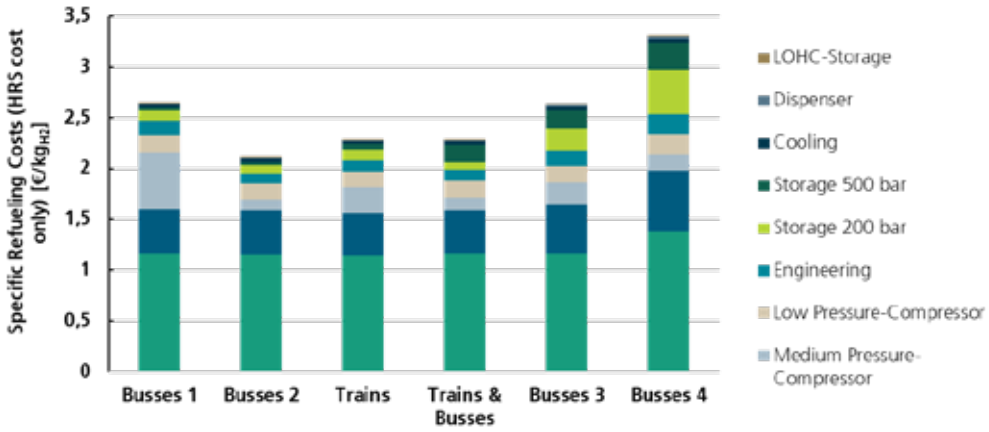

Figure 3. Results of the sensitivity analysis of different refueling profiles for a LOHC-based HRS

CONCLUSIONS

Looking only at the cost of a 350 bar HRS, a solution based on H_2-supply via LOHC is not economically competitive to a CGH_2-trailer supplied HRS in the assumed scenarios. However, the picture can change if the whole H_2 supply chain including preconditioning and transport would be part of the scope as well. Furthermore, it becomes clear that measures to reduce the energy demand for dehydration are crucial. Research activities in this direction are being undertaken and include the usage of LOHC materials with improved properties, such as Benzyltoluene (BT) and heat integration solutions. A smart refuelling strategy of a vehicle fleet can have a significant impact on the specific refuelling costs of a LOHC-HRS. Considering the estimated footprints and the fact that bus depots are preferably placed in inner city locations with high prices for land, costs for their expansion by adding HRS infrastructure can be significant.

ABSTRACT

Hydrogen is a promising energy storage and generation alternative to ensure that renewable energy sources are available to meet all energy needs in the long term. Many factors should be considered for sustainability of the environment while designing a hydrogen supply chain which consists of different production, storage, and transportation methods. Hydrogen energy is a new and innovative area especially for developing countries, so there can be high uncertainty during the decision process because of lack of expertness. In this study, available hydrogen production alternatives of Turkey are evaluated by using an integrated Pythagorean fuzzy AHP and interval type-2 fuzzy TOPSIS based methodology by considering technical, economic, environmental, and social aspects.

Keywords: AHP, Hydrogen production, Interval type-2 fuzzy set, Pythagorean fuzzy set, TOPSIS.

INTRODUCTION

Energy consumption overall the world is increasing day by day. Therefore, renewable energy (RE) sources gained importance for providing sustainable environment. However, the energy production capacity of the RE power plants are fluctuating because of the environmental dependencies of them. This issue hinders to trust the RE sources to handle the basal electricity demand. Hydrogen is a promising energy storage alternative that gives ability to transport with different techniques to use for different purposes. Hydrogen energy can be produced from multiple clean sources. It can also be produced from fossil fuels, which is an important advantage in making the hydrogen a sustainable energy storage method for the gradual transition to clean energy sources.

In recent years, research on hydrogen energy (HE) has gained momentum in Turkey as well as in the world [1]. As a comprehensive study, Hydrogen Technologies Association published a hydrogen technology (HT) roadmap report in 2021 explaining hydrogen production, storage and transportation techniques and presenting a future projection for potential usage area in Turkey [2]. Turkey has high potential for rapid dissemination of hydrogen energy because Turkey holds 72% of the total boron reserves of the world and the boron minerals can be used for carrying hydrogen [3] and has the largest geothermal energy resources in Europe [4]. There are several studies investigating the natural resources of Turkey in the direction of hydrogen production capabilities. Karayel et al. analyzed the green hydrogen production potential of the cities of Turkey with solar energy [5] and wind energy [6]. Genç et al. [7] evaluated four locations in terms of their hydrogen production capacities via electrolysis (ELE) systems supplied by wind energy. Uysal et al. [8] focused on the hydrogen production from the ELE of water by comparing the potential of the coastal seas, biggest lakes, and rivers. Coşkun et al. [9] examined the annual biogas and hydrogen production potential of Turkey from a milk-processing wastewater. Eroğlu et al. [10] conducted a comparative study with four olive mill wastewater types to investigate the hydrogen gas production amounts of them.

Hydrogen energy investments should be made by considering the accordance with multiple factors such as international standards and the environmental effects, cost, and technical restrictions. The expertness and the operating experience about HT are not sufficient in Turkey so the decisions about HT investments include high uncertainty. The traditional uncertainty modeling approaches may not yield applicable decisions about the HT investments because of the high uncertainty. In this study, the best hydrogen production alternative is decided by using a hybrid Pythagorean fuzzy AHP and interval type-2 fuzzy TOPSIS based methodology to be able to model high certainty in MCDM process.

MATERIALS AND METHODS

Decisions about HE investments include high uncertainty because of lack of expertness and environmental factors. FST is the most popular approach for modeling the uncertainties of real-life problems. In FST, the uncertainty is modeled with the membership degree concept. A set element can be both member and non-member of the set partially at the same time [11]. It should be noted that the use of Fuzzy Set Theory (FST) in multi-criteria decision making (MCDM) has provided important breakthroughs [12]. The study aims to decide the best hydrogen production method in Turkey by considering the uncertainty. An integrated two-stage methodology has been developed to

evaluate the hydrogen production alternatives depending on multiple criteria. Steps of the methodology are seen in Fig. 1. In the first stage of the methodology, weights of the criteria are decided by using Pythagorean fuzzy AHP and the alternatives are ranked by using interval type-2 fuzzy TOPSIS in the second stage.

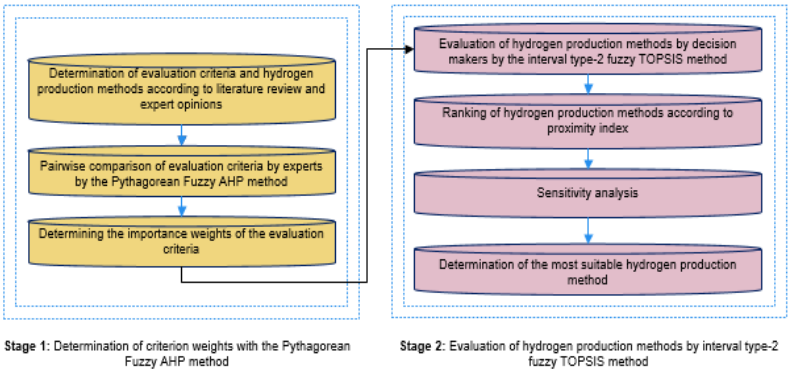

Fig. 1. Methodology

Pythagorean Fuzzy AHP

Traditional Fuzzy Sets (FSs) may not fully address the uncertainties related to decision making. Pythagorean FS (PFS), proposed by Yager [12] as an extension of Intuitionistic FS (IFS) to handle the uncertainties having indeterminacy and inconsistency about the evaluations. Owing to these advantages, it has begun to be applied to MCDM problems [13, 14]. AHP is brought to the literature by Thomas L. Saaty [15] as one of the MCDM methods. AHP facilitates the decision-making process by systematizing the assessment of alternatives' suitability to the criteria. In this way, decision makers can determine the best alternative in terms of satisfying the criteria. It also increases the decision maker's understanding and knowledge of the problem definition and components [16]. However, there are some limitations about the full reflection of human thoughts to the decision process in AHP. Fuzzy AHP has emerged by combining a concept of AHP and FST to eliminate this limitation. Instead of the deterministic evaluations of traditional AHP, the comparison ratios are determined as a series of values in fuzzy AHP. Then, PFSs were also integrated to AHP to gain the advantages of PFS theory to the decision process. In this methodology, decision makers use linguistic terms that are representing Pythagorean fuzzy numbers, which provide the ability to make more flexible assessments, rather than just assigning a precise number for evaluations [17].

Interval Type-2 Fuzzy TOPSIS

If the parameters of the uncertainty are determined faultlessly, traditional FSs can be preferred for modeling. However, the characteristics of the uncertainty can be complicated, and its parameters may not be determined easily in some real case problems such as decision making in a highly innovative field. Zadeh proposed Type- 2 FSs (T2FSs) to make it possible to model high uncertainties in which the uncertainty parameters are also uncertain variables [18]. Traditional FSs have two-dimensional membership function, while type-2 fuzzy sets are three-dimensional, and this third dimension provides additional flexibility in uncertainty modeling [21]. Nevertheless, the difficulty of making evaluations and calculations with such detailed data increases significantly. Therefore, Mendel et al. [19] extended the T2FS concept by integrating with interval-valued numbers to reduce the complexity of the operations, and proposed Interval Type-2 Fuzzy Sets (IT2FSs) whose membership function parameters are interval-valued numbers. Membership degrees are defined by a subrange in [0, 1] interval, rather than a single value as T1FS so the decision maker has more flexibility while assigning membership degrees. In this way, flexibility is almost preserved, while providing ease of operation compared to T2FS [20]. Because of these advantages, IT2FSs are widely used in MCDM problems in the literature. One of the most popular MCDM techniques is fuzzy TOPSIS in the literature that was developed by Hwang and Yoon [22]. Fuzzy TOPSIS also has limitations about representing the uncertainties because of being developed based on traditional fuzzy sets [23]. Chen and Lee [24] proposed interval type-2 fuzzy TOPSIS method to enable more realistic and flexible evaluations [25]. Decision makers have the opportunity to make assessments more freely without being too constrained by the method. Such a relaxation allows obtaining more reliable results in the cases where uncertainty is high.

Evaluation of Hydrogen Production Methods

As a preliminary step of the study, success factors for evaluation of hydrogen production methods were decided based on the literature review and the opinion of 3 experts and the criteria set was decided as shown in Fig. 2.

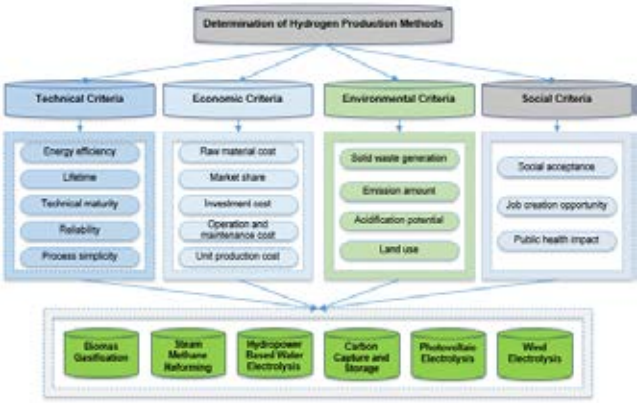

Fig. 2. Evaluation Model

The criteria were evaluated by the experts via Pythagorean fuzzy AHP method and the importance weights of the criteria were obtained. These importance weights were used as criteria weights in the decision process of interval type-2 fuzzy based TOPSIS method. According to the results yielded by the methodology and the sensitivity analysis, wind electrolysis has been decided as the most suitable hydrogen production method for Turkey within the current conditions.

CONCLUSIONS

Turning to renewable energy sources is essential for a sustainable environment. However, the energy production capacities of the renewable energy-based power plants are not stable because of the environmental conditions. Hydrogen is an effective energy storage alternative with low storage cost and the ability to transport with different techniques for the renewables. Hydrogen can also be produced from fossil fuels, which is an important advantage in making hydrogen a sustainable energy storage method for the gradual transition to clean energy sources. Turkey has high a potential for proliferation of hydrogen energy owing to the rich natural resources. Depending on this, hydrogen energy related studies gained attention in Turkey. Because of being an innovative field, the expertness about hydrogen technologies is inadequate in Turkey, therefore hydrogen energy related decision processes include high uncertainty. Traditional uncertainty modeling approaches may not produce beneficial results because of the lack of expertness-related high uncertainty. In this study, the best hydrogen production alternative is decided by using an integrated hybrid Pythagorean fuzzy AHP and Interval type-2 fuzzy TOPSIS methodology. As a future study, the best production, storage, and transportation combination can be decided to build the most effective hydrogen energy supply chain.

ABSTRACT

With the increase in digitalization, the demand for energy is increasing day by day. Web 3 version, IoT technologies, social media platforms, rapidly increasing online worlds with online games and the popularization of crypto technologies make people dependent on energy. One of the most important problems of crypto and metaverse technology is the insatiable use of electricity. The current research uses a PEM fuel cell system as a renewable energy source to meet the electricity demand required for crypto mining. The required amount of hydrogen and equipment for the fuel cell system are explained.

Keywords: Metaverse, Coin mining, Cryptocurrency, PEMFC, Hydrogen

INTRODUCTION

In the rapidly digitalizing and virtualizing age, the world's energy demand is increasing significantly. Since its rebranding as "Meta," Facebook has come up with the idea of an immersive virtual reality world. To create a world where traditional money is replaced by encrypted alternatives and where each user can shape everything according to their own purposes. This world is fundamentally reimagined as something physical, three-dimensional, with the internet and all its services, a reality that our digital avatars can navigate. In this digital world universe, you can instantly teleport as a hologram from your commute to the office, to a concert with your friends, or to be in your parents' living room to catch up. There will be many different technologies that enable this greater vision of the metadatabase as a convergence of physical and digital, or our digital lifestyles that capture our physical lives. Some technologies are currently in use, such as virtual reality glasses and blockchain. In order for the digital world to approach reality, many technologies such as haptic technologies need to be developed. This means that internet speeds still need to be greatly improved for the metadata store to function fully. It will require incredible connectivity and internet speed of 5G and beyond.

A digital currency was created to be developed with a technology that can prevent duplication of documents as well as modern digital communication. Although technologies were developed to make this currency safe, it was not enough to create digital money [1-2]. The biggest impact on this technology has occurred with the publication of the Bitcoin whitepaper [3]. The effort to write data to Bitcoin's blockchain is rewarded with transaction fees paid by users and the emission of newly minted digital currencies. Anyone can try to write a valid block of transactions to the distributed ledger, but the network will only accept it if they are the first to create a digital signature, known as a hash. An effort to generate a hash is an energy-intensive process called cryptocurrency mining, which, in the case of the Bitcoin network, requires the use of custom-built computational hardware known as ASICs (Application-Specific Integrated Circuits). The higher the mining capacity or hash rate a participant has, the higher the chance of being the first to find the right digital signature for the next block of transactions. The current proof-of-work infrastructure relies heavily on electrical power [4]. According to the University of Cambridge's bitcoin electricity consumption index, bitcoin miners are expected to consume roughly 130 Terawatt-hours of energy (TWh), which is roughly 0.6% of global electricity consumption. This consumption was 75 TWh in January 2020 [5].

Due to Metaverse and digital money technologies, which are rapidly increasing in popularity and use, as well as social media platforms, a high amount of energy is required to ensure both the protection of the emerging big data and the existence of the virtual world uninterruptedly. Today, the largest energy source for the world is still fossil fuels with high carbon footprints. Although the development in renewable technologies is visible, it is not sufficient to store and maintain energy. For this reason, Hydrogen energy, which is an alternative energy source, is an efficient energy carrier and storage that has been defined so far and can be obtained from both renewable and non-renewable sources.

In this study, a general point of view is discussed in terms of providing the energy that needs to be provided continuously for Metaverse and crypto money technologies from renewable hydrogen production sources. Necessary calculations were made by considering some critical factors such as the absence of a value chain for clean hydrogen, storage and transportation of hydrogen, high production costs, lack of international standards and investment risks.

MATERIALS AND METHODS

The general method applied in the present research is to first determine the number of mining units according to the size of the operation being decided; Then, based on this number, the power required to run these miners is calculated. The next step is to calculate the amount of hydrogen gas required for the PEMFC module to generate the required electricity. The massive computing power required for the Bitcoin network has been calculated with CPUs and GPUs, FPGAs and ASICs [7-8]. While the energy efficiency of these units increases over time, their “energy consumption” ” and its results still remain the determining factor in miners' decision to operate in this market and their profit or loss margins [9]. Bitcoin mining hardware and cost are summarized in Table 1.

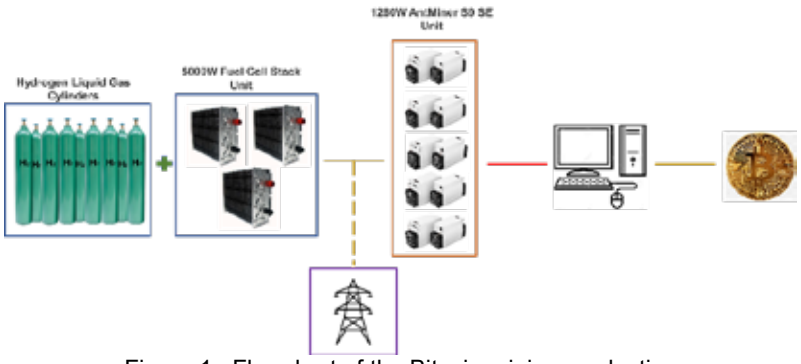

Figure 1. Flowchart of the Bitcoin mining production

There are several factors to consider when choosing the appropriate hardware and software for mining. The first is the cost of mining equipment, which depends on the hash rate and lead time; this cost is usually measured in terms of GHs. The second factor is energy costs; miners will prefer the equipment with the lowest power consumption as they are the most efficient and their heat emissions are relatively low. The third factor is the difficulty, an arbitrary dimensionless value that measures how problematic it is to find a hash below a given target. The difficulty would be recalculated every 2016 blocks, based on the assumption that if everyone was mining at this difficulty level, the 2016 blocks would be resolved in exactly 2 weeks [10].

Table 1. List of the Bitcoin mining equipment

Hardware generation	Device	Hash rate (Mhash/s)	Energy efficiency (Mhash/J)	Price ($)
Central Processing Unit (CPU)	Core i7 950 Atom N450	18.9 100	0.12 0.31	86 $
Graphics Processing Unit (GPU)	ATI 4850 ATI 5770	101 214.5	0.92 1.95	25 $
Field Programmable Gate Array (FPGA)	The Single Rig Box	832 50,000	10.40 20.40	140 $
Application-Specific Integrated Circuit (ASIC)	AntMiner S9i	14×1012	10,606	351 $
PEMFC	Hydrogen Fuel Cell 6000W Pem Electricity Generator	-	-	658 $
Hydrogen Gas	-	-	-	4.23 €/kgH2

RESULTS AND DISCUSSION

In this situation, the Bitcoin Blockchain's difficulty is increased by 1% per month for a period of four years, calculating an average difficulty value for each year. Then the BTC production of that year is calculated from these average difficulties. In PEMFC-based cases, electrical energy consumption, the CAPEX consists of; the Cost of the AntMiner S9 SE ($351 for each unit), the cost of an adequate power supply unit ($86 for each unit], the OPEX includes; Operation & Maintenance costs of mining and power supply units which are calculated as 5% of the corresponding CAPEX, electricity cost which is calculated by multiplying the electricity consumption (kWh) by the price of electricity

($/kWh) in each country. The cost of Hydrogen gas produced by grid-connected electrolysis has been calculated as approximately 4 €/kgH2 in Europe. Scenario-based analyzes of the current markets have shown that the system can make a profit if the products are fully purchased at prices above 20 €/kgH2. All of the system prices are 6020 $.

CONCLUSIONS

Cryptocurrency mining appears to be playing an increasing role in the transition to a clean, modern and more decentralized energy system. Miners can provide grid balancing and flexible demand response services and improve renewable energy integration. Cryptocurrency mining around the world is done with energy from hydroelectric, coal and natural gas. In order to meet the increasing demand day by day, cleaner and sustainable energy technologies are sought. In this study, the place that hydrogen energy can take in this production is discussed. It should be proven that the amount of carbon footprint, which is expected to increase with digitalization, can be reduced with renewable energy technologies. The energy industry, especially intermittent power producers based on natural energy sources, will be able to benefit from this hedging mechanism. Cryptocurrency mining may be preferred due to the simplicity of mining infrastructure construction, maintenance and cost-free migration. The findings of this paper could create incentives for the production and sale of cryptocurrency issued by energy producers, encouraging more timely completion of planned renewable power units. Investors in renewable power plants also benefit from this transition strategy, as they can generate higher returns with lower risk on their capital. Such a transition option can increase profitability while reducing risk, and its widespread use could stimulate the growth of the construction of new renewable energy sites globally.

ABSTRACT

Syngas is a mixture of CO and H_2 formed during the gasification process of coal and biomass. Additionally, H_2S is undesired gasification products of fossil fuels with high sulfur content. H_2S causes serious problems, such as catalyst poisoning and pipeline corrosion during production process of fuel from syngas. Hot gas desulfurization (HGD) enables to reduce the sulfur contents of the gasification products by eliminating thermal losses of endothermic syngas processes. This study aims to develop regenerable sorbents to remove H_2S from hot flue gas. Unsupported and SBA 15 supported Ca-based binary mixed metal oxides (CaO-CuO, CaO-FeO, CaO-MnO, CaO-ZnO) were synthesized as sulfur sorbents by wet impregnation method. The crystal structure of sorbents was determined by X-ray diffraction (XRD), while BET analysis was used to determined the surface area and pore size distribution of the Ca based mixed metal oxide sorbents. The initial results of the XRD and BET analysis revealed the mixed metal oxide formation and high surface area of SBA 15 supported sorbents, respectively. Desulfurization performance of the sorbents was examined by gas chromatography analyzer equipped with Flame Photometric Detector. The best desulfurization performance with breakthrough sulfur capacity of 22.72 g S/100 g sorbent and 46.65% capacity usage ratios was obtained for CaO-CuO adsorbent.

Keywords: Desulfurization, Ca-Based Sorbents, SBA 15, Mixed Metal Oxide

INTRODUCTION

The increasing fuel consumption in the world leads to serious environmental problems. Gasification is one of the important alternative technologies for the environmentally friendly energy production. However, H_2S which is highly toxic and corrosive, is a gasification product of fossil fuels with high sulfur. Furthermore, since fuel production from syngas is endothermic process, H_2S should be removed from the hot gases without cooling. As a result, hot gas desulfurization (HGD) enables to reduce the sulfur contents of the gasification products by eliminating thermal losses.

Metal oxides are thermodynamically favorable sorbents for sulfur removal [1, 2]. Ca oxide is one type of sulfur sorbents having a high sulfur capture ability. Since it is both accessible easily and economical, Ca based adsorbents were preferred in this study. In a previous review study, Meng et al. was reported that naturally available Ca based sorbents such as dolomite and limestone can be used to remove sulfur [5]. Abbasian et al. found that sulfur capture efficiency is independent on temperature and it is higher for dolomite than limestone due to the difference in pore structure. The presence of $MgCO_3$ in dolomite allows the higher porosity and less sintering of CaS [6]. Compared to limestone and dolomite, calcium acetate and calcium magnesium acetate were reported as more effective sulfur sorbents due to their higher surface area and porosity [3-5]. One of the main drawbacks of the Ca based sorbent utilization is defined as the $CaSO_4$ formation during sorbent regeneration. Since $CaSO_4$ is very stable, sorbent regeneration becomes unfavorable [5]. The utilization of support materials and mixed metal oxides can be considered as alternative solution to solve the $CaSO_4$ formation. Yang et al. studied sulfur removal performance of calcium silicates and the silica supported lime as regenerative sorbents. They reported that the most of calcium silicates and silica supported calcium oxide are more reactive than pure calcium oxide. The regeneration rates of these sorbents were found higher than that of calcium oxide [7]. At that point, the utilization of silica based SBA 15 and Ca based mixed metal oxides can be considered as sulfur sorbent alternates.

In this study, unsupported and SBA 15 supported CaO-CuO, CaO-FeO, CaO-MnO, CaO-ZnO were selected as sorbents. Their preparation methods, characterization, and sulfur removal performance results are summarized in the following parts.

MATERIALS AND METHODS

Synthesis and characterization of Ca based mixed metal oxides sorbents

Wet impregnation method was used to prepare the Ca based mixed metal oxides. After Ca $(NO_3)_2{\cdot}4H_2O$ was dissolved in deionized water, other metal (Cu, Fe, Mn, and Zn) nitrates were added in 1/1 (wt/wt) ratio. The metal nitrate precursors were mixed by magnetic stirrer for 2 hours. The solution was dried at 105°C over night. The dried solid mixture was calcined at 550°C under air stream for 5h. SBA 15 was used as a support material synthesized in our laboratory, and Ca-based metal oxides were loaded on SBA 15 by again wet impregnation method.

Crystal structure of Ca based mixed metal oxides were determined by X-ray diffraction (XRD) (Panalytical Empyrean model, Anode material, Cu 1.56 A wavelength). Micromeritics 3Flex 3-port BET device was employed to analyze the surface structure of the sorbents in the presence and absence of SBA 15.

Desulfurization testing of Ca based mixed metal oxides sorbents

Sulfidation performance of Ca based sorbents is tested by using Agilent 6890N model gas chromatography analyzer equipped with Flame Photometric Detector.

RESULTS AND DISCUSSION

BET Results

BET results of unsupported and SBA 15 supported Ca based sorbents are presented in Table 1. As seen in Table 1, surface area and pore volume of the Ca based sorbents are significantly higher in the presence of SBA 15 than in the absence of SBA 15. The BET findings revealed the metal oxide deposition inside SBA 15 hexagonal channels.

Table1. BET results of supported and unsupported Ca based metal oxides.

Sorbent	Surface area (m^2/g)	Pore size (nm)	Pore volume (cm^3/g)
CaO-CuO	3.94	11.58	0.011
CaO-FeO	2.51	6.77	0.004
CaO-MnO	5.07	15.07	0.019
CaO-ZnO	3.21	6.59	0.005
SBA 15	763.20	6.38	1.217
CaO-CuO on SBA 15	143.21	10.34	0.370
CaO-FeO on SBA 15	151.58	9.99	0.378
CaO-MnO on SBA 15	152.64	10.56	0.403
CaO-ZnO on SBA 15	139.80	10.46	0.365

When the pore size distribution of unsupported and SBA15 supported sorbents is compared, the expanding pore size distribution in the presence of SBA 15 can be interpreted as the stable metal oxide loading on SBA 15.

XRD Results

In order to determine the metal oxide formation, the specific Bragg angle values of metal oxides were employed. The crystal structure of SBA 15 supported sorbents is shown in Figure 1. As seen in the figure, XRD patterns of metal oxides indicate the metal oxide formation.

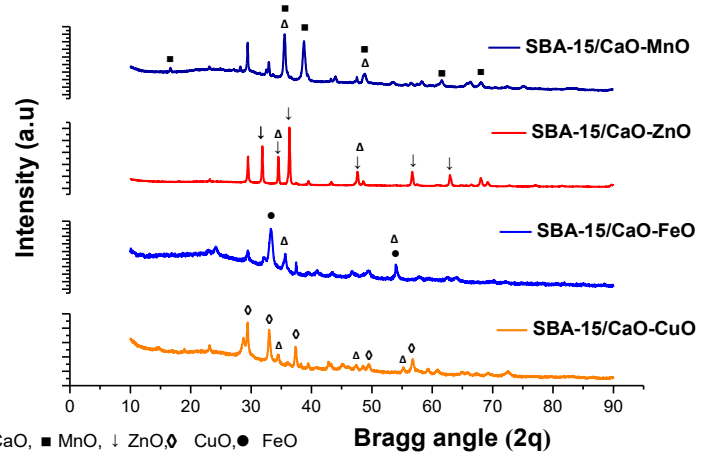

Figure 1. XRD patterns of SBA 15 supported CaO-ZnO [8, 9], CaO-FeO [8, 10], CaO-MnO [8, 11] and CaO-CuO [8, 12] mixed metal oxides.

Sulfur Sorption

Desulfurization test results of the unsupported and SBA 15 supported CaO based sorbents revealed that CaO-CuO has the highest breakthrough sulfur capacity of 22.72 and 46.65% Capacity Usage Ratios (CUR) among the unsupported Ca based mixed metal oxides. The maximum sulfur capacity was also determined as 11.57 with the CUR of 47.49% for the SBA 15 supported CaO-CuO. The sulfur sorption performance of Ca based mixed metal oxides is compared in Figure 2a for unsupported CaO-MeO and Figure 2b for SBA 15 supported CaO-MeO sorbents.

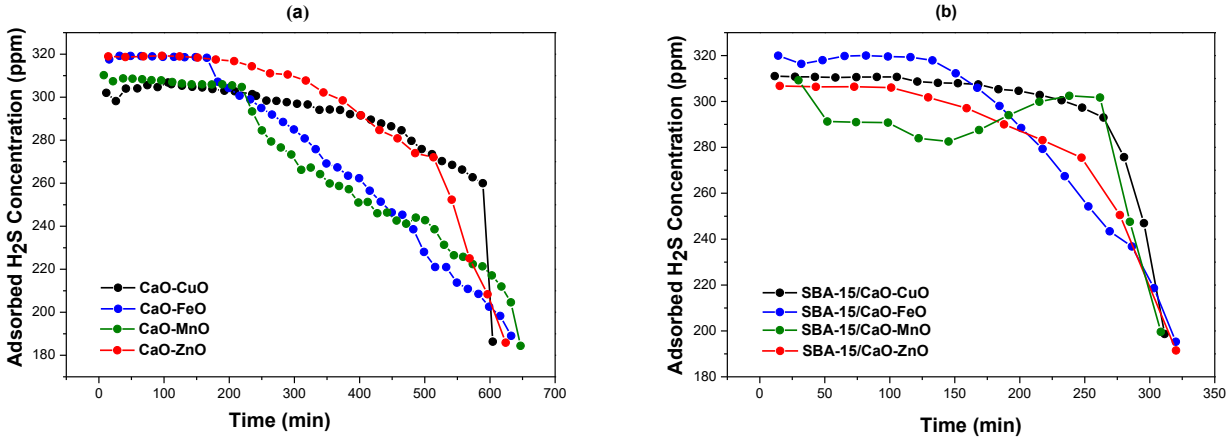

Figure 2. The sulfur sorption performance of Ca based mixed metal oxides. (a) unsupported CaO-MeO and (b) SBA 15 supported CaO-MeO sorbents.

CONCLUSIONS

New sorbents are developed using mixed metal oxides for the removal of H2S from gases at high temperature (800°C). BET results reveal that the presence of SBA 15 increases the surface area of metal oxides. Undefined peaks in XRD patterns can be interpreted as Ca based mixed metal oxides formation. Among the CaO based sorbents, unsupported and SBA 15 supported CaO-CuO mixed oxide show the best desulfurization performance with the sulfur capture capacity of 22.72 g S/100 g and 11.57 g S/100 g sorbent, respectively.

ABSTRACT

Moving towards a cleaner transportation is necessary for a more sustainable future. Hydrogen, as a clean energy carrier, can play an important role. It can be used in fuel cell vehicles (FCV) or in internal combustion engines. In this paper, a life cycle assessment of a FCV with 5 different fuel cycles including steam methane reforming (SMR), coal gasification, photovoltaics, solar thermal and grid electrolysis is conducted for Iran. Also, the FCV is compared with a conventional gasoline vehicle. It is concluded that for all of the considered pathways, the FCV is more environmentally benign than the gasoline vehicle, except when its hydrogen is produced from the electrolysis of water using national grid electricity. The total greenhouse gas (GHG) emissions of the FCV with grid electrolysis are found to be 0.465 kg CO_2 eq./km, which is 56% higher than those of a gasoline vehicle. It is also shown that the material production and manufacturing phase of the FCV's vehicle cycle is the main contributor to the total GHG emissions of the vehicle. The glider, hydrogen tank and fuel cell stack manufacturing have the most impacts on the environment. A FCV powered by clean hydrogen produced from electrolysis of water with the electricity produced from photovoltaics produces 0.135 kg CO_2 eq./km which is less than half of the emissions associated with a gasoline vehicle.

Keywords: Fuel Cell Vehicle, Hydrogen Production, Life Cycle Assessment, Greenhouse Gas Emissions

INTRODUCTION

Iran is a country rich in fossil fuels, but as these resources are depleting and the concerns about the environment is intensifying, their use must be limited. Transport sector is one of the most important sectors of a country's economy and welfare with huge energy requirement. Based on Iran's Ministry of Energy report, the transport sector devours an amount of 318 millions barrel of oil equivalent which is more than 17% of the country's total energy demand per year [1]. About 85% of Iran's transport sector energy use is based on petroleum products and less than 15% is from natural gas [1]. In 2016, about 590 million tonnes of carbon dioxide equivalent was emitted to the atmosphere of which 24% associated to transport sector [1,2]. Therefore, by utilization of more environmental benign vehicles and fuels, the amount of produced pollutants can be affected significantly. Fuel cell vehicles and hydrogen fuel can help us achieve this aim.

Evangelisti et al. [3] conducted a life cycle assessment study for a FCV and compared it to a battery electric vehicle and an internal combustion engine vehicle (ICEV). The focus of the study was on the manufacturing phase of the fuel cell system itself. It was concluded that most of the emissions produced from a FCV are related to its manufacturing phase while its total life time emissions are about 32% less than that of the ICEV [3].

Yoo et al. [4] conducted an LCA study for a FCV in South Korea with the GREET Model. It was shown that if the hydrogen is produced from Korea's grid with electrolysis, the GHG emissions associated with the total lifetime of the vehicle are more than 2 times higher than that of a conventional gasoline vehicle [4].

No publication has been found on an LCA of a FCV with various hydrogen production methods specific to Iran. The objective of this paper is to evaluate the GHG emissions of a FCV and a conventional gasoline vehicle which is currently used in Iran with the life cycle assessment methodology. Various hydrogen production pathways are considered. The vehicle manufacturing, operation and disposal as well as the fuel cycles are investigated and various scenarios are compared in this paper.

METHODOLOGY

A life cycle assessment (LCA) consists of four phases [5]: The goal and scope definition, including the reasons for performing the study, the functional unit, and the system boundary, inventory analysis, including data collection and

the quantifying inputs and outputs of each unit operation, impact assessment, in which the significance of potential environmental impacts is evaluated, and interpretation where the findings from the inventory analysis and the impact assessment phases are considered together to present consistent results based on the goal and scope definition phase of the study. The vehicle cycle studied includes raw material extraction, vehicle component fabrication, vehicle assembly, vehicle operation, vehicle disposal/recycling. The fuel cycle includes raw material extraction, feedstock transportation, fuel production, fuel transport and distribution. The functional unit is 1 km of driving and the lifetime of the vehicle is 150,000 km.

SYSTEM DESCRIPTION

The fuel cell vehicle considered in this study is similar to Toyota Mirai 2019. It is a proton exchange membrane fuel cell vehicle which is a 4 door family sedan. The total power of the fuel stack considered here is 113 kW with a fuel consumption of 0.76 kg H_2 per 100 km. Also, the net weight of the vehicle is 1850 kg [6].

Five pathways are considered for the production of hydrogen. The first one is the steam reforming of natural gas. In this pathway the natural gas is extracted from the Asaluyeh gas field in the southern Iran and is transported by a 0.6 m pipeline to the hydrogen production facility located in Tehran. The second pathway is the coal gasification in which the coals are extracted from an underground coal mine in Kerman province and transported by rail to the hydrogen production facility. The other three pathways include alkaline water electrolysis using photovoltaic, parabolic trough solar collector power plants, and the national grid.

Hydrogen is transported 30 km in tube trailers to the fueling station.

RESULTS AND DISCUSSION

Figure 1 shows the GHG emissions associated with the manufacturing of the FCV components. The manufacturing of the glider, hydrogen tank and fuel cell stack emits 0.0337, 0.0151, and 0.0135 kg CO_2 eq./km, respectively. The total GHG emissions of the fuel cell vehicle cycle are 0.0942 kg CO_2 eq./km.

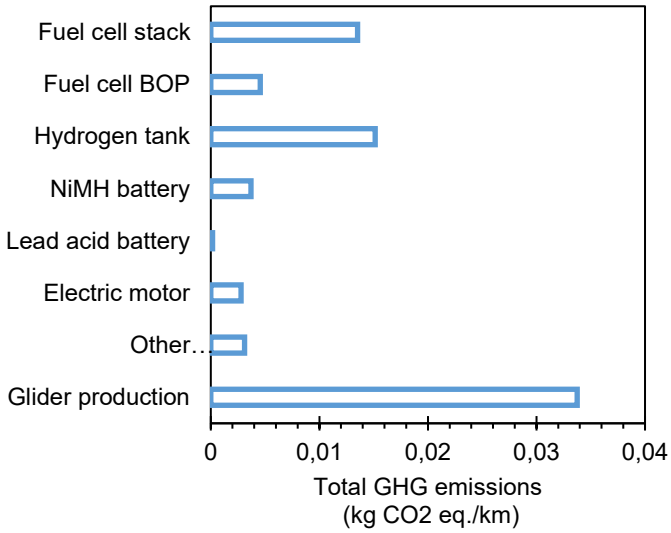

Fig.1. GHG emissions associated with FCV component fabrication

Figure 2 shows a comparison between GHG emissions associated with each fuel cycle and vehicle cycle of various scenarios considered in this paper.

The total life cycle GHG emissions of the gasoline vehicle are 0.297 kg CO_2 eq./km. The total GHG emissions of the FCV with grid electrolysis are 0.465 kg CO_2 eq./km which are significantly higher than those of the gasoline vehicle. Other FCV scenarios have lower GHG emissions than the gasoline vehicle.

Among the scenarios studied in this paper, FCV with PV electrolysis hydrogen has the lowest total life cycle GHG emissions equal to 0.135 kg CO_2 eq./km.

It is noted that even the FCVs with fossil-fuel-based hydrogen production have lower total GHG emissions than the gasoline vehicle. As Iran is rich in natural gas resources, SMR is suggested as an appropriate method for hydrogen production. The total life cycle GHG emissions of a fuel cell vehicle with SMR hydrogen production is about 36% lower than those of a gasoline vehicle in Iran.

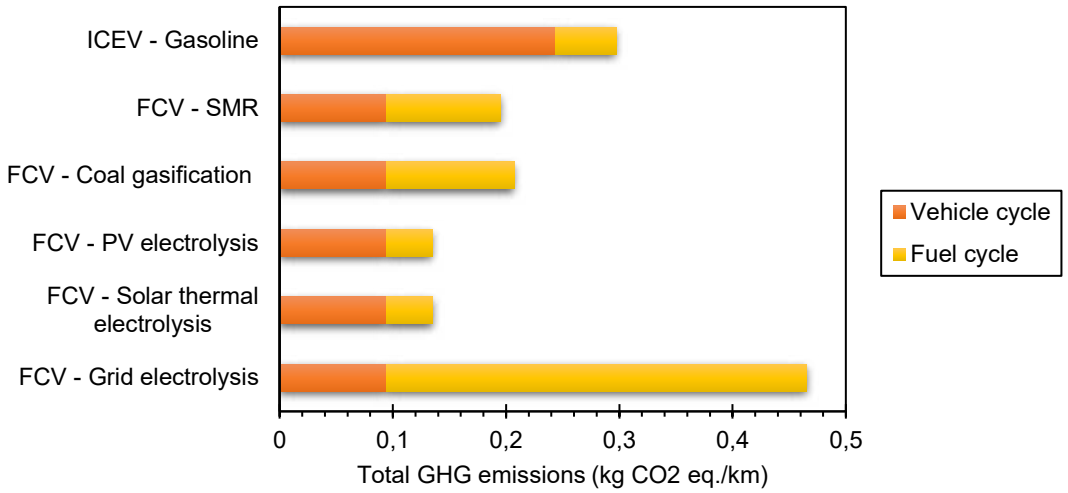

Fig. 2. GHG emissions of fuel and vehicle cycles of various scenarios

CONCLUSIONS

A life cycle GHG emissions assessment is conducted for a fuel cell vehicle in Iran using alternative hydrogen production methods. It is shown that the material production and manufacturing phase of the vehicle contributes significantly to the life cycle emissions. GHG emissions associated with a fuel cell vehicle with grid electrolysis hydrogen are 0.465 kg CO_2 eq./km, which are 56% higher than those of a gasoline vehicle. Among the scenarios studied in this paper, FCV with PV electrolysis hydrogen production has the lowest total life cycle GHG emissions equal to 0.135 kg CO_2 eq./km.

STEAM METHANE REFORMING INTEGRATION AND INCREASE OF CARBON DIOXIDE PRODUCTION

[1*] *M. Tagliabue*

INTRODUCTION

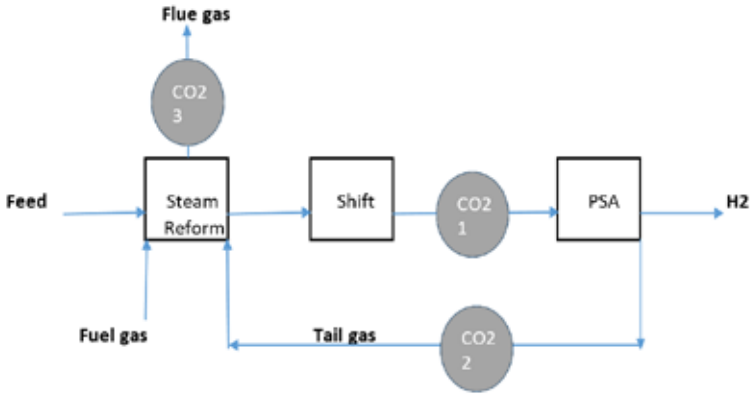
The present work is a study of the efficiency optimization of a H_2 production plant through natural gas reforming, and contributes to preserving the environment. In recent years, H_2 has been attracting great interest as a clean fuel for combustion engines and fuel cells. H_2 can be produced using several routes. The main route is the catalytic reforming of methane, which includes, among others, steam-methane reforming (SMR) and dry-methane reforming (DMR) [1]. In recent times, the Refineries of the world have considerably increased the demand for H_2, in order to be able to hydrogenate their different fuels in order to fit within the legislation of each country regarding the maximum limits of contaminants in each of them. Currently one of our business units to produce H_2 (which is sent to a Refinery) has two SMRs. One of them is side fire (SMRI) and the other one is top fire (SMRII). The first is designed to be fed with NG, and the second can work with both NG and ROG. The business unit on the other hand has a CO_2 absorber unit of the syngas stream of the first SMR, which uses an aqueous solution of MDEA additive with Piperazine as absorbent agent. In addition, a CO_2 absorber uses an aqueous solution of MEA. In this way, the business unit markets food grade CO_2 that leverages the entire project. The typical reactions that are involved, both when running NG and ROG, are shown below. The only difference is that the plant that ROG treats has a pre reformer, to transform CH_4+ hydrocarbons into H_2, CO, CO_2 and CH_4.

SMR reactions [2, 5]:

$$CH_4 + H_2O \rightarrow CO + 3H_2 \qquad \Delta H°298 = 206\ KJ/mol \tag{1}$$

$$CO + H_2O \rightarrow CO_2 + H_2 \qquad \Delta H°298 = -41\ KJ/mol(WSR) \tag{2}$$

DMR reaction [3, 6]:



$$CH_4 + CO_2 \rightarrow 2CO + 2H_2 \qquad \Delta H°298 = 247\ KJ/mol \tag{3}$$

These reforming reactions (1, 3) are strongly endothermic, while the concomitant reaction of water displacement is moderately exothermic (2). This process therefore requires a reactor in which heat management is extremely important.
In practice, an SMR unit can contain from 40 to 1000 tubes, each of which is typically 6-13 m long, 70-160 mm in diameter, and 10-20 mm in wall thickness. In our case, the SMR I consists of 52 tubes of ID 86.2 mm, and a length of 13 m. The number of burners is 72 and they are arranged on the sidewall.

The SMR II consists as main difference the inclusion of a pre reformer of 1,300 mm ID, and a height of 3,320 mm, without MDEA unit. The reactor consists of 46 tubes of ID 125 mm and 18 burners, which are arranged at the top of the home.
These pipes are arranged vertically in a household or rectangular combustion chamber, the so-called radiant section. The reactor tubes contain a nickel-based catalyst, usually in the form of small cylinders or rings.

If our interest is not only the production of hydrogen, but also reduce CO_2 emissions, and produce it for sale in the industries that use it, there are several points in the scheme of an SMR for recovery.

In a modern steam reforming hydrogen plant fed by natural gas, up to approx. 60% of the total CO_2 produced is contained in the shifted gas (and then in the PSA tail gas), while the remaining 40% is the product of the combustion of the additional fuel gas required by the steam reformer. In our case to recover CO_2, we use points 1 and 3 shown in Figure 1.

Fiq. 1. Flowchart of recover CO_2

EXPERIMENTAL, THEORY AND/OR CALCULATIONS

The plant used to develop this study is the first reformer a side fire type, with a feeding of natural gas. This SMR plant consists of a high temperature shift plant (HTS), a CO_2 capture plant through an absorption process with activated amines, and a CO_2 liquefaction plant (for its later sale). This work was a theoretical and practical study with the objective to see how a stream of non-condensable usually vented to the atmosphere (rich in CO_2 and H_2) and coming from the stripper of the CO_2 liquefaction plant could be added to the feed of the SMR plant, in order to reduce the emissions of CO_2 and other compounds responsible of the greenhouse, and to reduce the consumption of natural gas, keeping hydrogen production. In the second stage, once made the theoretical study of the impact on the SMR when this feed is added, it was decided to proceed to the experimental work to learn how the major variables of the process were affected [4]. In the fieldwork, a line was built to link the non-condensable pipe, coming from the CO_2 liquefaction, whose pressure was 17.0 barg with the suction line to the natural gas compressor whose pressure was 7 barg. Additionally, the use of H_2 from non-condensable was considered to supplant part of the recycled H_2 (extracted from the flow of H_2 produced) usually necessary to eliminate sulfur from natural gas in the hydro treatment, which consists of a reactor with two beds, the first one filled with CoMo catalyst, to transform the possible organic sulfur compounds into SH2 and then an OZn bed that is responsible for absorbing SH2 through the following chemical reaction:

$$SH_2 + OZn \rightarrow SZn + H_2O \quad (4)$$

The practical results of the test were very encouraging. As dry reforming is more endothermic than the conventional reforming, the natural gas consumption increases initially because of the necessity of a bigger input of combustible and a lower flow of Off Gas from the pressure swing adsorption (PSA) due to the bigger conversion of CH_4. When the tubes wall cool down the excess air could be diminished (which in addition to provide the O_2 for the complete combustion is used to cool down the tubes), and so could be reduced the consumption of natural gas.

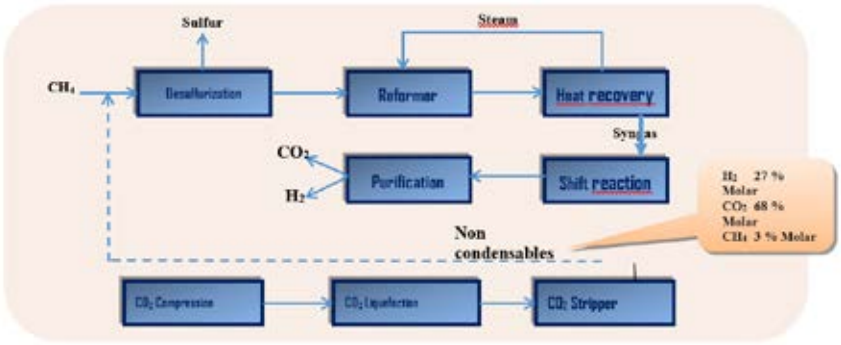
STAGE 3

In a third stage, in order to increase the profits of the business unit and mainly to continue reducing the emissions of CO_2 to the environment, a non-utilized active (a CO_2 production plant burning natural gas to produce it) was used to capture CO_2 from the SMR flue gases vented into the atmosphere. Thus, about 25 tons/day of CO_2 are recovered for the CO_2 local market, reducing emissions into the atmosphere in the same amount. For this, the stack of the combustion gases of the SMR was linked to the absorber (of the plant previously disused) by means of a duct and two blowers, one hot next to the fireplace and one cold after having reduced the temperature to the flow of flue gas after the exchange with cooling water. Absorber and stripper were operated at low pressure, and an 18% vol MEA solution was used. The liquefaction of CO_2 was carried out at 17 barg, using a refrigeration circuit with NH_3. This technique is very favorable for the industry since the stream rich in CO_2 is a waste. However, the practical use of this technique has some disadvantages, which must be known in advance to do not commit costly errors. As is well known, when the SMR already incorporates a sequestration of CO_2 in the syngas stream (MDEA), the flue gases are poor in CO_2 (4-8% v), and the separation is more difficult. On the other hand, the current in question has a high concentration of NOx, even using low NOx burners, which needs to the inclusion of a purification unit. Additionally, depending on the charge to the SMR, the stack gases may have an O_2 concentration, which may be in the range of 1 to 2% v, for 100% charge and 8% v for 50% charge. This last situation can lead to the degradation of solutions capable of absorbing CO_2, causing serious corrosion problems. To try to mitigate this situation, it is very important to choose the indicated amine for each process, its concentration, pressure and operating temperature. It is also advisable but not imperative to use stainless steel in key places of the process, and use an O_2 sequestrant to alleviate

corrosive problems. It is also advised to place before the absorber entry into the poor MEA solution, activated carbon filter to retain degradation products of the MEA solution which should be changed between three and six months of operation depending on the load at the unit. Normally when using MEA a good “reclaimer” is required, which should be in service as long as possible to partially reverse the degradation and recover the MEA.

STAGE 4

As the rules on clean fuels are increasingly demanding, the consumption needs of H_2 by refineries continues to increase. In this sense, our company installed a new SMR very close to the first. In this case, the technology is a Top fired, which has no units to recover CO_2.



To try to mitigate as much as possible the CO_2 emissions to the atmosphere, and taking into account that the flue gas vented has about 19% vol of CO_2, it was decided to change the location of the chimney outlet to this second SMR, to add a Stripper to the absorption plant, and use an old liquefaction plant with NH_3 refrigerant circuit to recover in total about 80 Tn/day of CO_2. In this case, as the second reformer operates almost to its design capacity, the degradation problems of the MEA solution disappeared because the concentration of O_2 in the flue gas is in the order of 2 to 3% vol.

RESULTS AND DISCUSSION

Stages 1 and 2 show us very satisfactory results, since we managed to maintain H_2 production by reducing CO_2 emissions, and reducing the consumption of natural gas.

In stage 3, we had process complications caused by the composition of the raw material (flue gas), which made the absorption/desorption process difficult. Fundamentally, we had to take many precautions to abolish the corrosive processes in the derivative MEA solution of the high amount of O_2 present. Fortunately, with an exhaustive study of the problems, we were solving them one by one and we achieved the objective of reducing emissions and increasing CO_2 production.

In stage 4, since the composition of the flue gas was much friendlier, the operation of the absorption plant was much easier, achieving our final objective without any inconvenience, reducing emissions, significantly increasing the production of CO_2, reducing the consumption of natural gas, maintaining H_2 production and using disused assets of our company. In the scheme shown in **Figure 2**, the process of producing H_2 and CO_2 from natural gas can be visualized, and in a dotted line the injection of non-condensable.

Fiq. 2. The process of producing H_2 and CO_2 from natural gas

In the **Figure 3**, you can see the installation of the old plant not previously used to which a revamping was carried out and some equipment was added to adapt it to the recovery of CO_2 from the flue gas stream. In a yellow circle, you can see the flue gas outlet in the steam-reforming stack.

Fiq. 3. The installation of the old plant

CONCLUSIONS

The aforementioned possible drawbacks were solved by adding a suitable NOx filter as well as a formulation of the MEA solution suitable for O_2 present. As a result, production could be increased by around 25 Tn/day of CO_2. With the addition of SMRII, the amount of CO_2 recovered was increased and when taking another quality of flue gas with a much higher percentage of CO_2 and O_2 much lower under the absorption process, it was much easier to operate. In total, the amount of CO_2 that was avoided to be sent to the atmosphere was 82 Tn/day, and the reduction in natural gas consumption was 6,500 Nm^3/day. Our next step will be to send the non-condensable of these liquefaction units to the SMRII, to continue lowering the polluting emissions and reducing the consumption of fossil fuels (natural gas).

ABSTRACT

Atmospheric, laminar, diffusion flames of hydrogen and air are numerically investigated. A detailed hydrogen combustion reaction scheme, in combination with the extended Zeldovich mechanism for the thermal nitrogen oxide formation are used. For comparison purposes, a global mechanism is also applied. The numerical procedure is first validated by comparisons with results of other authors. Subsequently, parametric studies are performed to find optimal solutions with respect to the related to the operation parameters of such flames to achieve minimum low nitrogen oxide emission levels. The question that are addressed include the Reynolds number effect on nitrogen emissions, and the interaction of neighbouring flames, when they are applied in an array. For ensuring an adequately fine resolution of the flame fronts, local adaptive grid refinement techniques are applied to track the flame front. For preliminary results the radiative heat loses has assumed to be insignificant however it should be taken into the account for the further analyses. The maximum temperature is predicted to be ~2040 K which is higher than the reported adiabatic stoichiometric flame temperature, 2023K for the exit velocity of 0.5 m/s. The radial mole fractions of N2 and H2 at the centerline are observed to be 0.66 and 0.41 respectively at the axial distance of 10 mm. Furthermore, the width of the high temperature region of the flame is observed to be ~6.5 mm.

Keywords: Hydrogen combustion, Laminar diffusion flame, Thermal nitrogen oxide formation, CFD

INTRODUCTION

Power generation largely depends on the conversion of the chemically bound energy by the combustion process. Parallel to new energy sources and recovery techniques [1], combustion continues to play an important role in power generation. Combustion of H_2-blend fuels enable clean energy supply. On the one hand, H_2 represents an attractive alternative to storing excess energy in renewable power generation [2]. On the other hand, instead of combustion [3,4] gasification [5] is a good possibility for clean power generation, synthesis gas containing, in addition to CO and small amounts of CH_4, significant amounts of H_2. Additionally, there is a growing interest in hydrogen production using nuclear power plants [6].

In power generation, the state-of-the-art technology for gas turbines is the lean premixed combustion, due to its high potential for achieving very low NO_x emissions. A principal problem here is the so-called “flashback” [7]. This makes the use of H_2-blend fuels to a great challenge, since their high reactivity increases the flame speed and flashback propensity. Combustion of H_2 has relevance also for safety engineering. H_2 has a high diffusivity, and its leakage is more likely to be an issue compared to other gases. H_2 also plays a special role in conjunction with the safety of nuclear power plants on conjunction with the storage of the released slightly radioactive H_2-steam mix.

To circumvent the problem of flashback, many researchers started to revert to the more conventional non-premixed combustion technology and explore means of reducing NO_x emissions within this framework, with some success. In such applications that can be found in different areas, such as power generation [8], or domestic boilers [9], the main principle utilized to reduce the thermal nitrogen oxide formation is the reduction of the residence time in the hot flame zone. Principally, this is achieved by designs that utilize arrays of a large number of micro-scale diffusion flames. Due to the small sizes of the injectors, the resulting flames may turn out to be laminar, as e.g., observed in Ref. [9], which brings the combustion in the laminar flow regime again in focus of investigation as a relevant flow mode for certain applications.

Although the main principle of using micro diffusion flames is declared to be the reduction of the residence time of the combustion gases in the flame zone, there still is a need for further studies on the quantification of the various effects and optimization of the configuration. This constitutes the focus of the present contribution.

Hydrogen diffusion flames will be numerically analyzed. The thermal NO_x formation will be investigated. Due to the relevance to the present context, laminar flames will be considered at the present stage of the investigation. The study consists out of several stages. In the first stage, a detailed validation study will be performed, using the published data of other authors on H_2 flames [10]. Upon this basis, the question will be addressed, within the

framework of parametric studies. First, the combined role of the jet velocity and diameter for a power will be investigated. The question to be answered here is, if there is an optimum point for a given power, or in other words, if there is an optimal Reynolds number leading to lowest NOx emissions for a given power. Secondly, the $EINO_x$ scaling of H_2 diffusion flames will be addressed for the laminar flow, as the existing $EINO_x$ data [11] is mainly referring to the turbulent regime. A further question to be addressed is the interaction of neighboring flames in an array. In the known applications [8, 9] the number of micro-diffusion flames are applied in an array. To spare space, close arrangement of the flames is advantageous, where, however, the interaction between the flames may cause negative effects (eventual positive effects are to be identified). This point, which has not been numerically investigated for H_2 flames so far, will be studied to suggest an optimal spacing, allowing a minimum distance between neighboring flames, without a substantial performance deterioration.

MODELING

The differential transport equations of the chemically reacting mixture are numerically solved, assuming a subsonic flow and an ideal gas behavior [12], considering multi-component diffusion [13]. The specific heat capacities as function of temperature are obtained using a pair of fourth order polynomials [13], for low and high temperature ranges. Transport properties are obtained from the kinetic theory [13]. Chemical kinetics rate coefficients are modeled by Arrhenius expressions [13]. Laminar diffusion flames in a generic co-axial configuration are considered. Thus, modelling errors with respect to the modelling of turbulence [14] and turbulence-chemistry interaction [15,16] are avoided. For the numerical simulations, ANSYS Fluent 19.0 [17] is used. As Navier-Stokes solver, the SIMPLEC [17] scheme is used. For discretizing the convective terms, a second-order upwind scheme [17] is applied. The chemical kinetics software Cantera [18], is also used for verification purposes. As the reaction mechanism for H_2 combustion, the detailed mechanism of Conaire et al. [19] is used. For comparison purposes, the global mechanism of Marinov et al. [20] is also be considered. Thermal nitrogen oxide formation is modelled using the extended Zeldovich mechanism [12]. For coping with the high grid resolution requirements dictated by the small length scales of the flame front, adaptive gridding techniques are used. The radiative heat transfer has not been considered for the initial simulations however Toro et. al. has considered optically thin radiation model. The dimension of the computational domain is 60 cm in axial and 9.5 cm in radial directions meshed with 13500 quadrilaterals cells. Species Transport has been activated along with the Volumetric Reactions adopting the Finite-Rate/No TCI for the Turbulence -Chemistry Interaction in order to model laminar diffusion flames. Diffusion Energy Source, Full Multicomponent and Thermal Diffusion are all activated for the sake of the complete mathematical modeling.

RESULTS

Figure 1 shows the species radial mole fraction profiles at the axial distance of 10 mm for the fuel feeding speed (V) of 0.5 m/s, while Figure 2 contains the contour plot of flame temperature. Similar results have been obtained in comparison to Toro et.al.'s reported profiles in their work [10] for detailed mechanism of H2/Air laminar microdiffusion flames, which implicates that such flames may be analyzed with detailed chemistry for gaining a better understanding on the pollutant preventions in gas turbines adopting micromix layout for fuel feeding system. The radial mole fractions of N2 and H2 at the centerline are observed to be 0.66 and 0.41 respectively while they are reported to be 0.57 and 0.43 in Ref. [10]. In the current study the maximum temperature is predicted to be ~2040 K which is higher than the reported adiabatic stoichiometric flame temperature, 2023K for the maximum stream velocity considered in the study of 0.5 m/s as seen in Figure 2. Furthermore, the width of the high temperature region of the flame is observed to be ~6.5 mm in the current study being wider than the reported value which is ~4.5 mm in Ref. [10]. The differences for the mole fractions, flame temperature width and the maximum flame temperature between the current study and Ref. [10] might be explained by the adopted detailed chemical mechanism adopted in the current study as well as the lack of a radiation model for the initial simulations.

CONCLUSIONS

Laminar hydrogen-air diffusion flames are numerically investigated with emphasis on thermal nitrogen oxide formation. Results are validated by comparisons with calculations and measurements of other authors. The detailed H2/Air chemical mechanism is adopted and tested the validity of the laminar diffusion flame predictions in comparison to the existing literature. The preliminary results are promising which is able to extend the literature adopting detailed H2/Air chemical mechanism for laminar diffusion flames. The predicted maximum flame temperature has been observed to be higher than the reported adiabatic temperature, and the high temperature region's width is seen to be wider than the reported value in Ref. [10] which can be explained by the adopted chemical mechanism in the current study and lack of radiation modeling in the current study. For the future works, the grid independency of the CFD analyses must be ensured as well as the optimum Re number leading to the possible NOx emissions for a predetermined power.

Additionally, interaction between the flames in array and optimizing the spacing which will allow the minimum interval dimension between neighboring flames while preventing a substantial deterioration of performance.

ABSTRACT

Hydrogen (H_2) has been widely recognized as a crucial alternative regarding an imminent energy transition, due to its use as an energy vector and its environmental innocuousness at usage. Steam Methane Reforming (SMR) is the most common H_2 production method, and standardizing its emissions is key to ensure long term benefits from using H_2. This work aims at comparing several existing standards and proposing an emission reduction target for Colombia. SMR has an average carbon footprint of 10.74 kg CO_2-eq/kg H_2. Additionally, it was found that existing standards concur on an emission reduction target of 60%. Factoring Colombia's low emission factor in energy production, as well as its existing piping system, it was concluded that this target is achievable and, due to the advantages of complying with international standards, it is recommendable to institute it in future regulations.

Keywords: Greenhouse Gases, Hydrogen, Life Cycle Assessment, Steam Reforming

INTRODUCTION

Climate change has turned into one of the most afflicting concerns in modern society, and the evolution of energy production is a key challenge in mitigation and reversion of its effects [1]. Using conventional energy sources, such as fossil fuels, provoke greenhouse gases (GHG) emissions [2]. Fossil fuels are responsible of about 65% of GHG emissions [3], and the fact that their sources will face scarcity in the future creates the need for an energy transition where renewable energies, such as solar power, wind power, geothermal, among others, play a key role.

In Colombia, hydrogen (H_2) has been identified as an ideal energy carrier that will allow the distribution of renewable energy since it can be stored and transported [4]. It is expected that the use of H_2 will allow the country to take advantage of the renewable energy potential located in the north Caribbean region, especially regarding solar and wind power, by supplying the whole country with low emission energy. Several countries, such as Canada, Japan, and members of the European Union, have identified the same opportunity, since H_2 is an energy vector that can be produced, stored, transported, and recycled. Besides, H_2 oxidation in fuel cells will produced water as by product, and consequently, mitigating carbon footprint [5]. By incorporating H_2 into the energy grid of a country, emission reduction and energy availability targets, (e.g., reducing 20% of CO_2) could be achieved [4]. Furthermore, moving towards H_2 will contribute significantly to the fulfillment of the Sustainable Development Goals proposed by the United Nations [6]. Specifically, goal 7 (i.e., affordable and clean energy), goal 11 (sustainable communities), and goal 13 (climate change action) will be the main targets on the use of H_2 to fulfill the aforecited goals. To warrant the benefits that H_2 could be offered, it is important not only to promote H_2 use but also to guarantee clean H_2 production through its entire life cycle. Currently, H_2 is produced either from fossil fuels through SMR, partial oxidation of hydrocarbons, and coal gasification, or from renewable energies through the electrolysis boosted by solar, wind, or hydropower [7]. All processes must be regulated to guarantee a minimum emission reduction when compared with conventional energy sources. Guarantees of origin (GO) have been commonly used to evaluate alternative energies, and they constitute a viable option for H_2. Countries such as Germany, United Kingdom, United States, France, and Australia have been developing standards for H_2 GO, by establishing emission reduction targets [8]. Hence, the aim of this research is to propose a GO scheme under Colombia scenario.

METHODOLOGY

To determine an appropriate requirement for low-emission H_2 in Colombia, it is important to identify current emission levels regarding the method of interest (SMR). Through literature review, common emission levels for this technique were retrieved. Then, following current regulation proposals, and considering Colombia's current energy grid, raw material obtention, and availability, a suitable level of emission reduction target was fulfilled.

SMR common emission levels and reduction target

Several studies have performed Life Cycle Assessment (LCA) processes regarding H_2 production through SMR. LCA determines environmental impacts of processes or products, contemplating not only their final uses, i.e., energy production using H_2, but also considering related processes, such as raw material extraction, plant decommissioning, waste disposal, among others [9]. By comparing existing LCA information from H_2 producing countries, common emission levels were verified, and differences between them were weighed. As aforementioned, several countries

have defined minimum emission reduction levels required to consider H_2 as low emission. Existing regulations were compared. Following this comparison and considering differences in the energy infrastructure, a fitting minimum reduction level for Colombia were proposed.

RESULTS AND DISCUSSION

SMR comparison using LCA

Table 1 presents the reported LCA results for SMR across several countries, considering systems without carbon capture and storage (CCS) or other emission reduction alternatives. According to Table 1, the average carbon footprint is 10.74 kg CO_2-eq/kg H_2, which is close to the value reported for the GO scheme proposed for the European Union (i.e., 10.92 kg CO_2-eq/kg H_2). Aside from the information presented in Table 1, relevant studies showed that CCS could reduce SMR emissions to 3.45 kg CO_2-eq/kg H_2 [10], while alternative technologies may improve the process, e.g., using chemical looping combustion (CLC) as a heat source for SMR can reduce emissions to 3.01 kg CO_2-eq/kg H_2 [12].

Table 1. Emissions and yield of SMR for current hydrogen producers.

Country	Emissions (kg CO_2-eq/kg H_2)	Yield (kg H_2/kg natural gas)	References
Spain	10.57	0.32	[10]
Canada	11.89	0.34	[11]
China	10.76	0.36	[12]
United States	11.88	0.34	[13]
Germany	8.59	0.15	[14]

Reduction target

Several countries are currently developing H_2 regulations, and some have already established their emission reduction requirements. Existing and developing standards and their requirements are presented in Table 2. All emission reduction requirements are based on SMR average emission levels, since it is the most common H_2 production method. A consensus can be observed in Table 2: Most countries expect reductions of about 60% CO_2-eq emissions to classify H_2 as “green” or “low emission”. While organizations like California Air Resources Board (United States) and the Department of Energy and Climate Change (United Kingdom) present higher and lower targets, respectively, there seems to be a global agreement on a 60% emission reduction.

Table 2. Emission reduction requirements in existing and developing hydrogen regulations.

Country	Current emission factor (kgCO_2-eq/kWh)	Status	Organization	Maximum emissions (kgCO_2-eq/kgH_2)	Other requirements
United States	0.38 [15]	Active	California Air Resources Board [16]	3.6 (67% reduction)	None
European Union	Not applicable	Active	CertifHy [17]	4.37 (60% reduction)	Renewable energy sources for green hydrogen label
United Kingdom	0.4 [18]	In process	Department of Energy and Climate Change [19]	3.33-8.33 (in discussion)	None
Germany	0.48 [20]	Active	TÜV SÜD [21]	4.37 (60% reduction for conventional sources) 2.73 (75% reduction for electrolysis)	None
Canada	0.79 [22]	Proposal	Natural Resources Canada [23]	4.37 (60% reduction)	None

When analysing Table 2, it is important to consider the emission factor in each country, since this value could limit a country’s ability to reach emission reduction targets. From Table 2, Canada has the highest emission factor, 0.79 kg CO_2-eq/kWh. Germany, with 0.48 kgCO_2-eq/kWh, United Kingdom, with 0.4 kgCO_2-eq/kWh and United States, with 0.38 kgCO_2-eq/kWh has similar emission factors. Colombia has a substantial advantage in the emission factor subject: in 2020, Colombia’s emission factor was only 0.16 kg CO_2-eq/kWh [24], which is substantially inferior when compared with current H_2 producers and prospects. Since Colombia has a well functioning pipeline, which could be

adapted for H_2 transport, it is reasonable to adopt current world trend and establish a 60% emission reduction target with respect to the average emission level of SMR processes, considering the future advantages that doing so would present, including exportation possibilities and international protocol compliance.

CONCLUSIONS

Natural Gas Steam Reforming is a suitable technology as starting point into a H_2 oriented energy grid. Thanks to the fact that it is currently used worldwide, and that technologies like CCS and CLC allow it to meet emission reduction targets, its viability for low emission H_2 production is evident. Current pipeline system, emission factor and natural gas availability position Colombia as a country with immense potential to adopt H_2 as a solution for energetic transition. Current H_2 leaders agree on a 60% emission reduction target, and Colombia's circumstances and advantages will allow the country to level with them and become a H_2 leader in Latin America. With an appropriate strategy and investment, this emission reduction target is reasonable, achievable and a potential driving force to fulfill energetic, environmental, and socio-economic targets.

ABSTRACT

Hydrogen is often discussed as an energy carrier of the future. In this paper economic and environmental benefits of hydrogen use in passenger car mobility are analysed in comparison to the conventional vehicles. In spite of many hypes over the last decades, fuel cell vehicles are still a rarity on the streets. However, with the pressing environmental problems and possibility to use hydrogen as a fuel for mobility as well as storage for surplus electricity from renewable energy sources, role of hydrogen in the future energy and transport system is becoming more important.

Keywords: hydrogen, fuel cell vehicles, mobility, costs, emissions

INTRODUCTION

With the growing environmental problems, rise a need for low-carbon fuels and technologies. The transport sector, which is still almost completely dependent on fossil fuels, is a huge challenge for decarbonization. Although, currently major focus is put on electrification of mobility, hydrogen and fuel cell vehicles (FCV) are very often seen as a long-term solution for the transport sector. Hydrogen and fuel cells vehicles have already a long history. The major milestones of hydrogen use in the transport sector are presented in Fig. 1. There were many hypes in the history of hydrogen. The new one is driven by the increasing use of volatile renewable energy sources (RES), which leads to a need for the additional storage options. The advantage of hydrogen is that it can be used as a fuel, feedstock or energy storage.

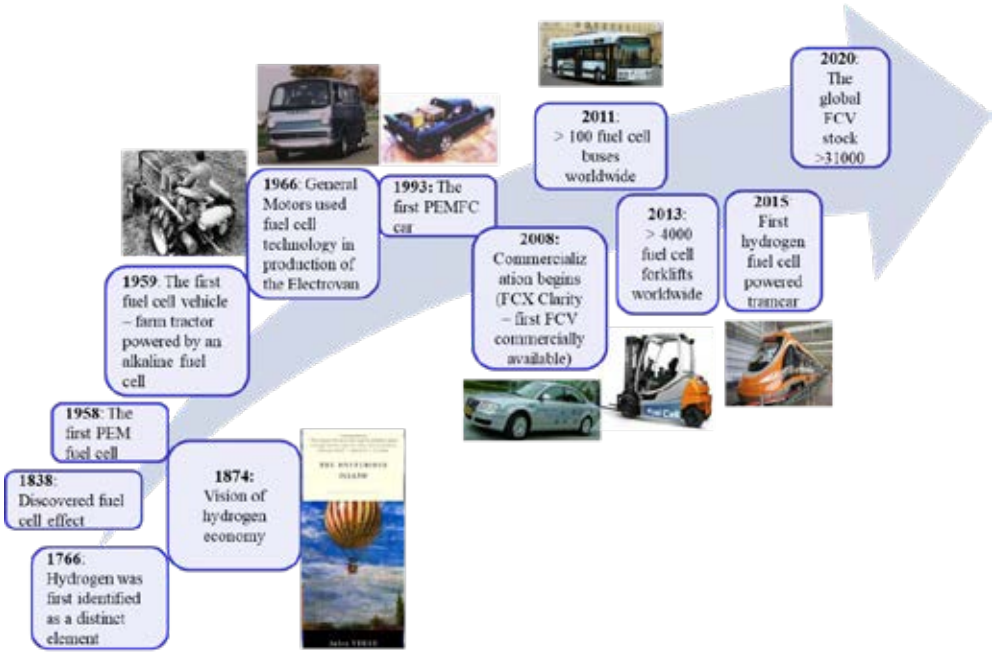

Fig. 1. Major milestones in the deployment of fuel cell vehicles (adapted from [1])

In the transport sector, besides battery electric vehicles, fuel cell vehicles powered by hydrogen are the only zero-emission options currently available.

The core objective of this paper is to discuss the economic and environmental performances of hydrogen and fuel cell passenger vehicles in comparison to conventional internal combustion engine (ICE) vehicles.

This topic has been already discussed by several authors [2-4], however, in this paper most recent data are included.

METHOD OF APPROACH

Since the future perspective of hydrogen and fuel cell vehicles is very dependent on their economic performance, total mobility costs per kilometer driven are calculated considering current energy and vehicles prices. These costs are calculated using following equation:

$$TMC = \frac{IC \cdot CRF}{skm} + P_e \cdot EC + \frac{C_{o\&m}}{skm} \quad (1)$$

Moreover, future investment costs are calculated considering possible technological learning through the increasing production of fuel cell vehicles:

$$IC(x_t) = IC(x_{t0}) \cdot (\frac{x_t}{x_{t0}})^{-b} \quad (2)$$

Environmental assessment is conducted considering well-to-tank (WTT) and tank-to-wheel (TTW) emissions, as well as emissions caused during car manufacturing and disposal ($CAR_{emissons}$). Total emissions caused by vehicles are calculated as:

$$CO_{2\ total\ emissions} = WTT_{emissions} + TTW_{emissions} + CAR_{emissions} \quad (3)$$

RESULTS AND DISCUSSION

Currently, fuel cell vehicles are economically not competitive with conventional ICE vehicles, mostly due to high investment costs. However, these costs are continuously decreasing. In the future, through the technological learning as well as increasing CO_2 taxes, which should better reflect the environmental costs of fossil fuels, it can be expected that fuel cell vehicles in combination with green hydrogen could become competitive with other automotive technologies. Figure 2 shows current and future mobility costs with fuel cell vehicles in comparison to conventional cars. As it can be seen, currently mobility cost with FCV is about 55% higher than those of conventional cars. In 2050, the cost difference could be just about 3%.

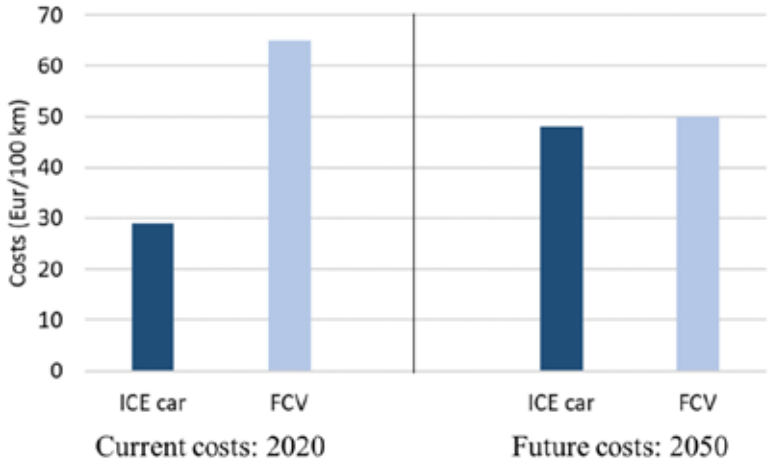

Fig. 2. Current and future mobility costs, FCV vs ICE vehicles

In opposite to poor economic performance, fuel cell vehicles have already now significant environmental benefits in comparison to conventional cars, see Fig. 3. Currently, the largest emission saving can be reached in the case that hydrogen is produced from RES (e.g. wind- and solar energy), so called green hydrogen. In such case total emissions of FCV are about four time lower in comparison to ICE vehicles. However, hydrogen is mostly produced by steam reforming of natural gas (NG) due to the lowest hydrogen production costs, and in this case, emission reduction is much lower. It is obvious that in the case of FCV, the largest contributor to the total emissions are WTT emissions, which are very dependent on the kind of primary energy sources used for hydrogen production.

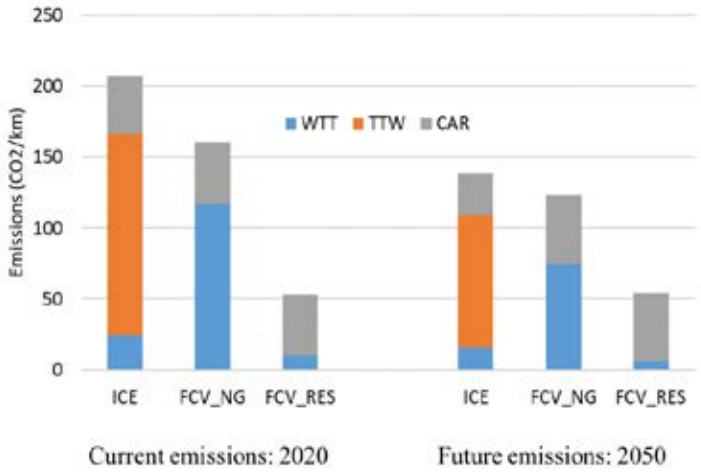

Fig. 3. Current and future emissions, FCV vs ICE vehicles

CONCLUSIONS

Hydrogen and fuel cell vehicles can contribute to the decarbonisation of the transport sector, especially if hydrogen is produced from RES. However, major current challenges are high investment costs of fuel cell vehicles and lack of necessary infrastructure. Future role of hydrogen and FCV is very dependent on policy framework. To reduce investment risks, it is important to have clear targets and long-term vision. With the increasing use of RES, interest in hydrogen which can be used also as a storage for the surplus electricity from RES, is growing every day.

ABSTRACT

Steam reforming technology integrating a membrane reactor and/or CO_2 capture for H_2 production from olive mill wastewater (OMW) was developed. The objective is to use a multifunctional reactor combining OMW reforming (using a stable/active catalyst) and the simultaneous products removal from the reaction zone in a single device: H_2 through an H_2-selective membrane and CO_2 through a CO_2 sorbent. Thus, the benefits of using different multifunctional reactors (sorption-enhanced reactor (SER), membrane reactor (MR) and sorption-enhanced membrane reactor (SEMR)), comparatively to the traditional reactor (TR), were assessed in this work in terms of H_2 production through the steam reforming of OMW (OMWSR). Using a SEMR, an H_2 yield enhancement of ≈ 44 % was observed compared to the TR – H_2 production of ≈ 11.5 mol_{H2}/mol_{OMW} in the SEMR.

Keywords: Olive mill wastewater; Steam reforming; CO_2 sorbent; H_2-selective membrane; Multifunctional reactors.

INTRODUCTION

Olive oil production is a major activity in the economy of Mediterranean countries, but also one of the agro-industrial sectors with major destructive environmental impacts. For instance, the OMW is a pollutant by-product of this process [1]. This effluent has a high pollutant organic load and is mainly composed of water, polyphenols, fatty acids and sugars. To decrease the environmental impact of this sector, it was suggested the application of the OMWSR, which can treat and economically valorize this waste (production of green H_2). A new multifunctional reactor configuration combining the OMWSR with H_2 and/or CO_2 selective removal is proposed herein for the 1st time, due to its potential to overcome some restrictions like the thermodynamic limit of the reversible reaction(s). In this work, it will be studied and compared the performance of a TR, a SER (with a CO_2 sorbent), a MR (with an H_2-selective membrane) and the SEMR (integrating both separations in the same device).

MATERIALS AND METHODS

The thermodynamic analysis of OMWSR was done employing the Aspen Plus V8.8® software [2]. The simulations were made at different temperatures, pressures and removal fractions of H_2 and CO_2 to identify the best operational conditions. Also, CO_2 equilibrium isotherms and breakthrough curves were obtained through static and dynamic tests, respectively, with both commercial sorbents and prepared doped-hydrotalcites (HTCs) at 300 ºC [3]. Further, a catalytic screening study (@ 350/400 ºC and 1 bar) was performed with commercial and prepared catalysts in a TR. After that, stability tests (24 h of time-on-stream) were performed with the best catalysts to be subsequently used in the above-mentioned multifunctional reactors [4]. The physicochemical characterization of all these samples was realized through several techniques (XRD, TPO, TPD, etc.). Finally, different multifunctional reactors (SER vs. MR vs. SEMR) were tested and compared to a TR (@ 350 and 1 bar, or 400 ºC and 4 bar) [5]. In all reactor configurations, a prepared Ni-Ru/Ce-SiO_2 catalyst was used, combined in the SERs with an HTC-based sorbent to capture CO_2. Additionally, in the MR and SEMR configurations, a Pd-Ag membrane was utilized to separate H_2 from the reaction medium.

RESULTS AND DISCUSSION

The optimum operating conditions for the OMWSR in a SEMR were determined in the thermodynamics analysis [2]. The H_2 yield increases with the H_2 and/or CO_2 removals – see Fig. 1a) for the hydrogen removal. It was also verified that the advantages of the SEMR are more perceptible at lower temperatures (300-400 ºC), and so this reactor configuration can be operated under milder conditions, which favor CO_2 sorption by the HTCs and membrane stability.

Among the prepared HTCs, the one modified with gallium and doped with potassium (HTC-CO_3(Ga)_K) presents the highest CO_2 sorption capacity (1.45 $mmol \cdot g^{-1}$, @ p_{CO2}= 1 bar and 300 ºC) in comparison with the other synthesized HTCs and even commercial sorbents – see Fig. 1b) [3].

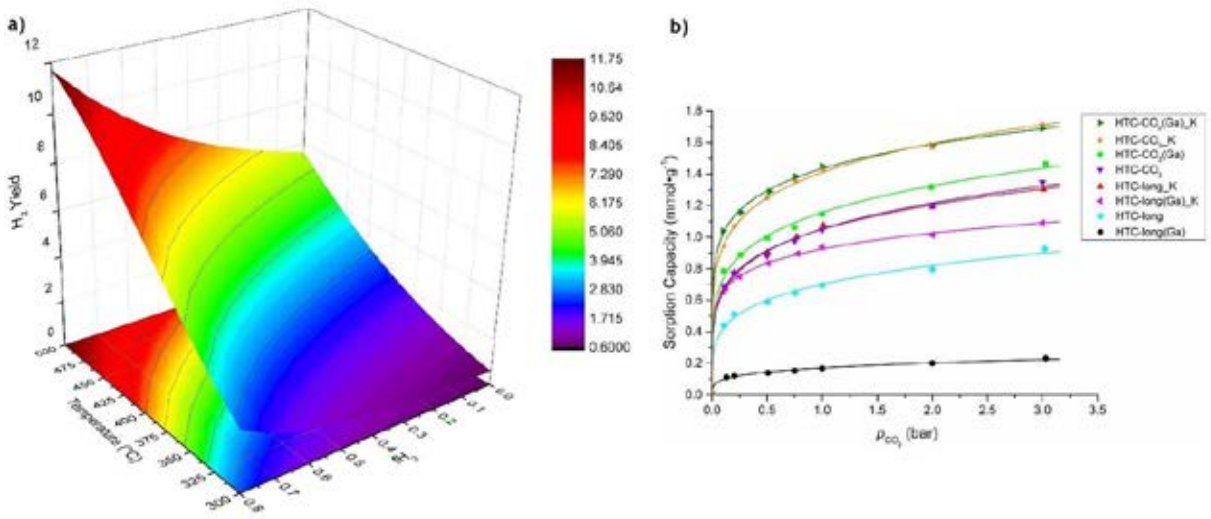

Fig. 1. a) Yield of H_2 as function of temperature and H_2 removal fraction at 1 bar in a MR – thermodynamic analysis. b) H_2 yield obtained using commercial and prepared catalysts. c) CO_2 equilibrium isotherms of prepared HTCs at 300 ºC.

Regarding the catalysts screening study, the Rh-based, as well as the Ni/SiO_2-Al_2O_3 and Ni-Ru/SiO_2 samples, reached the highest values of H_2 yield among the 10 commercial and 5 prepared catalysts tested (materials with different active phases/support and distinct metal loadings). Among them, the Rh/Al_2O_3 and Ni/SiO_2-Al_2O_3 catalysts presented a high and relative stable H_2 yield (ca. 9 mol_{H2}/mol_{OMW}) during 24 h of time-on-stream – Fig. 2.

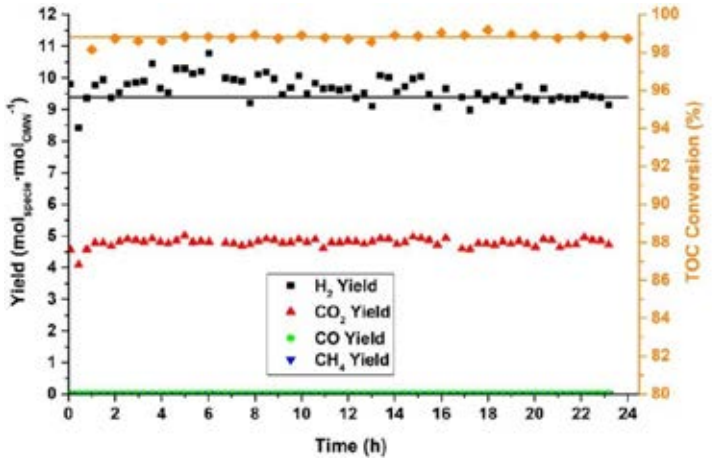

Fig. 2. Gaseous species yield and TOC conversion during 24 h time-on-stream for the Rh/Al_2O_3 catalyst at 400 ºC and 1 bar.

The removal of H_2 and CO_2 allowed reaching higher and stable H_2 yields in the SEMR (c.a. 11 mol_{H2}/mol_{OMW}) during the pre- and pos-breakthrough time in comparison with the TR (see Fig. 3a-b)) [5]. This allows the simultaneous production of highly pure H_2 in the retentate and ultra-pure H_2 on the permeate side. A higher improvement in terms of H_2 yield was observed when the MR and particularly the SEMR was applied (see Fig. 3c) - H_2 yield enhancement of ≈ 44 % was noted compared to the TR). It was also demonstrated that the steam reforming process, when implemented in a SEMR, can efficiently handle real OMW effluents, with high productions of H_2, with practically complete removal of the pollutant load. Considering the limit emission values of several parameters for the discharge of wastewater in Portugal, it was also observed that the condensable samples (liquid effluent) obtained during the tests present suitable physicochemical characteristics, namely in terms of pH (between 6.0 and 9.0), color (no visible color after a 1:20 vol dilution), smell (no smell after a 1:20 vol. dilution), total organic carbon (<55 $mg_C \cdot L^{-1}$ - removal of ≈ 100 %) and chemical oxygen demand (<150 $mg_{O2} \cdot L^{-1}$ – removal of ≈ 100 %).

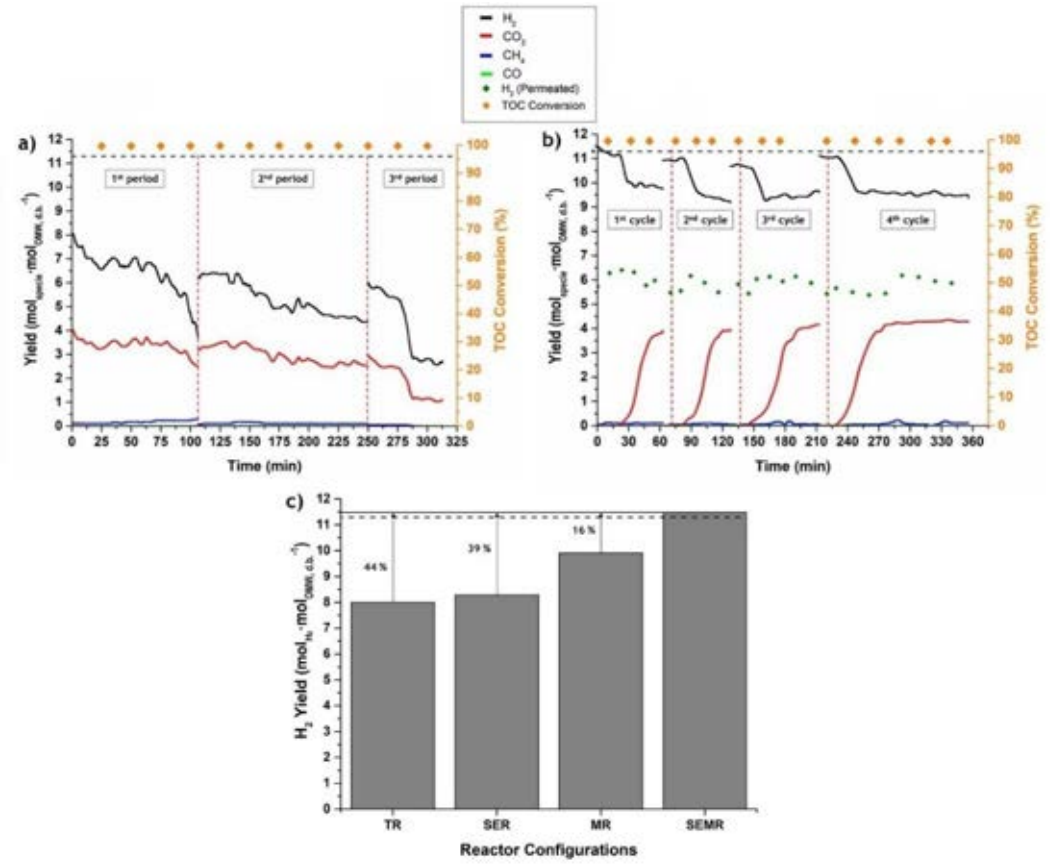

Fig. 3. Gaseous species yield and TOC conversion using a Ni-Ru/CeO_2-SiO_2 catalyst in a) TR or b) SEMR at 400 °C and 4 bar. c) H_2 yield with the different reactor configurations at 400 °C and 4 bar.

CONCLUSIONS

Thermodynamic analyses showed that the SEMR has several advantages in comparison with other reactor configurations. An HTC was prepared (HTC-CO_3(Ga)_K) showing high CO_2 sorption capacity under conditions suitable for a SEMR. Several commercial and new catalysts have shown high catalytic performance for OMWSR, some of them with high stability during 24 h of reaction (e.g. Rh/Al_2O_3). It was demonstrated that the use of multifunctional reactors in the OMWSR allows reducing considerably the pollutant load of such effluents, while economically valorizing this waste with the production of green H_2.

ABSTRACT

The eGHOST project is the first milestone for the development of eco-design criteria in the European hydrogen sector. In the framework of this project, a life cycle sustainability assessment (LCSA) of a proton-exchange membrane fuel cell (PEMFC) stack was performed to estimate its potential environmental, economic, and social impacts. This assessment supports the identification and development of future sustainable design criteria that could be incorporated at early stages of the product development. The methodologies applied in the framework of the LCSA include environmental life cycle assessment (LCA), life cycle costing (LCC), and social life cycle assessment (S-LCA). Environmental (climate change, acidification, eutrophication, and resource use), economic (e.g., total production cost) and social (child labour, contribution to economic development, health expenditure, etc.) life-cycle indicators are evaluated for the product at the manufacturing phase, leading to the identification of sustainability hotspots. The results will support the development of future eco-design guidelines adapted to current and future fuel cells and hydrogen (FCH) technologies.

Keywords: eco-design, hydrogen, proton exchange membrane fuel cell, life cycle assessment, life cycle cost, social impacts

INTRODUCTION

Increasing concerns on climate change and natural resource depletion have raised interest in renewable energy sources and low-impact technologies. Among other solutions, fuel cells and hydrogen (FCH) technologies look promising provided that sustainable technologies for hydrogen production and use are effectively implemented. Therefore, the sustainability performance of FCH systems must be assessed in a holistic approach embracing environmental, economic, and social aspects [1]. The European project eGHOST involves a full life cycle sustainability assessment (LCSA) of a proton-exchange membrane fuel cell (PEMFC) stack, a rather mature technology for which the focus of researchers in the field of energy systems analysis has been mainly placed on its environmental life cycle assessment (LCA), while rarely on its life cycle costing (LCC) and almost never on its social life cycle assessment (S-LCA).

METHODOLOGY FOR LIFE CYCLE SUSTAINABILITY ASSESSMENT

The evaluated reference product for the PEMFC technology is a 48 kW_{el} PEMFC stack that can be used in light fuel cell electric vehicles (FCEV; single or multiple stack units). The detailed specifications and bill of materials (BoM) were provided by the industrial partner SYMBIO. The automotive PEMFC stack consists of 280 MEA (membrane electrode assembly) units with an active area of 200 cm^2 each. The amount of platinum in the 48 kW_{el} PEMFC stack is 0.5425 g/kW.

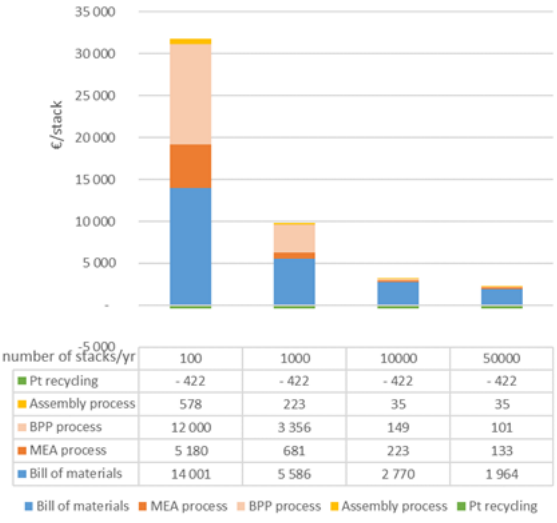
Environmental Life Cycle Assessment framework

For the environmental evaluation of the PEMFC stack, a conventional life cycle assessment (LCA) was applied considering international standards [2,3] and ILCD guidelines [4]. The functional unit was defined as “the manufacturing of one PEMFC stack of 48 kW electrical power output (balance of plant excluded)”. The data for the inventory of the PEMFC stack was collected by a manufacturer company, SYMBIO. In addition, for background processes, the ecoinvent database and extended databases for precious metals and critical materials were used. The Environmental Footprint 3.0 method was used to evaluate a set of environmental life-cycle indicators: climate change, acidification, eutrophication, resource use linked to minerals and metals, and resource use linked to energy carriers.

Life Cycle Costing framework

Conventional life cycle costing (LCC) is a method for evaluating all relevant costs over the lifetime of a product. It takes into consideration all costs including first costs, such as manufacturing costs, purchase, and installation costs; future costs, such as energy costs, operating costs, maintenance costs, capital replacement costs, financing costs; and any resale, salvage, or disposal cost, over the lifetime of the product. The LCC study applied was conducted following the same scope as the LCA study.

$$C = MP + P + D \quad (1)$$



In Eq. (1) *C* is the cost of the stack, *MP* cost of raw materials and consumables, *P* cost of production involving tool depreciation, labour, energy and consumables, and *D* miscellaneous cost (premises, facilities, etc.).

Social Life Cycle Assessment framework

Updated guidelines for S-LCA of products have been developed within the framework of the United Nations Environment Programme [5] and were considered in this case. As in the case of environmental LCA, an S-LCA comprises four phases: goal and scope definition, social life cycle inventory, social life cycle impact assessment, and interpretation. The system boundaries were set according to the supply chain definition. Spain was considered as the stack manufacturing country. The supply chain of the product involves three tiers: tier 1 for the stack manufacturing plant itself, tier 2 for the plants related to the production of the components and energy flows required by the stack manufacturing plant, and tier 3 for the plants related to the material and energy flows required by the components manufacturing plants. The identification of the countries involved was carried out according to Martín-Gamboa et al. [6]. The inventories used for LCA and LCC, together with the working hours associated with each manufacturing plant considered, constitute the main source of data for the social life cycle inventory. PSILCA was used as both an auxiliary database and an assessment method [7]. Child labour, forced labour, and fair salary were selected as indicators within the stakeholder category “workers”, while health expenditure and contribution to economic development were considered within the stakeholder category “society” [8].

RESULTS AND DISCUSSION

Among the environmental results, the carbon footprint of one manufactured 48 kW PEMFC stack was estimated at 1200 kg $CO_{2eq.}$, which corresponds to 25 kg $CO_{2eq.}$ per kW_{el}. Platinum and, to a lesser extent, electricity production were found to have the highest contribution to the carbon footprint, namely platinum would represent 74% and electricity 14% of the total climate change impact.

number of stacks/yr	100	1000	10000	50000
Pt recycling	- 422	- 422	- 422	- 422
Assembly process	578	223	35	35
BPP process	12 000	3 356	149	101
MEA process	5 180	681	223	133
Bill of materials	14 001	5 586	2 770	1 964

Fig. 1. LCC of the 48 kW PEMFC stack according to production scale

The cost (LCC results) was found to be very dependent on the production rate (Fig. 1). The transition from laboratory to industrial scale could enable to divide the cost more than three times acting on both process and material costs. For 50,000 units produced per year, a cost of 2233 €/stack was calculated, and the main contributor comes from the bill of material and in particular the uncompressible cost of platinum. Finally, the results of the Social-LCA emphasizes that platinum production in South Africa was found to be the main social hotspot, arising –despite the limited amount

used– as the major contributor to all the social life-cycle indicators with a negative connotation (Fig. 2). The social risks associated with energy flows were found to be negligible.

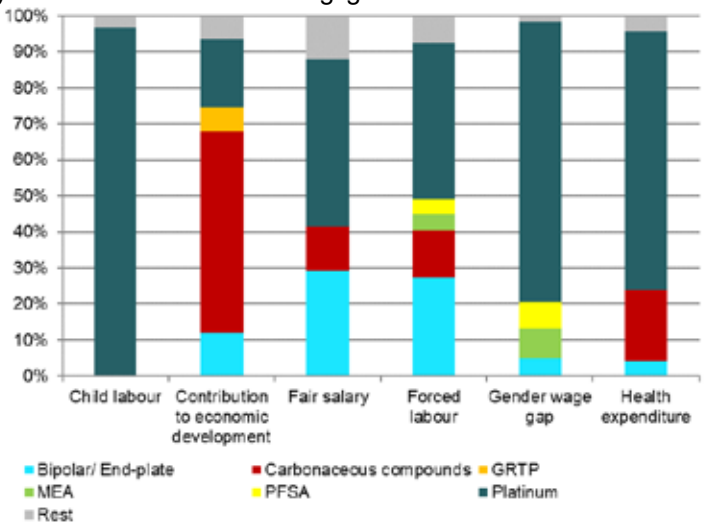


Fig. 2. Contribution to the potential social impacts for the 48 kW PEMFC stack

CONCLUSIONS

Even though platinum accounts only for 0.074% of the total mass of the stack, it is the main environmental and social hotspot, which highlights the importance of using low platinum loading and the new end-of-life possibilities to recover Pt from FCH technologies. Costs are highly dependent on the production rate: a transition from laboratory to industrial scale could allow a cost reduction of more than three times. Assuming a production capacity of 50,000 units, the estimated costs reach 2233 € per PEMFC stack. The sustainability assessment presented in this work arises as a key input to improve the life-cycle sustainability profile and provide eco-design guidelines for FCH product and supports the identification and development of future sustainable design criteria that could be incorporated at early stages of the product development.

THE ENERGY-ENVIRO-ECONOMIC EVALUATION AND MULTI-OBJECTIVE OPTIMIZATION OF THE HYDROGEN PRODUCTION PROCESS FROM COAL-BIOMASS CO-GASIFICATION CONSIDERING UNCERTAINTY IN CARBON PRICES

[1] Han Yang, [1] Min Dai, [1*] Fusheng Yang, [1]Yunsong Yu, [1]Zhen Wu, [1]Zaoxiao Zhang

ABSTRACT

Hydrogen has attracted more and more attention due to its advantages of low environmental impact and high energy density. However, the current hydrogen production process based on coal is usually accompanied by high energy consumption and CO_2 emission. Therefore, it is particularly important to develop efficient and clean hydrogen production technology. Based on this, a poly-generation system based on the co-gasification of coal and biomass coupled with carbon capture was proposed. Carbon dioxide emissions pricing is employed as an approach to mitigate climate change. Therefore, the impact of carbon prices on co-gasification system is analyzed, and the energy-enviro-economic evaluation of the system is carried out. Besides, the trade-off between exergy efficiency, annual gross profit and annual carbon emissions is conducted by multi-objective optimization. The results show that the system can be operated successfully under the optimum settings, achieving green and efficient hydrogen production while obtaining high economic benefits.

Keywords: Hydrogen production, Carbon price, Multi-objective optimization, Co-gasification

INTRODUCTION

Hydrogen is regarded as one of the most promising energy sources due to its high energy density, environmentally friendly and renewable characteristics [1]. Hydrogen production from coal gasification will lead to the consumption of fossil energy and damage to the environment. Biomass is renewable, clean and carbon neutral. Unfortunately, biomass cannot completely replace coal for power generation because it is seasonal and has low heat density [2]. The co-gasification of coal-biomass provides a better alternative for hydrogen production, and the system is often evaluated from the perspective of energy-enviro-economic(3E) [3]. However, the traditional method based on fixed price cannot precisely reflect the actual situation due to the fluctuation of carbon prices. The main purpose of the current paper is to figure out the impact of carbon prices on performance of co-gasification system based on the energy-enviro-economic evaluation and multi-objective optimization.

MATERIALS AND METHODS

Fig. 1 shows the basic contents of this paper. Firstly, a process model for hydrogen production from co-gasification is established by using Aspen Plus software, as shown in Fig. 2. This system is mainly divided into four units: gasification, purification, water gas shift, carbon capture and pressure swing adsorption (PSA). Gasification unit decomposes coal and biomass according to their composition as described through cracking module, and then the gasification process is implemented through RGIBBS module. The purification unit adopts the rectisol process to remove sulfide. Afterwards, purified syngas converts CO into CO_2 and H_2 through water gas shift [4]. Next the hydrogen is purified through PSA [5], attaining a purity of more than 99.999%. Then a quantitative sustainability evaluation method was introduced for the performance analysis of this system, including an energy model aiming at improving the exergy efficiency, a dynamic econometric model considering the fluctuation of carbon prices, and an environmental assessment model based on annual CO_2 emissions (ACE). Finally, the multi-objective optimization method was adopted based on the energy, economy and environment (3E) of the system.

RESULTS AND DISCUSSION

Model validation

Table 1 shows the comparison between the data under actual working condition and the simulated data of this study. Good consistency is achieved with the mean relative error of less than 7%, which indicates that the model can be used to analyze and optimize the process.

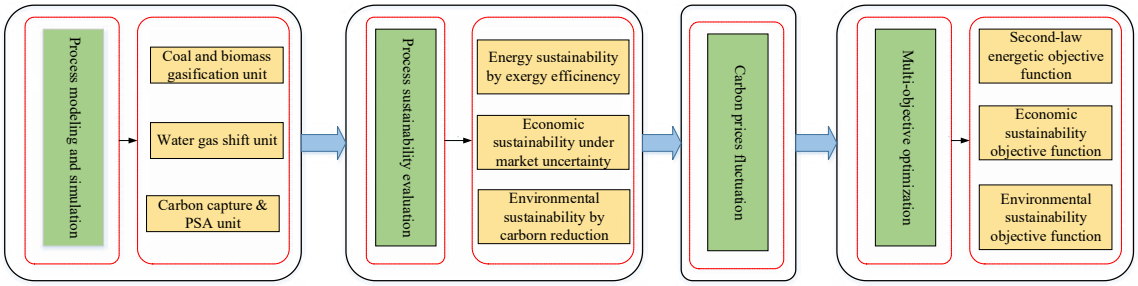

Fig. 1. The analysis procedure of the proposed system

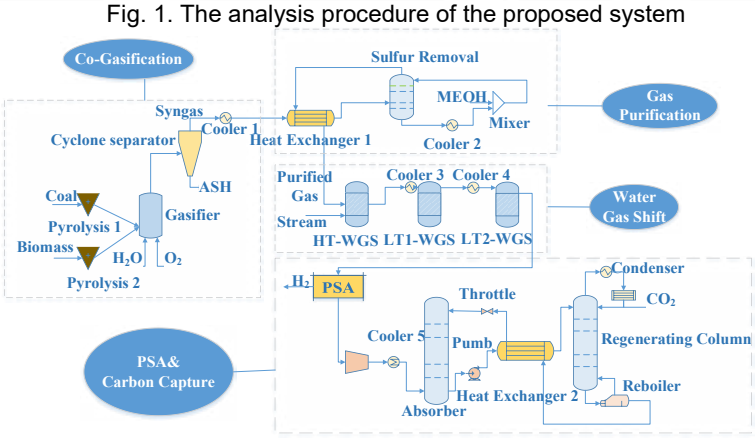

Fig. 2. Aspen plus flow sheet for co-gasification simulation

Table 1 Model validation

	Condition	Literature [6]	Simulation
Gibbs Reactor	Temperature (℃)	1074℃	1074℃
	Pressure (bar)	28.5bar	28.5bar
Initial Stream Data	Coal (kg/h)	21600	21600
	Biomass (kg/h)	14400	14400
	Stream (kg/h)	10800	10800
	O_2 (kg/h)	14400	14400
Syngas Component	H_2 (%)	0.31	0.33
	CO (%)	0.44	0.42
	H_2O (%)	0.14	0.14

Analysis of optimization results

Fig. 3 shows the Pareto-optimal fronts obtained by NSGA-II and the ultimate optimum solutions selected by TOPSIS. From Fig. 3, the optimum value of exergy efficiency changes from 40.86% to 48.80%, annual gross profit is between 7.130×10^7 \$/year and 1.161×10^8 \$/year, and accordingly, annual carbon emissions changes from 5.703×10^5 t/year to 8.488×10^5 t/year. Compared with the actual operating condition, the exergy efficiency and annual gross profit can be increased by 7.60% and 12.71% when the CO2 emission reduces by 1.50%. Further, the main decision variables corresponding to this Pareto front are shown in Figure 4. As can be seen from Fig. 4(a), exergy efficiency and carbon emission of the system decrease with the increase of oxygen content. This is because increasing the oxygen content will promote the combustion reaction, leading to the gradual rise of the internal temperature of the gasifier, thus increasing the exergy destruction caused by the temperature difference. At the same time, high temperature promotes the conversion of fuel, thus the CO_2 content decreases. As for the annual gross profit of the system, it increases with the growth of oxygen content because of promoted transformation of C and thus increasing total H_2 product. From Fig. 4(b), with the increase of steam, 3E index presents an upward trend, and the optimal range of the above three is [7500,12750], [8000,12000] and [2500,9500], respectively. The reason is that the increase of mass flow for steam will reduce the gasification temperature, thus reducing the exergy destruction caused by the temperature difference. Meanwhile, when the steam increases, the exothermic water-gas shift reaction intensifies, and a large amount of CO is converted into H_2 and CO_2. In this case, hydrogen production increases, thus increasing the system profit [6]. In addition, increasing carbon emissions are also generated.

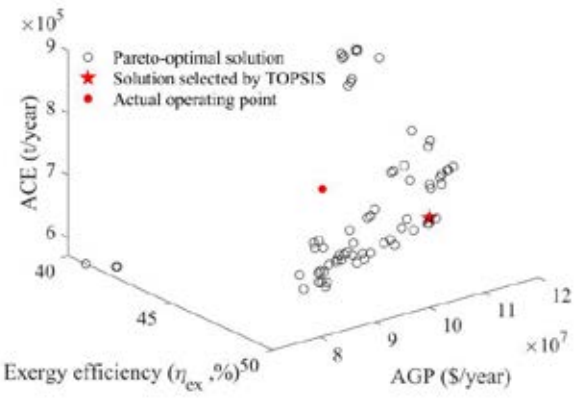

Fig. 3. Pareto front and the final optimal solution selected by TOPSIS for the H_2 production process

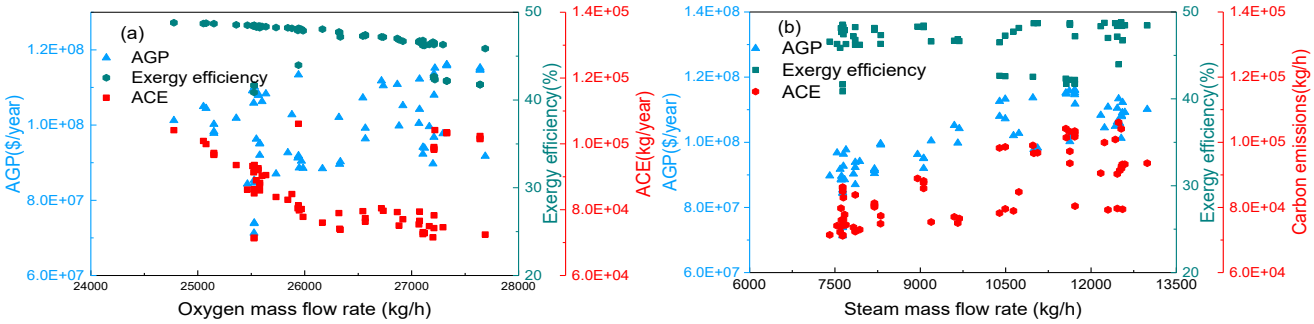

Fig. 4. Optimal values corresponding to the Pareto-optimal front, (a) Effect of oxygen flow (b) steam flow on 3E index.

CONCLUSIONS

In this paper, a process model for hydrogen production from coal-biomass co-gasification with carbon capture, is proposed and evaluated by 3E multi-objective optimization. The simulation results show exergy efficiency and carbon emission of the system decreased with the increase of oxygen content, meanwhile the annual gross profit of the system will increase. With the increase of steam, 3E indices present an upward trend, and the optimal range of the above three is [7500,12750], [8000,12000] and [2500,9500], respectively. The follow-up work is dedicated to discussion on the impact of carbon prices on economy and the analysis of other parameters.

ABSTRACT

Water electrolysis technologies enable the decarbonization of the industry, energy and transport sectors. Significant increases of electrolysis deployment are expected and will cause extensive material requirements. The current study investigates to which extent prospective electrolysis deployment affects raw material demand in relation to production volumes and reserves as well as environmental impacts related to further construction materials. The methods life cycle assessment and criticality analysis are used to exploit sustainability potentials of three water electrolysis technologies (AEC, PEMEC, and SOEC). LCA revealed minor contributions to climate change caused by materials required for plant construction. Clear changes of environmental impacts up to the year 2050 are given for SOEC as their life time significantly increases and material demand decreases. The work on the criticality analysis identified nine different raw materials, which are considered potentially critical and are required for water electrolysis plant construction. The expected demand for iridium and platinum, nickel, lanthanum and yttrium are particularly critical. Graphite, potassium, titanium and zirconium, on the other hand, do not exhibit raw material criticality. Results show different electrolysis technologies are likely to be used in parallel. Possible risks in the future raw material supply will thus be spread and mitigated overall.

Keywords: Hydrogen, water electrolysis, Power-to-Gas, Life Cycle Assessment, criticality analysis

INTRODUCTION

Climate protection is currently one of the greatest global challenges. Against the background of the Paris Climate Agreement, the EU aims at climate neutrality by 2050. Achieving this will require, in particular, a move away from the use of fossil fuels and their substitution with renewable energies. Water electrolysis technologies are seen as a technical solution to improve the integration of renewable energies and to replace fossil-based energy carriers. These technologies convert electricity into gaseous energy carriers, applicable in different sectors and can also be referred to as Power-to-Gas technologies. Therefore, water electrolysis is considered an important tool for the transformation and decarbonization of the industry, energy and transport sectors [1]. However, in order to contribute to the decarbonization of sectors in Europe in the long term, they must be technologically mature and sustainable in terms of their raw material requirements [2]. Thus, technological development of water electrolysis technologies supported by studies using life cycle assessment (LCA) and criticality analyses is needed to exploit sustainability potentials. A former review dealing with water electrolysis revealed that data about plant construction and materials used for it are mostly left out or the level of detail is rather low [3]. There is only a limited number of LCAs with a higher level of detail about the materials required for electrolyser construction (e.g. [4]) and those assessments typically focus on only one water electrolysis technology. Furthermore, the combination of LCA and in-depth criticality analysis rarely takes place. As significant increases of water electrolysis deployment is expected, detailed knowledge about environmental impacts and criticality of applied (raw) materials have to be obtained as early as possible to identify sustainable manufacturing pathways.

Due to this research need, this study presents detailed assessments and comparisons of three different electrolysis technologies, using the LCA and criticality analysis methods. The study aims to answer if and to which extent the expected multiplying water electrolysis deployment affects the demand for raw material in relation to their respective production volumes and reserves as well as environmental impacts provoked by further construction materials. Transparent life cycle inventories and environmental impacts, especially provoked by material use for electrolyser construction, and raw material criticalities are presented up to the year 2050 to show how even material use for hydrogen production can be as green and sustainable as possible.

MATERIALS AND METHODS

Objects of the current investigation are water electrolysis technologies. Following three water electrolysis technologies are currently under intense discussion for large-scale production and deployment [5] and consequently assessed within the current study: Alkaline Electrolysis Cell (AEC), Proton Exchange Membrane Electrolysis Cell (PEMEC), and High

Temperature Steam Solid Oxide Electrolyzer Cell (SOEC). All three technologies have in common that they split water into hydrogen and oxygen under supply of electrical energy. However, they use different reaction mechanisms, cell structures, and electrolytes as well as diverse raw materials and further materials required for their construction. To assess their impacts and to compare them the two sustainability-oriented methods LCA and criticality assessment are applied. Both assessment methods consider European and prospective conditions up to the year 2050. For the presented assessments, results of the centre of excellence “Virtual Institute - Power to Gas and Heat” project framework are considered.

The established method of LCA is applied for the environmental assessment on the different electrolysis technologies. Material, energy, emissions, and further flows occurring along the entire chain from raw material extraction, production, distribution, operation up to its final use are initially quantified and hereafter evaluated in terms of environmental impacts. This procedure as well as the consideration of the four typical LCA phases is based on the ISO standards 14040 and 14044. To compare life cycle impact assessment results they are based on a functional unit of 1 kg hydrogen. Beside foreground data, generic data is taken from the ecoinvent database. Special attention is paid to the analyses of the impact category global warming potential (GWP). In addition to this indicator, further impact categories were analyzed according to the established ReCiPe methodology. The LCA is limited to the construction and operation phase. The end of life phase is not included due to lack of information and standardization not yet fully completed.

Main objective of the criticality analysis is to examine whether future capacity additions of electrolyzer technologies may result in bottlenecks with regard to individual raw materials. To this end, the critical raw materials and their specific demands were first determined for each technology. In order to identify the total raw material requirements for Germany and Europe, these specific demands were extrapolated in a second step using modeled capacities of the technologies in 2050 derived from energy scenarios of the underlying project. Total demands were then compared to the annual production volumes and global reserves of the respective materials. An extensive literature research of potential critical raw materials, their used quantities (e.g. in g/kW_{el}) as well as the lifetime of the technology took place. A range from the minimum to the maximum researched raw material demand is considered in the criticality analyses. This range represents the "optimistic" and "pessimistic" estimates of the literature and underlines the fact that a large proportion of the technologies are still in development with uncertainties regarding actual future raw material requirements. Classification of raw materials as critical for the purposes of this study is primarily based on the European Commission's list of critical raw materials [6]. The two central parameters for compiling this list are the economic importance and the supply risk of the raw materials analyzed. In addition, classifications according to existing studies on the use of critical mineral raw materials in specific individual technologies or different technology groups are also considered (e.g. [7]).

RESULTS AND DISCUSSION

The LCA revealed minor contributions of materials required for plant construction to the GWP. Plant operation clearly dominates the GWP in case of operation with wind energy with contributions clearly above 80 %. This is mainly caused by upstream impacts of the electricity used for hydrogen production. A comparison of GWP results of the electrolysis technologies shows advantages for PEMEC as illustrated in Table 1. However, SOEC reveals the best performance for further environmental impact categories. Materials with noteworthy effects on further environmental impacts are e.g. chromium steel and polytetrafluoroethylene (PTFE) used for gaskets in AEC stacks. Chromium steel shows the highest individual contributions on several environmental impact categories for SOEC.
The work on the criticality analysis illustrates in Table 1 that nine different raw materials, which are considered potentially critical in the literature, are generally required for the construction of the assessed water electrolysis capacities. From the extrapolation of cumulative raw material requirements caused by water electrolysis utilisation in Germany and Europe in the long term up to 2050, only some of these nine raw materials investigated are likely to be deployed to a critical extent. The expected demand for iridium and platinum (PEMEC), nickel (primarily for AEC), and lanthanum and yttrium (SOEC) are particularly critical. Graphite, potassium, titanium and zirconium, on the other hand, do not exhibit raw material criticality based on applied criteria and assumed future installed electrolysis capacities.

Previously mentioned results of LCA and criticality analysis to compare the three water electrolysis technologies are summarized in Table 1.

Table 1. Qualitative comparison of LCA and criticality results for the three considered water electrolysis technologies (green: uncritical or lowest impacts, yellow: possibly critical or increased impacts, red: critical or significantly higher impacts, dark gray: raw material is not needed for the respective technology)

		AEC	PEMEC	SOEC
Criticality analysis results	*Graphite*			
	Iridium			
	Potassium			
	Lanthanum			
	Nickel			
	Platinum			
	Titanium			
	Yttrium			
	Zirconium			
LCA results	*GWP*			
	Further impacts			

With regard to the research objective, it can be seen that different electrolysis technologies (AEC, PEMEC, and SOEC) are likely to be used in parallel. Possible risks in the future raw material supply of the pathways will thus be spread and mitigated overall. Concerning environmental aspects a lower developed technology like SOEC should be part of the electrolysis deployment as this will lead to technological learning with effects on life time and environmental impacts.

CONCLUSIONS

Future research can build on the data and results presented and take into account new findings and further technologies. In addition, further methods and indicators can be used to compare water electrolysis technologies. One example is Life Cycle Costing, where levelised costs of hydrogen production are only one possible indicator. The classification of raw material criticalities needs to be verified by a more detailed analysis of previously used and additional indicators. Examples include a stronger focus on competitive applications and megatrends beyond water electrolysis deployment, and a comprehensive consideration of circular economy aspects. As shown a combined deployment of water electrolysis can lower the criticality to individual critical raw materials. Suchlike combination can also be reasonable from a technological or economic point of view as the electrolysis technologies have different strengths depending on operation strategies (e.g. flexible operation or heat integration).

ACKNOWLEDGEMENT

Funding of the center of excellence “Virtual Institute - Power to Gas and Heat” (EFRE-0400151 and EFRE-0400154) by the “Operational Program for the promotion of investments in growth and employment for North Rhine- Westphalia from the European fund for regional development” (OP EFRE NRW) through the Ministry of Economic Affairs, Innovation, Digitalization and Energy of the State of North Rhine-Westphalia is gratefully acknowledged.

ABSTRACT
In this study, a comparative life cycle assessment (LCA) of hydrogen production is presented using the spectrum of hydrogen colors. The main hydrogen colors are studied depending on their varying energy sources and hydrogen production processes. The aim of the study is to investigate the environmental impacts of main hydrogen colors. The study results are illustrated in 6 different impact categories namely; global warming potential (GWP), ozone layer depletion potential (ODP), human toxicity potential (HTP), photochemical oxidation potential (POP), acidification potential (AP), and eutrophication potential (EP). The results show that brown hydrogen is the opposite of green hydrogen in the hydrogen spectrum, and it is the most environmentally harmful hydrogen type. Brown hydrogen emits 0.325 kg of CO_2 eq per 1 kg of hydrogen production while green hydrogen produce only 0.0072 kg of CO_2 eq per 1 kg of hydrogen production. Grey hydrogen is the second most harmful hydrogen type after brown hydrogen, with a value of 0.178 kg of CO_2 eq per 1 kg of hydrogen production. Turquoise hydrogen with a value of 0.079 kg of CO_2 eq per 1 kg of hydrogen production. Green hydrogen is the most environmentally friendly and sustainable option among the studied hydrogen production options.

Keywords: Hydrogen production, Life cycle assessment, Hydrogen colors, Environmental impact, Global warming.

1. INTRODUCTION
An intimate relationship exists between energy, the environment, and sustainable development. Ideally, a community pursuing sustainable development would only use energy products that do not have any environmental impacts. However, because all energy resources have some impact on the environment, it is fair to say that some of the concerns about the constraints placed by environmental emissions on sustainable development and their harmful impacts can be partially resolved by increasing energy efficiency. Clean, boundless, and highly competitive energy sources are renewable energy sources. They differ primarily in their variety, availability, and capacity for use anywhere on the planet from fossil fuels, but primarily in that, they generate neither greenhouse gases nor polluting emissions that cause climate change. Their expenditures are also declining and at a sustainable rate, despite their current uncertainty, the general cost trend for fossil fuels is in the opposite direction [1]–[3]. Due to the constantly falling cost of renewable energy generation, "green" hydrogen (i.e. hydrogen produced via electrolysis using renewable energy) is considered as a promising energy carrier for a variety of applications.

The main objectives of this study are listed as follows:

- conducting a cradle-to-grave LCA of hydrogen production methods considering hydrogen colors.
- determining the critical hot spots in the system for their environmental loads, and
- comparing the LCA results of hydrogen colors.

2. MATERIALS AND METHODS
Green Hydrogen
Green hydrogen is the color of hydrogen produced with no damaging greenhouse gases (GHGs) in the spectrum of hydrogen colors. Green hydrogen is created by electrolyzing water with clean electricity generated from surplus renewable energy sources such as solar or wind power. Electrolysis divide water into hydrogen and oxygen via an electrochemical reaction, producing no carbon dioxide in the process. Green hydrogen currently accounts for a small percentage of total hydrogen due to the high cost of generation. Green hydrogen will become more affordable as it becomes more widely available, just as wind energy has.

Blue Hydrogen
The most common source of blue hydrogen is natural gas, which is produced through a process known as steam reforming, which combines natural gas and heated water in the form of steam. Hydrogen is produced, but carbon dioxide is produced as a by-product. To catch and store this carbon, carbon capture and storage (CCS) is required. Because the steam reforming process does not actually avoid the generation of GHGs, blue hydrogen is sometimes referred to as "low-carbon hydrogen."

Turquoise Hydrogen
This is a new addition to the hydrogen color wheel, and scale manufacturing has yet to be confirmed. Turquoise

hydrogen is created using the methane pyrolysis process, which produces hydrogen and solid carbon. Turquoise hydrogen could be regarded as a low-emission hydrogen in the future, assuming that the heating process is supplied by renewable energy and that the carbon is permanently stored or utilized

Grey Hydrogen
This is currently the most frequent method of hydrogen synthesis. Grey hydrogen is manufactured from natural gas or methane, and by steam methane reformation, but without capturing the greenhouse gases produced.

Brown Hydrogen
This brown hydrogen is the complete opposite of green hydrogen in the hydrogen spectrum and the most environmentally harmful. They are produced using black coal or lignite (brown coal) in the hydrogen-making process. To add to the confusion, any hydrogen produced by the 'gasification' of fossil fuels is sometimes referred to as black hydrogen. [4]. The major hydrogen colors differ depending on the energy source and the hydrogen synthesis process, as shown in Fig. 1.

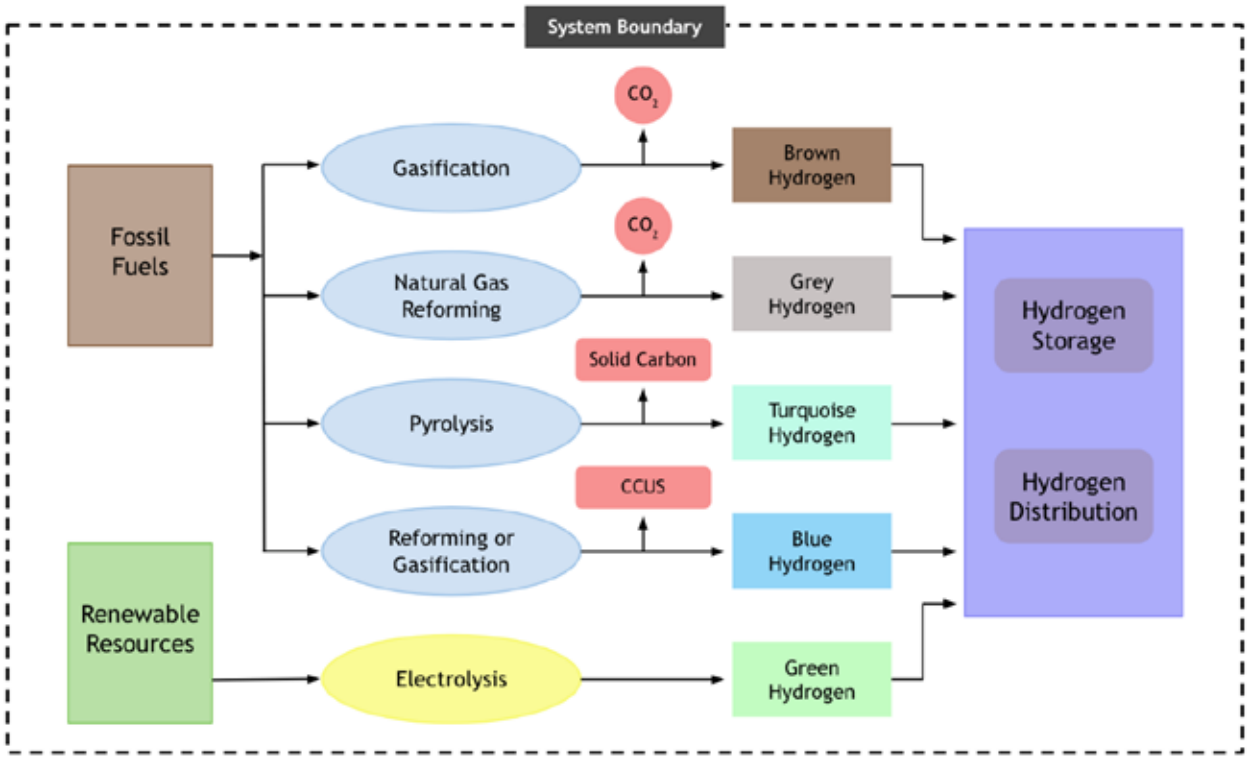

Fig. 1: Simplified layout of the proposed system boundary and major life cycle stages considered in this study

3. RESULTS AND DISCUSSION

A comparison of LCA results for hydrogen production methods using the spectrum of hydrogen colors is presented with Table 1. Impact assessment results displays five different hydrogen colors based on the hydrogen production sources and processes. The results shows that the brown hydrogen is opposite of green hydrogen in the hydrogen spectrum and it is the most environmentally harmful hydrogen type. Brown hydrogen is produced using black coal or lignite (brown coal) in the hydrogen-making process. Brown hydrogen emits 0.325 kg of CO_2 eq per 1 kg of hydrogen production while green hydrogen produce only 0.0072 kg of CO_2 eq per 1 kg of hydrogen production. Grey hydrogen is the second most harmful hydrogen type after brown hydrogen with value of 0.178 kg of CO_2 eq per 1 kg of hydrogen production, followed by turquoise hydrogen with a value of 0.079 kg of CO_2 eq per 1 kg of hydrogen production. Blue hydrogen is the most environmentally friendly option among the fossil-based hydrogen production options. This is because hydrogen is produced, but carbon dioxide is produced as a by-product. To catch and store this carbon, carbon capture and storage (CCS) is required. However, the steam reforming process does not actually avoid the generation of GHGs.

The impact assessment results show that grey hydrogen has the highest ozone layer depletion impact among the hydrogen production methods. Grey hydrogen is manufactured from natural gas or methane, and by steam methane reformation, but without capturing the greenhouse gases produced. The absence of capturing the greenhouse gases in the blue hydrogen production method results in higher emission values. The depletion of the ozone layer is primarily caused by nitrogenous chemicals such as NO_2, NO, and N_2O. Turquoise hydrogen production has the second highest

ozone layer depletion value, and then followed by brown hydrogen and blue hydrogen. Green hydrogen production techniques emerge as the most promising and sustainable hydrogen production method. As a result, using clean energy production techniques is crucial for achieving lower environmental impacts in the long term.

Table 1: Life cycle impact assessment results of the hydrogen colors

Impact category	Unit	Brown Hydrogen	Green Hydrogen	Turquoise Hydrogen	Grey Hydrogen	Blue Hydrogen
Global warming (GWP100a)	kg CO_2 eq	0.325	0.0072	0.079	0.178	0.0198
Ozone layer depletion	kg CFC-11 eq	3.09E-09	9.57E-10	1.02E-08	2.32E-08	1.97E-09
Human toxicity	kg 1,4-DB eq	0.126	0.0147	0.0317	0.0179	0.0526
Photochemical oxidation	kg C_2H_4 eq	2.49E-05	2.76E-06	7.89E-06	1.37E-05	5.21E-06
Acidification	kg SO_2 eq	0.00078	2.75E-05	9.55E-05	0.00015	6.67E-05
Eutrophication	kg PO_4 eq	0.00067	1.96E-05	3.17E-05	3.28E-05	4.68E-05

4. CONCLUSIONS

This paper deals with environmental impacts of hydrogen production methods using the spectrum of hydrogen colors. The main hydrogen colors are studied depending on their varying energy sources and hydrogen production processes. The key concluding remarks of this study can be summarized as follows:

- The results show that the brown hydrogen is the opposite of green hydrogen in the hydrogen spectrum and it is the most environmentally harmful hydrogen type.
- Brown hydrogen emits 0.325 kg of CO_2 eq per 1 kg of hydrogen production while green hydrogen produces only 0.0072 kg of CO_2 eq per 1 kg of hydrogen production.
- Blue hydrogen is the most environmentally friendly option among the fossil-based hydrogen production options.
- The impact assessment results shows that grey hydrogen has the highest ozone layer depletion impact among the hydrogen production methods.
- The LCA calculation results indicate that brown hydrogen produces the highest human toxicity during hydrogen production process.
- Brown hydrogen and grey hydrogen have the highest acidification potential impacts.
- Brown hydrogen has the highest eutrophication values in comparison to all other hydrogen production techniques with a value of 0.00067 kg of PO_4 equivalent per 1 kg of hydrogen production.

ABSTRACT

Green hydrogen is expected to play an important role in European decarbonisation efforts. This work investigates whether shipping green hydrogen within Europe could be a better climate solution than producing it locally. Three options for delivering hydrogen are analysed: hydrogen compression, liquefaction, and chemical bonding to other molecules (i.e., using ammonia, liquid organic compounds, methanol, or synthetic natural gas as hydrogen carriers). A distance compatible with the European territory was considered: i.e., production in Portugal and end-use in the Netherlands. The life cycle greenhouse gas emissions of shipped hydrogen are compared to the emissions arising from producing hydrogen locally, via either steam methane reforming or electrolysis powered by the electric grid. Preliminary results show that all the delivery options would guarantee in 2030 a supply of hydrogen with a lower global warming potential than locally produced hydrogen. Liquefaction appears to be the least greenhouse gas intense delivery solution, thanks to the lower volumes transported and the lack of an energy intensive transformation process at the delivery site. Nevertheless, much of the infrastructure for large scale hydrogen delivery does not yet exist, and therefore assumptions on technologies and emissions are subject to a high degree of uncertainty. Different delivery conditions (e.g., distances, means of transportation) can also alter the GHG emission ranking. Moreover, the present analysis was limited to the global warming impact, but an assessment of the overall environmental consequences is necessary to avoid shifting the burden from one environmental issue to another.

Keywords: Hydrogen delivery; Greenhouse gas emissions; Life cycle assessment

INTRODUCTION

Hydrogen transportation is included in the European Hydrogen strategy as an enabler of green hydrogen penetration in the European market [1]. The Joint Research Centre (JRC) of the European Commission is assessing the costs and energy demand of hydrogen transport and distribution to find the most advantageous economic and energetic solution [2]. This work aims at integrating the previous assessment with a life cycle greenhouse gas (GHG) analysis. The goal is to understand whether the cheapest option is also the best in terms of climate change mitigation. Results should provide new information to policymakers, stakeholders, and the public on the potential global warming impact of shipping hydrogen.

MATERIALS AND METHODS

The attributional life cycle assessment (LCA) methodology [3] is applied to compare the GHG emissions of eight different hydrogen delivery pathways: two on-site hydrogen productions (steam methane reforming and electrolysis powered by the electrical grid mix), and six pathways including green hydrogen shipping. These pathways assume that hydrogen is produced via renewable electricity in a location where solar energy is cheap, and subsequently packed in suitable forms for shipping by sea. The packing modes considered are: compressed hydrogen (CH_2), liquefied hydrogen (LH_2), ammonia (NH_3), a liquid organic hydrogen carrier (LOHC), methanol (MeOH), and synthetic natural gas (SNG).

Scope of the assessment

The system boundaries are the raw material extraction to produce hydrogen (e.g., to manufacture the electrolyser and to generate electricity), storage and its delivery to the end user: i.e., from cradle to gate. A simplified flow chart with the main processes included in the assessment is presented in Fig. 1.

Fig. 1. System boundaries of the assessment

The functional unit considered for the assessment is the delivery of 1 kg of hydrogen (30 bar, 99.97% purity) at an industrial site in the Netherlands, assuming that 1 Mt of hydrogen need to be delivered each year from 2030.
Data from the JRC techno-economic assessment [2] are combined with inventories found in the literature and the version 3.7 of the ecoinvent database for the life cycle inventory. The cut-off system model from ecoinvent is used as background database.
The analysis is limited to the global warming potential of the different options, considering a 100-year time horizon. The characterization factors for the different greenhouse gases are taken from the fifth assessment report of the IPCC: e.g., 30.5 kg CO_2e/kg fossil methane, 27.75 kg CO_2e/kg biogenic methane, and 265 kg CO_2e/kg nitrous oxide. Moreover, a global warming potential for hydrogen emissions of 5.8 kg CO_2e/kg H_2 was considered [4].

Main assumptions

Shipped green hydrogen is assumed to be produced via water electrolysis (50 kWh/kg H2), assuming an emission factor for photovoltaic electricity of 20 g CO_2e/kWh [5]. As for the average grid emissions in the Netherlands, the emission factor for electricity in Europe in 2030 estimated by the European Commission for the EUCO3232.5 scenario (150 g CO_2e/kWh) was considered [6].
To guarantee a constant supply of hydrogen, a storage facility is assumed to be available both at the production and use sites. Ships are assumed to travel on biodiesel, since large electric or hydrogen-powered ships will not likely be available yet in 2030. Greenhouse gas emissions from the combustion of biodiesel are taken from the inventory of the United States Environmental Protection Agency: 2.84 kg CO_2, 42.0 mg CH_4, and 150 g N_2O per kg of biodiesel [7]. When carbon is necessary to transport hydrogen (i.e., methanol and SNG pathways), CO_2 sourced via direct air capture is assumed to be used. When processes require external heat (e.g., direct air capture, unpacking stage for LOHC), extra green hydrogen is assumed to be produced and delivered to the processing plant (via the carrier considered for that pathway). The direct air capture unit is assumed to be at the green hydrogen production site.

RESULTS AND DISCUSSION

The comparison of the life cycle GHG emissions arising from the delivery of 1 kg of hydrogen at 30 bar is presented in Fig. 2. Based on our assumptions, in 2030 the delivery of hydrogen from a location where renewable energy is cheaper would emit less GHG than producing it on site from either steam methane reforming (SMR) or electrolysis powered by the grid mix. Despite the reduction in carbon intensity expected from the electricity grid mix of European countries, the residual fossil component in the mix would lead to significant GHG emissions when producing electrolytic hydrogen (i.e., more than more than 7 kg CO_2e). Although better than hydrogen produced via SMR, electrolytic hydrogen produced via the electricity grid mix is not expected to meet the taxonomy criterion for climate change mitigation of 3 kg CO_2e/kg hydrogen. On the other hand, our results show that the delivery of hydrogen from other parts of Europe where electrolytic hydrogen can be produced via renewable sources at a lower cost would likely meet the criterion in 2030. In our baseline scenario, the life cycle GHG emissions for the different carriers varied from a minimum of 1.4 kg CO_2e/kg H_2 delivered for liquefied hydrogen to a maximum of 2.8 kg CO_2e/kg H_2 delivered for SNG. The transportation advantage of packing hydrogen into a more manageable carrier does not seem to translate in a GHG advantage. On the contrary, the energy required to pack the carrier at the hydrogen production site and unpack it at the delivery site significantly increase the impact with respect to the compressed and liquefied hydrogen options. Compressed hydrogen results in higher emissions compared to liquefied hydrogen, mainly due to the higher transportation impact. However, more information is needed on the greenhouse gas effect resulting from the emissions of hydrogen in the atmosphere. In the reference scenario, a global warming potential over 100 years of 5.8 kg CO_2e per kg of H_2 was used; a higher value could change the ranking proposed here due to the boil-off from shipping liquefied hydrogen. As for the other carriers, results were very similar: the options emitting less GHG resulted to be ammonia and methanol, with a total impact of 2.3 kg CO_2e/kg H_2 delivered.

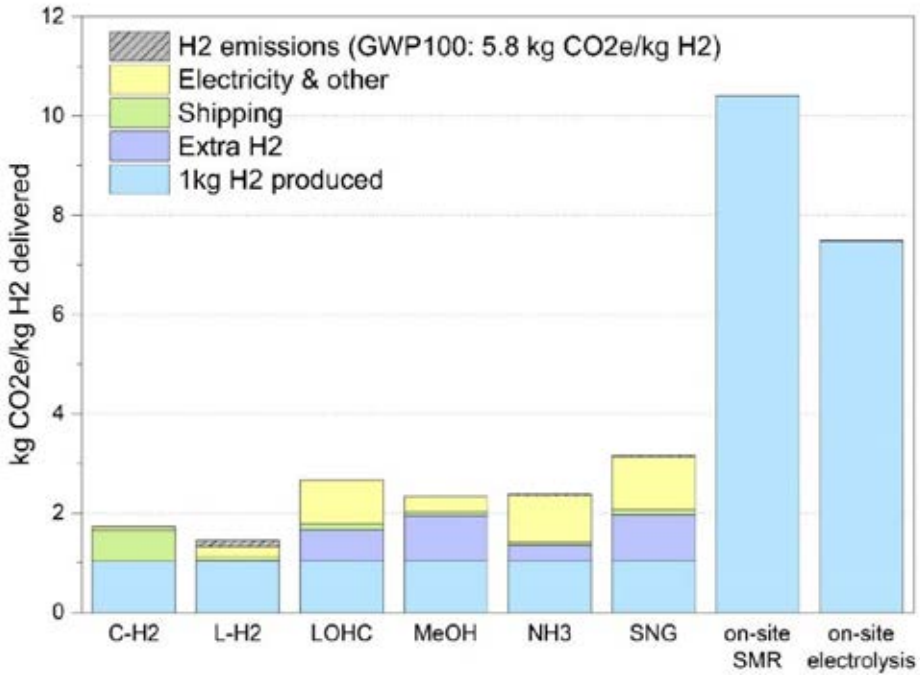

Fig. 2. Life cycle greenhouse gas emissions from hydrogen delivery

CONCLUSIONS

This analysis aimed at investigating the global warming impact of delivering hydrogen to an industrial site, comparing on-site production to hydrogen delivery from a location where renewable electricity is cheaper. Based on our assumptions, the least GHG intense option is to ship liquefied hydrogen. Energy required to pack and unpack hydrogen into more suitable carriers for shipping (i.e., ammonia, LOHC, methanol, and SNG) makes this option less attractive in terms of global warming potential.

The results presented here are subject to a high level of uncertainty, based on the numerous assumptions made throughout the assessment. A thorough sensitivity analysis is planned to ascertain the robustness of the results. Moreover, different delivery conditions (e.g., distances, means of transportation) may alter the GHG emission ranking. Finally, the present analysis was limited to the global warming impact, but an assessment of the overall environmental consequences is necessary to avoid shifting the burden from one environmental issue to another.

ABSTRACT

The main components of the synthesis gas formed during gasification is H_2 and CO. In addition to these gases, it contains H_2S due to the sulfur contents of organic matters. Since H_2S causes corrosion of system equipment and catalyst poisoning, it should be removed from flue gas stream. Furthermore, since fuel production from synthesis gas is an endothermic process and cooling of syngas causes energy loss, desulfurization should be carried out at high temperature. This study aims to determine the hot gas desulfurization performance of unsupported and SBA-15 supported MeO-MeO (Me: Cu, Fe, Mn, and Zn) sorbents. Sorbents prepared by wet impregnation method were characterized by X-ray diffraction (XRD) technique and Brunauer, Emmet ve Tellere (BET). In the characterization part, metal oxide formation was indicted by XRD findings, while BET results showed that SBA-15 supported CuO-ZnO sorbent has the largest surface area. Finally, desulfurization performance of sorbents was analyzed by gas chromatography equipped with a fixed bed quartz reactor at 800°C. Ar balanced simulated coal gas including 330 ppm H_2S, 9% H_2, 13.5% CO, and 4.5% CO_2 was used as the flue gas. The results of the desulfurization experiments revealed that the sorbents including MnO indicated the similar good sulfidation performance among the unsupported sorbents, while the best desulfurization performance was obtained for FeO-MnO among SBA 15 supported sorbents.

Keywords: Hot gas desulfurization, SBA 15, mixed metal oxide

INTRODUCTION

Gasification is the process of producing synthesis gas as a result of partial oxidation of organic materials. In addition to CO and H_2, syngas gas contains H_2S due to the sulfur contents of organic matters. Since fuel production from syngas is an endothermic process, H_2S should be removed at the highest possible temperature to protect process equipment and catalysts [1]. In thermodynamic and kinetic studies, Westmoreland et al.[2] indicated that Fe, Zn, Mn, Ca, and Cu oxides are suitable sorbents for hot gas desulfurization. However, single metal oxides used as adsorbents cause problems of sintering, evaporation, pore blockage, capacity, loss in surface areas, and mechanical disintegration. In order to overcome these problems, metal oxides can be either mixed with each other or they can be loaded on support materials. Al_2O_3, TiO_2, ZrO_2, SiO_2 and zeolites are the most commonly used support materials to provide the sorbents with high surface area. In the desulfurization study performed with SBA-15 supported CuO, it was noted that the surface area and pore structure of SBA-15 did not change, but the capacity of the sorbent decreased during the 3 repetitive reduction and oxidation cycles of the sorbent [1]. A zeolite with a high silica content supported CuO and MnO were used as active sulfur sorbents. The results of the studies revealed that these metals significantly increased the sulfur holding capacity of the material and the presence of Mn increased its mechanical resistance [3, 4]. Hong et al. [5] tested the SBA-15 supported Cu−Mn mixed oxide for the hot flue gas desulphurization process at 800°C. The best desulfurization activity of was obtained for the sorbent with 1Cu-9Mn/SBA-15 as 13.8 g per 100 grams of sorbent. Iron oxide (FeO) based sorbents have been extensively preferred to remove H_2S due to their good regenerability, high reactivity, and cheapness. However, since iron oxide converts to iron carbide at temperatures higher than 550°C in the presence of the CO and H_2, its desulfurization potential is lower compared to other metal oxides [1, 3]. Wang et al.[6] studied on sulfidation of SBA-15 supported Fe_2O_3 sorbents. The highest sulfur capture capacity of 7.01g S/100g sorbent was recorded for the sorbent with 31.3 wt.% Fe content. Desulfurization performance of Mn-Zn loaded SiO_2 was examined at 873 K by Ko et al. in 2007 [7]. It was reported that the increasing amount of sorbent increased the metal sulfide formation, but the rapidly formed metal sulfide layer made the mass transfer of H_2S difficult. In the light of literature summarized above, the aim of this study is to prepare SBA-15 supported MeO-MeO (Me: Fe, Cu, Zn, Mn) sorbents by wet impregnation method and to investigate their desulfurization performance.

MATERIALS AND METHODS

Unsupported and SBA-15 supported binary metal oxides were synthesized by wet impregnation method. Ar balanced simulated coal gas including 330 ppm H_2S, 9% H2, 13.5% CO, and 4.5% CO_2 was used as the flue gas. H_2S removal from simulated coal gas was tested in the presence of unsupported and SBA 15 supported mixed metal oxides. Agilent 6890N gas chromatography analyzer was used to follow exit H_2S concentration.

Synthesis and characterization of unsupported and SBA-15 supported sorbents

In order to prepare mixed metal oxides, nitrate salts of Cu, Fe, Mn, and Zn were mixed by wet impregnation method. SBA-15 supported mixed metal oxides were prepared at a mass ratio of 1/1 wt/wt (MeO/MeO, Me: Cu, Fe, Mn, Zn). After SBA-15 was wet with 1-2 drops of water, it was added to mixed metal oxides solutions. Calcination at 600°C for 6 hours followed the overnight drying.

Crystal structure of CuO, FeO, MnO, and ZnO were determined by X-ray diffraction (XRD) (Panalytical Empyrean model, Anode material, Cu 1.56 A wavelength). Micromeritics 3Flex 3-port BET device was employed to analyze the surface structure of the sorbents in the presence and absence of SBA 15.

Sulfidation performance of unsupported and SBA-15 supported sorbents

Sulfidation performance of mixed metal oxide based sorbents was tested by using Agilent 6890N model gas chromatography analyzer equipped with Flame Photometric Detector. The simulated gas mixture flow rate was 100 cm^3/min. The outlet sulfur concentration 100 ppm was defined as the breakthrough point.

RESULTS AND DISCUSSION

Sorbents were characterized by PANalytical Empyrean model XRD device. In order to define the metal oxide and metal sulfide formation, specific Bragg angle values of metal oxides and sulfides are given in Table 1. SBA-15 supported MeO-MeO and MeS formations were shown in Fig. 1. CuO [8], FeO [9, 10], MnO [5, 7-9, 11], ZnO [10] were characterized in the left hand side of Fig. 1, while CuS [12, 13], FeS [14], MnS [15], ZnS [16].

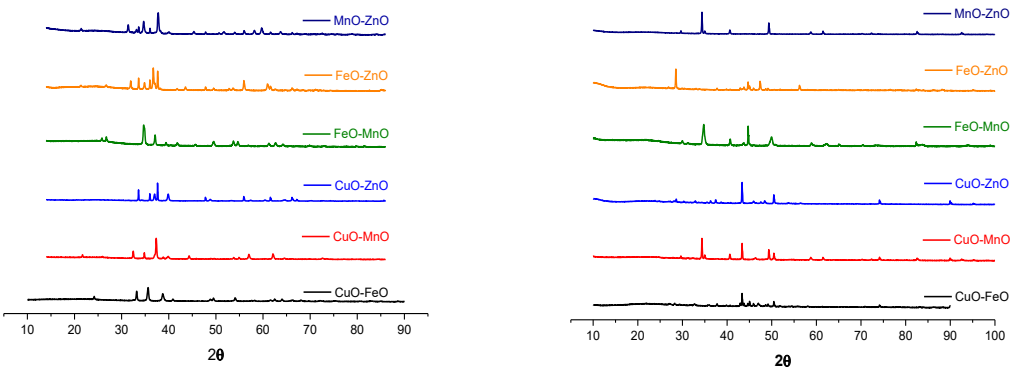

Fig. 1. SBA 15 supported MeO (left) and MeS formation (right).

The presence of SBA-15 increases the surface area of metal oxides. BET results showed that unsupported CuO-FeO (37.1 m^2/g) and SBA 15 supported CuO-ZnO (313 m^2/g) sorbents have the largest surface area. In Fig. 2, sulfidation performance of unsupported and SBA 15 supported MeO-MeO was indicated with respect to H_2S emitted to atmosphere at 800°C. As seen in Fig. 2, the unsupported sorbents including MnO show the better sulfidation than that of the other sorbents. Furthermore, the most important improvement on the sulfidation performance was recorded for SBA 15 supported FeO-MnO.

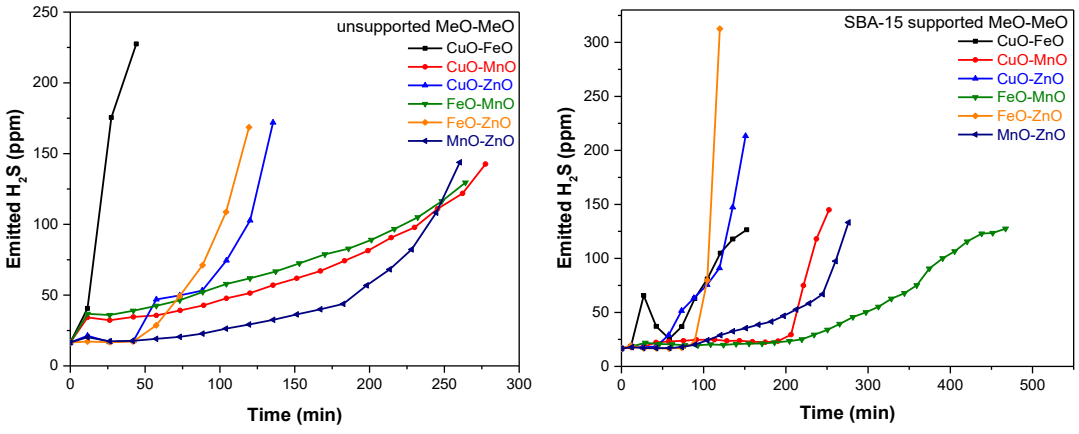

Fig. 2. The amount of H_2S emitted to atmosphere at 800°C.

CONCLUSIONS

BET results showed that SBA 15 supported FeO-ZnO sorbent has the largest surface area of 313 m^2/g. CuO-MnO, FeO-MnO, and MnO-ZnO were reported the best sulfidation performance among the unsupported sorbents, while the best desulfurization performance was obtained for FeO-MnO among the SBA 15 supported sorbents.

ABSTRACT

The co-combustion of traditional methane gas and alternative fuels importance to reduce emissions in combustion has been increased in recent years. In this study, the effects of the combustion of methane-hydrogen and methane-ammonia-hydrogen fuel mixture on system performance and emissions were numerically investigated. Firstly, the effects of methane and 5%, 10% and 15% hydrogen mixture were investigated. Then, methane and 5% fixed hydrogen ratio with 5% ammonia, 10% ammonia and 15% ammonia mixtures were examined. As a result of the study, combustion chamber temperature, carbon and NO_X emissions are presented comparatively for each case. In addition, the Sandia D model used in the study is presented by verifying with the literature data. The findings obtained in the study showed that increasing hydrogen and ammonia increased NO_X emissions while decreasing CO_2 emissions.

Keywords: Hydrogen, Ammonia combustion, Flame, Emissions

INTRODUCTION

The depletion of fossil fuels and the formation of greenhouse gases that cause global warming because of combustion makes it necessary to use clean fuels in combustion engines. Hydrogen and ammonia are used as clean fuels to reduce carbon emissions. These fuels are currently used in combination with conventional fossil fuels to reduce carbon emissions [1].

Ammonia is one of the most likely fuels to be used as an alternative in the future due to having carbon-free and being obtained from renewable sources [2]. Therefore, it can be used to reduce greenhouse gas (GHG) emissions. In the last two decades, many experimental and numerical studies have been carried out on the use of ammonia as an alternative fuel. In the previous studies, various parameters such as ammonia production, ignition mode, combustion mode were investigated. However, it has several disadvantages when compared to a fossil source fuel. Studies have shown that ammonia has higher ignition energy due to its low flammability [3].

Hydrogen as a fuel is expected to be widely used due to its high energy potential and its feature of being a clean fuel. However, various problems such as the storage and safe transportation of hydrogen remain unresolved [4]. Hydrogen is secondary energy that acts as a carrier between different sources. Hydrogen is produced in nature from basic raw materials such as water. The fact that it is so easy to produce and is one of the renewable energy sources has enabled hydrogen to be included in the energy planning of most countries. The lower energy consumption of hydrogen simultaneously reduces emissions in various fields such as transport and industry. Compared to wind, solar and geothermal energy, whose uses are limited due to their volatility and stability, hydrogen's high cleanliness and efficiency make it of great value for use in future energy systems [5].

In this study, parametric studies were carried out based on the Sandia D model, which was previously validated experimentally and numerically in the literature [6]. The effect of the mixture of hydrogen, ammonia and methane on the combustion chamber temperature and emissions on the validated model was numerically investigated. Thus, the effect of ammonia and hydrogen fuels that do carbon-free on the emission and performance parameters have been investigated.

MATERIALS AND METHODS

The study was carried out on the methane-air flame pilot model by the Sandia National Laboratory. As demonstrated in Fig. 1, the model consists of three inlets: the jet, where the fuel is supplied with the air, the pilot, where the burnt gases are supplied at high temperature, and the airflow [6].

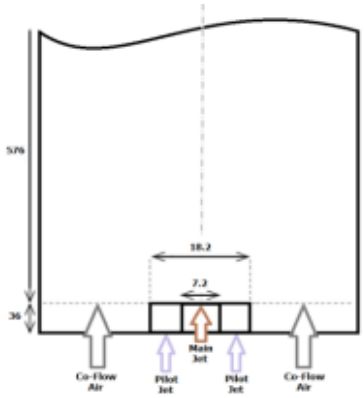

Fig. 1. Sandia flame model

Methane, hydrogen and ammonia were used as jet fuel on the model and a total of seven parametric studies were carried out. The boundary conditions used for numerical analysis are presented in Table 1.

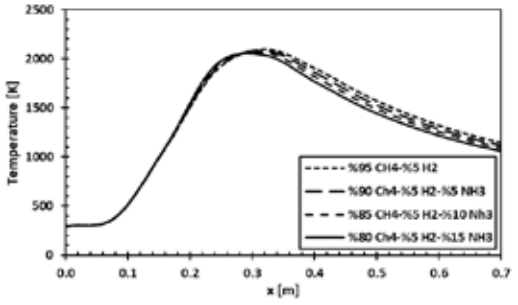

Table 1. Boundary conditions

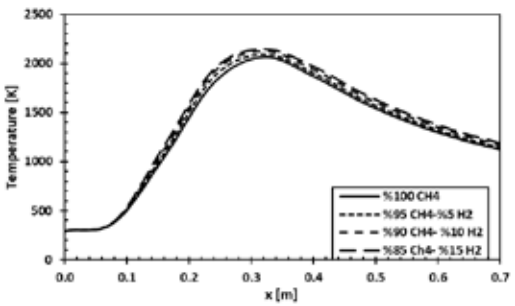

Jet	Mixture fraction [% mass]	0.156
	Velocity [m/s]	49.6
	Temperature [k]	294
	Gases	CH_4, H_2, NH_3
Pilot	Velocity [m/s]	11.4
	Temperature [K]	1880
	Gases	CO_2, H_2O, N_2, O_2
Co-flow	Velocity [m/s]	0.9
	Temperature [K]	294

The study was carried out numerically with computational fluid dynamics. Combustion was carried out in steady-state conditions using GRI-Mech 3.0 mechanism [7]. The numerical model was solved with the *k-ε* turbulence model, and the solution was also provided with species transport model using volumetric reactions. The experimental results were compared with numerical analysis and it was observed that the results were compatible [8].

RESULTS AND DISCUSSION

In this study, temperature, NO_X and CO_2 emissions were determined as a result of the mixture of clean alternative fuels such as hydrogen and ammonia with methane gas. It was determined that the combustion chamber temperature values increased with increasing hydrogen addition. However, the addition of ammonia lowers the combustion chamber temperature. This is due to the potential for higher combustion energy of hydrogen. In addition, NO_X emissions increase only with the addition of hydrogen. The increase in NO_X emissions with hydrogen addition is due to the formation of thermal NO_X with the effect of temperature. However, the increase in NO_X emissions with the addition of NH_3 is due to the conversion of N atoms in its structure to NO due to the unstable structure of NH_3. The carbon-free of both hydrogen and ammonia fuel has reduced CO_2 emissions. Fig. 2 shows the combustion chamber temperature, NO_X and CO_2 emissions formed by the combustion of hydrogen, methane and ammonia mixture at different rates.

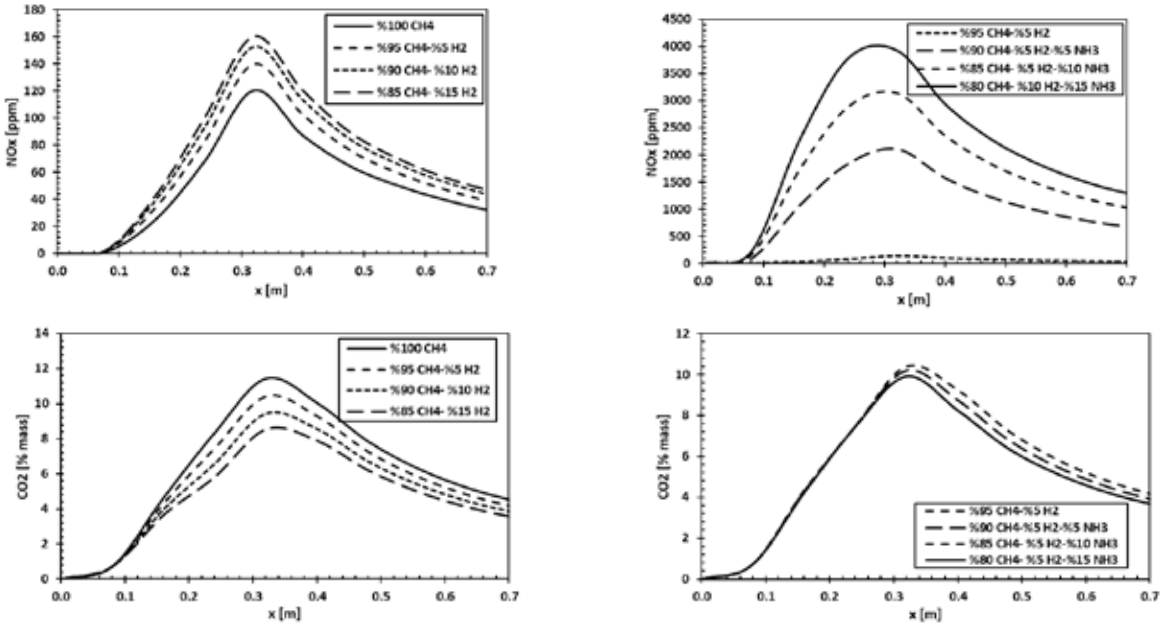

Fig. 2. Combustion chamber temperature and emissions

CONCLUSIONS

In this study, the effect of the use of alternative fuels on the emission and combustion temperature based on the Sandia Flame D model, from which literature data was taken, was investigated numerically. As a result of the study, it was determined that the combustion chamber temperature increased with the addition of hydrogen and decreased with the addition of ammonia. Another parameter determined is that NO_x emissions increase with increasing hydrogen and ammonia amount. Finally, the fact that hydrogen and ammonia do carbon-free ensures a reduction in CO_2 emissions because of combustion.

ABSTRACT

Gasification of different types of biomass in a lab scale up-draft fixed bed gasifier is evaluated from the environmental effect perspective through Life Cycle Assessment (LCA). Biomass is an energy source which has a lot of potential for electricity generation, and it is considered as an environmentally friendly renewable energy source. Gasification of the biomass has been considered as a significant renewable energy production alternative to fossil fuels. Biomass through gasification forms a syngas which includes H_2, CH_4, CO and as a solid by-product biochar is produced at high temperatures. In this study, LCA is used as a tool for assess the different environmental impact categories of the energy production from green waste and biological treatment sludge gasification studies, with the cradle to grave approach. Different hydrogen conversion technologies via LCA have been also assessed. LCA calculations were performed by using SimaPro 9.1 software and experimental data collected from LCA database and a lab scale gasifier operated in Dokuz Eylul University, Turkey.

Keywords: Life Cycle Assessment, Biomass, Gasification, Green Waste, Treatment Sludge, Hydrogen Conversion

INTRODUCTION

Biomass gasification has been considered as an important renewable energy alternative to deal with the environmental problems originating from fossil fuels and climate change effects. Biomass has the potential for electricity generation and biofuels, and it is considered as one of the most important renewable energy sources for the future and now [1]. In this study, two different biomass has been used: green waste, and biological treatment sludge. First biomass used in this study is green waste and collected from urban parks and gardens. It is a lignocellulosic-rich resource and can be obtained in large quantities at low cost [2]. Green waste is basically a composition of branches, grasses, and leaves. Green waste can be a good choice for biomass gasification because it can be easily gathered, it is economically affordable, and its water content can be easily reduced by drying. Other biomass kind used in this study is the biological sludge, which is produced in huge amounts at different treatment stages in wastewater treatment plants. The organic content of the treatment sludge is very high and if it is considered as a waste then it will create a lot of environmental problems. However, treatment sludge can be used as a feedstock to the gasification process because it has high calorific value and at the same time, using treatment sludge as a feedstock to the gasification process reduces the waste sludge amount.

Gasification process converts carbon containing materials to a syngas which is a combustible gas includes H_2, CH_4, CO. This syngas can be used as a fuel for electricity generation [3]. Gasification process is known as an environmentally friendly power system although to see its positive affect to the environment assessing its environmental impacts are very important. There are several hydrogen conversion technologies are available. In this study, three of the existing hydrogen to energy conversion technologies' environmental impacts are evaluated. The technologies are internal combustion, electrochemical electricity generation (fuel cells), and syngas fermentation. Hydrogen is a fitting fuel for internal combustion engines and turbines. Hydrogen engines as the same way of gasoline used in engine, burns hydrogen in an internal combustion engine, and hydrogen powered internal combustion engines are approximately 20% more efficient than gasoline powered engines [4]. Other hydrogen conversion technology is electrochemical electricity generation (fuel cells), with this technology, the hydrogen can combine with oxygen in an electrochemical reaction, where this reaction takes place is called the fuel cell [4]. And the last one is syngas fermentation. Syngas fermentation is a microbial process, and in this process, syngas used as a carbon source, and through the agency of microorganisms, syngas converted into fuel and chemicals such as ethanol [5].

LCA is an assessment of the environmental impacts of any product or process and includes the procurement of its raw material, production, transportation, use, recycling or end of life treatment, and final disposal furthermore it is not only assessing the chosen process or products environmental impact, but also considers the energy production [6]. It is evaluated as a powerful tool for analyzing the environmental impacts of a process throughout its life cycle [1].

In this study, it is aimed to assess the environmental effects of green waste and treatment sludge gasification applications for the energy production in three different routes, applying a LCA approach, as shown in Fig 1. First stage includes the different types of biomass, their production, and their shipment to the gasifier. Second stage represents the gasification of feedstock biomass, and it includes the cleaning of the synthetic gas. The third stage shows the hydrogen conversion technologies.

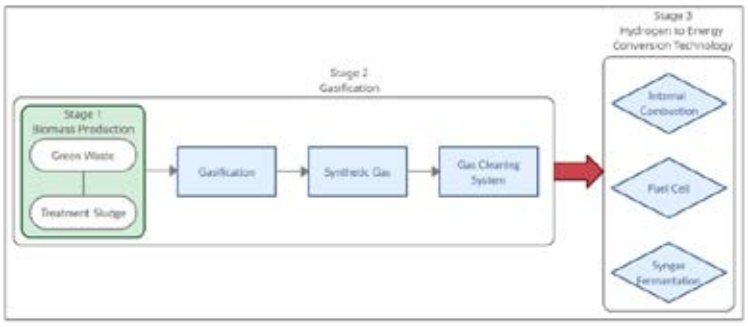

Fig. 1. LCA stages of the process

Six different scenarios are created to compare the LCA of the process. There are two different types of biomass and three different types of hydrogen conversion technology exist in this study, with the combination of them six scenarios have created. Through these six scenarios, which biomass gasification and which kind of hydrogen conversion technology have better impact on the environment will be determined. Data for green waste gasification and treatment sludge gasification were collected from a lab scale gasifier in Dokuz Eylul University, Turkey. LCA calculations were performed by using SimaPro 9.1 software according to the cradle-to-grave approach for different impact categories.

MATERIALS AND METHODS

In this study, it is aimed to assess the environmental effects of green waste and treatment sludge gasification for the energy production through three different hydrogen conversion technologies, applying a LCA approach and following the recommendations of the ISO 14040 series. LCA calculations were performed by using SimaPro 9.1 software. Calculations were made according to the cradle to grave approach for every scenario. The “Ecoinvent 3 – allocation, cut-off by classification” and Center of Environmental Science of Leiden University (CML)-IA Baseline V3.06 / EU25 have been chosen as the main database and the calculation method, respectively. CML-IA Baseline calculates eleven different impact categories from the environmental aspect: abiotic depletion, abiotic depletion (fossil fuels), global warming, ozone layer depletion, human toxicity, fresh water aquatic ecotoxicity, marine aquatic ecotoxicity, terrestrial ecotoxicity, photochemical oxidation, acidification, and eutrophication. Functional unit is a quantified definition of a products function and it is the reference for all calculations through the impact assessment. The objective of the biomass gasification process is producing energy therefore the functional unit defined as the produced energy amount. The functional unit is defined as 20 kW of energy produced from gasification, and since this study was conducted for a laboratory-scale gasifier, the energy production amount was chosen relatively low. After defining the functional unit, scenarios can be created on this base. The six different scenarios were determined considering the defined functional unit through the objectives of the study. To compare the different biomass types as a feedstock to the gasification process and to compare the three different hydrogen conversion technologies these scenarios were created based on the above considerations

RESULTS AND DISCUSSION

Table 1 is the results of the calculated LCA of the scenarios for different impact categories. Results show that the treatment sludge gasification is more harmful to the environment than the green waste gasification. But the treatment sludge’s environmental harm as a waste is much higher than the waste scenario of the green waste. So, the gasification of treatment sludge is still an environmentally friendly energy production way. This scenario compares only the biomass difference of the process. Fig 2 also shows that the gasification of green waste is much healthier than the other scenarios from the aspect of environmental harm level; also, treatment sludge gasification is by far the most harmful gasification scenario. In addition, LCA calculations includes long-term effects of every process.

Table 1. Impact values for each scenario, associated with the functional unit, 20 kW energy obtained from the gasification

Impact category	Unit	Green Waste Gasification	Treatment Sludge Gasification
Abiotic depletion	kg Sb eq	0,003126013	0,01219133
Abiotic depletion (fossil fuels)	MJ	355,40519	1922,3803
Global warming (GWP100a)	kg CO_2 eq	34,380321	216,73917
Ozone layer depletion (ODP)	kg CFC-11 eq	2,22E-06	1,43E-05

Eutrophication	kg PO_4--- eq	0,14416724	0,349306

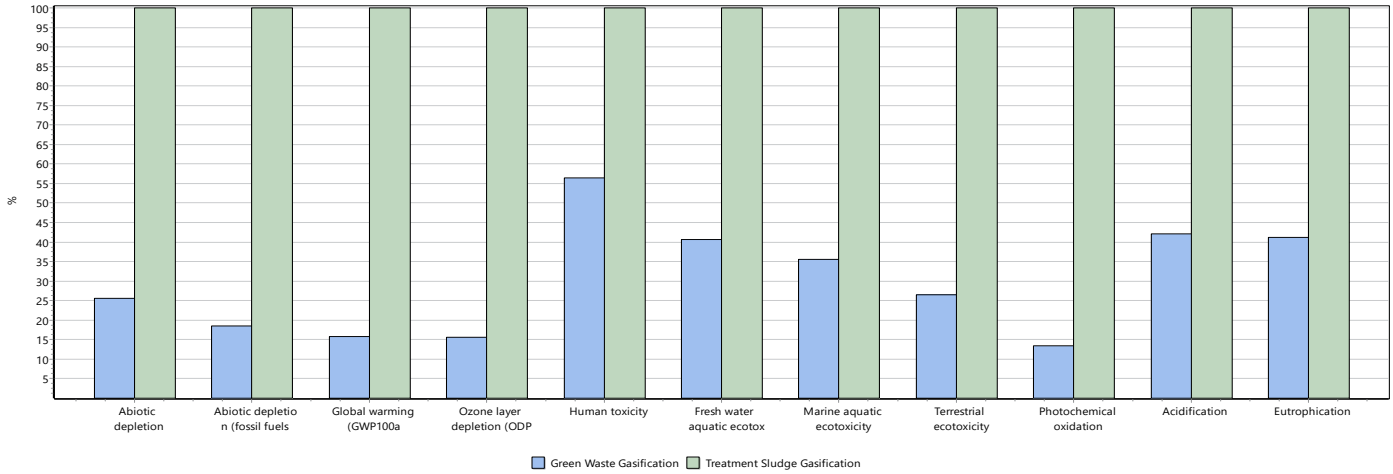

Fig 2. Impacts percentages for each scenario, associated with the functional unit, 20 kW energy obtained from the gasification

CONCLUSIONS

This study shows that the green waste gasification is more optimal than the treatment sludge gasification in the aspect of environmental pollution level. However, green waste takes up a lot of space in volume and therefore it is more difficult to transport and store. The study is still in progress, remaining scenarios will be discussed in detail. Three different hydrogen conversion technology's life cycle analysis will be evaluated and other than all six scenarios and also there will be another comparison with fossil fuels.

ABSTRACT

Converting Intercity buses to hydrogen buses is an effective approch for a sustainable public transportation systems. In the current study, a life cycle analysis of hydrogen fuel cell and diesel buses are conducted, using real-world driving cycles. In this study, hydrogen buses are compared to diesel buses in terms of both life cycle emissions and life cycle cost. The results indicate that hydrogen buses can be economically comparable to diesel buses. Meanwhile, teing environmentally benign, makes them a promising solution for the considered situations in Canada.

Keywords: Life cycle assessment, Fuel cell, Electric Vehicles, Hydrogen

INTRODUCTION

Transportation is Canada's second-largest energy consumer, accounting for approximately 30% of total energy consumption [1]. Transportation is one of the most reasons for air pollution. Consumption of fossil fuels is also rising dramatically as global transportation grows. The increased use of fossil fuels accelerates the air pollution process and the depletion of oil resources. One of the main public transportation systems is intercity buses. Therefore, reducing the pollution caused by these buses, or using sustainable energy will significantly help to improve the air quality and to reduce reliance on fossil fuels. Vehicles with internal combustion engines currently have the largest market share in the transportation sector. Hydrogen buses use non-combustible electrochemical reactions to generate electricity with wateras the byproduct. . As a result, these buses provide a type of transportation system that has the potential to emit no greenhouse gas (GHG) at the point of use. Hydrogen vehicles can use up to 60% of the energy stored in hydrogen fuel due to the high efficiency of the electrochemical reaction in the fuel cell. On the other hand, internal combustion engine buses consume approximately 20% of the fuel energy [2]. Energy conversion in fuel cells has a thermodynamic efficiency that exceeds the Carnot efficiency limit for internal combustion engines [3]. The issue with using hydrogen buses is that pure hydrogen is not available for use in these buses, so other methods such as steam methane reforming (SMR) and water electrolysis should be considered, which, in turn, result in GHG emissions.

The life cycle assessment (LCA), also recognized as cradle-to-grave assessment, evaluates the environmental impacts of all stages of a product's life cycle [4]. The bus and its fuel are evaluated at each stage of the LCA analysis, from raw material extraction to production and recycling, and their environmental impacts are assessed. The LCA analysis for different buses can vary greatly depending on the type of fuel and how it is prepared, especially for hydrogen buses. Although hydrogen vehicles have received much attention in recent years, no comprehensive study has been conducted to examine their environmental and economic impacts. Therefore, a comprehensive life cycle assessment and economic analysis of fuel cell buses are conducted in this study, and they are compared with diesel buses from various perspectives.

MATERIALS AND METHODOLOGY

The fuel consumption of each bus is considered for the pollutant estimation. The Simcenter Amesim software is used to model the buses. This software offers a high level of accuracy when simulating a vehicle in real driving situations. Amesim software is used for this investigation. A real driving cycle in Vancouver is considered in the study to increase the accuracy of the analysis. The primary purpose of the LCA analysis performed in this study is to make a comparison between hydrogen-powered buses and buses working with diesel. In this study, Afleet LCA software is utilized to perform LCA analysis. AFLEET (Alternative Fuel Life-Cycle Environmental and Economic Transportation) is a software for Clean Cities stakeholders to calculate fuel use, air pollutant emissions, GHG emissions, and the ownership costs of different vehicles. For a vast range of fuels and vehicles, this software can integrate driving cycles, engine efficiency, and vehicle parameters. Aside from the amount of pollution, the purchase price and the costs of operating and maintaining the bus are all significant considerations when selecting the type of city bus. As a result, the life cycle emissions can be mentonized, resulting in the same unit for all primary factors, simplifying the analysis. This study considers two types of emissions: GHG emissions and air quality emissions. The greenhouse gases in this study are CO_2, CH_4, and N_2O, and the air quality emissions are

Volatile organic compounds (VOCs), carbon monoxide (CO), particulate matter (PM), and Nitrogen oxides (NO_X). The Air quality external cost is calculated as [5]:

$$C_{AQ} = \sum_i P_i e_i \quad (1)$$

where the pollutant emission and external cost of i are denoted by P_i and in e_i, respectively. Also, the air pollutants external cost is indicated by C_{AQ}. The external cost of greenhouse gases is then calculated as follows:

$$C_{GHGs} = \sum P_j e_j \quad (2)$$

The pollutant emission and external cost of j are shown by P_j and in e_j, respectively. Moreover, C_{GHGs} denote the greenhouse gas external cost. The damage costs for all pollutants are available in reference [6].

RESULTS AND DISCUSSION

The most popular method for hydrogen production worldwide, steam methane reforming (SMR), is considered for hydrogen production in this study. The amount of GHG emissions from fuel cell buses are compared with diesel buses in Figure 1(a). As depicted, the amount of GHG emissions from intercity buses can be reduced up to 30% in Canada by employing hydrogen buses. The amounts of air pollutants from both diesel and hydrogen buses are shown in Figure 1(b). Using hydrogen buses decrease the amount of carbon monoxide (CO), Volatile organic compounds (VOCs), and Nitrogen oxides (NO_X). Also, the amount of particulate matter (PM) is almost the same in both buses.

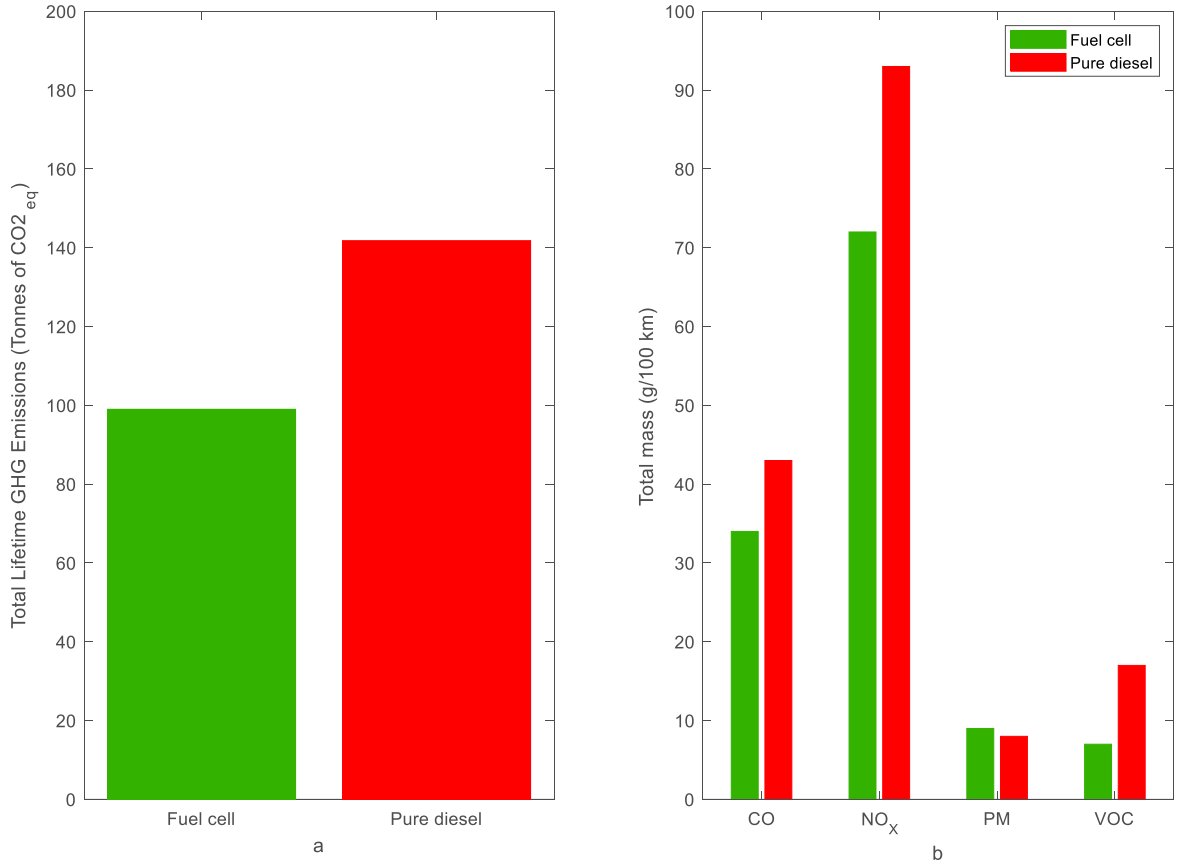

Figure 1. The emissions from fuel cell bus and diesel bus (a): the amount of GHG emissions; (b): the amounts of air pollutants

Both buses can be compared in the same unit since pollutants can be converted to costs. The life cycle costs of hydrogen and diesel buses are shown in Figure 2. Because the cost of producing hydrogen buses has decreased in the recent years, it can be seen that the lifetime costs of fuel cell buses have decreased as well, and if more than 400 of these buses are produced each year for Canada, the lifetime cost will be lower than diesel buses. Furthermore, with the costs of GHG and air pollution emissions rising each year, the use of fuel cell buses appears to be more important than ever.

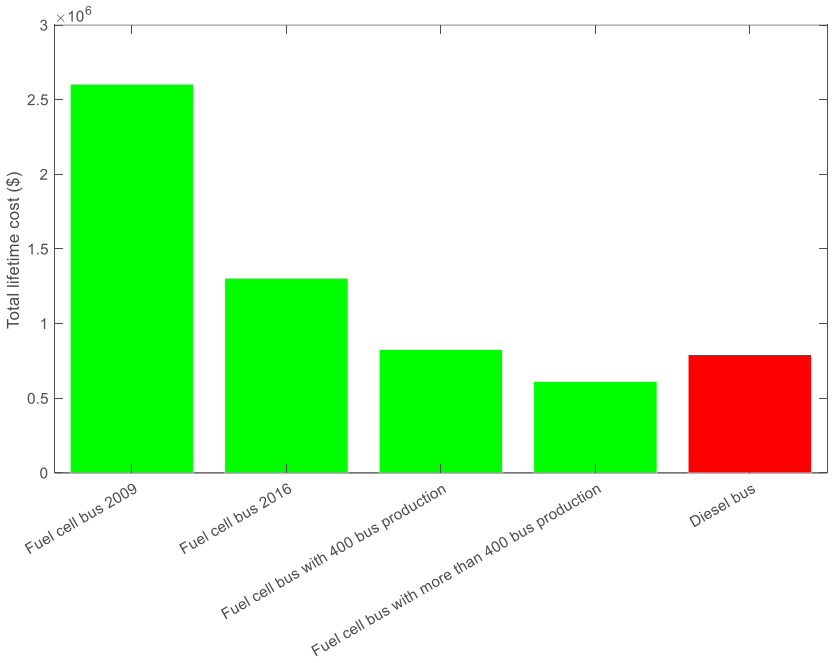

Figure 2. Lifetime cost comparison over the years

CONCLUSIONS

Dynamic models of hydrogen and diesel buses are developed in this study, and the amount of fuel consumption for both buses is computed in the real driving cycle and considering actual conditions. A comprehensive life cycle assessment of both buses was conducted, and it was observed that GHG emissions from fuel cell buses are 30% less than diesel buses. Moreover, comparing the amounts of air pollutants in the buses revealed that using hydrogen buses is more environmentally friendly. Furthermore, an economic study was conducted, and it was discovered that increasing the production of hydrogen buses reduces their lifetime cost; additionally, emission costs are rising, making fuel cell buses more cost-effective than diesel buses.

TOWARDS ETHICAL ENERGY STORAGE MATERIALS – COBALT FREE CATHODE ACTIVE MATERIAL LKMNO

* *Karolina Charzewska, Olga Surma, Gabriel Moskal, Agnieszka Węgrzyn, Marcin Molenda*

ABSTRACT

The replacement of fossil fuels by renewable energy sources will require batteries capable of storing significant amounts of energy. The effects of scientific studies on this subject are not limited to the research sphere, but have real economic, political and social consequences: independence from the supply of raw materials from distant areas or reduction of human rights violations in the case of conflict elements. Ethical and ecological supply of the elements is regulated by the EU and the US, among others – all of this must be taken into the consideration when proposing new materials for Li-ion cells. Based on these premises, this article is focused on the production of cobalt free and low-nickel lithium-ion cells using improved cathode material LKMNO. Its 3D spinel structure is capable of fast cation-mediated anionic redox reaction making it stable, reversible and efficient cathode material to use.

Keywords: energy storage; Li-ion batteries; cobalt-free cathode materials; defect spinel; green chemistry

INTRODUCTION

Due to the rapid technological development in recent years, the production and demand for devices using portable energy sources is increasing. Consequently, there is a high demand for inexpensive and durable cells with stable charge/discharge cycles, high energy capacity and high operating potential. Recently popular Li-ion batteries are meeting those requirements. However, there are still many venues to explore, improving its parameters and lessening the environmental impact of this product.

The energy produced by wind power, hydroelectric power or photovoltaic panels is dependent on the environment, and is not always delivered in a uniform and sustainable manner. In order to use its full potential in periods of increased production dependent on natural conditions, the energy produced should be stored safely so that these resources are available in case of periods of stagnation or reduced production. The same assumption applies to the production of green hydrogen. Its main advantage is that it can be produced from water or from any hydrocarbon fuel. Water electrolysis combined with renewable electricity is considered the most beneficial for the environment and it is expected to make a significant contribution to the future hydrogen production. There is continuous research on improving this process [1,2]. The most efficient process for providing energy to a hydrogen-powered grid using electrolysis assumes continuous operation of the electrolyser. As above, power consumption from the grid is not constant, excess of unused energy should be stored in battery cells to make it more sustainable.

This green approach to battery components is our main concern. Currently, the majority of the elements used in the production of lithium batteries is sourced in a few limited areas, often plagued with military conflicts. This can have an impact on the economic dependencies and political issues, driving up prices and limiting material availability. The biggest problem in the production of popular cathode materials is the price and availability of cobalt ore [3]. Substitution of cobalt with less pricey metals like manganese in cathode materials is an opportunity to answer rising market demand for energy storages for lesser cost.

LKMNO ($Li_{0.98}K_{0.01}Mn_{1.86}Ni_{0.11}O_4$) is a derivative of LMO ($LiMn_2O_4$) spinel which has limited applications due to low specific capacity and capacity retention. Modification of its chemical composition with Ni and K leads to the stabilization of spinel structure, higher speed and reversibility of electrochemical reaction. Performance and capacity was also boosted significantly in comparison to LMO [4].

MATERIALS AND METHODS

In this study we were focusing on sol-gel synthesis of cobalt free cathode material $Li_{0.98}K_{0.01}Mn_{1.86}Ni_{0.11}O_4$ and influence of calcination step on the structure and its function.

Synthesis of LKMNO

The sol-gel method was used. Aqueous solutions of lithium acetate, manganese acetate, nickel acetate, and potassium nitrate were combined under constant flow of argon to prevent oxidation of the mixture. Concentrated

ammonia solution (25%) was added as an alkalizing agent. After thorough mixing, the suspension was left in the air oven for 3 days at 90°C.
Obtained xerogel was calcined in two steps, first at the temperature of 300°C for 24h (heating rate of 1 °C min^{-1}) and second at temperature of 650°C for 6h (heating rate of 5 °C min^{-1}) in the air atmosphere using muffle furnace [4,5,6].
The second sample was calcined at 800°C instead of 650°C.

Infra-Red Spectroscopy (FTIR)

Sample before calcination (LKMNO), after calcination in 650°C (LKMNO 650), after calcination in 800°C (LKMNO 800) were measured. Additionally, cathode material LKMNO 650 supported on Al-foil has been characterized. Results can be seen in Fig.1.

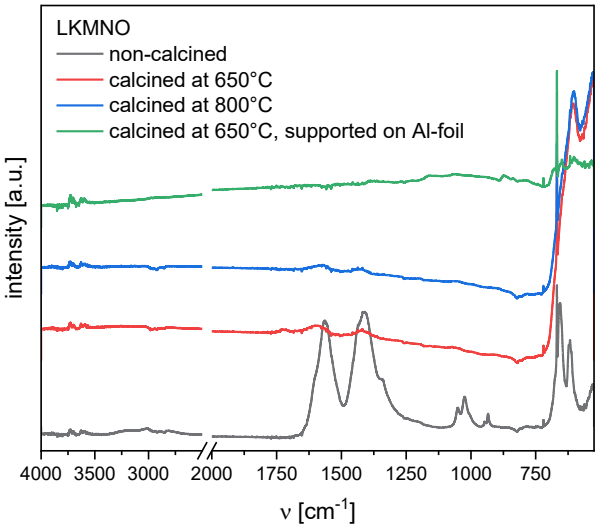

Fig1. FTIR results for the samples LKMNO, LKMNO 650, LKMNO 800 and LKMNO 650 electrode.

X-ray powder diffraction (XRD)

The same samples as listed above have been studied using x-ray powder diffraction. Recorded patterns are shown in Fig.2.

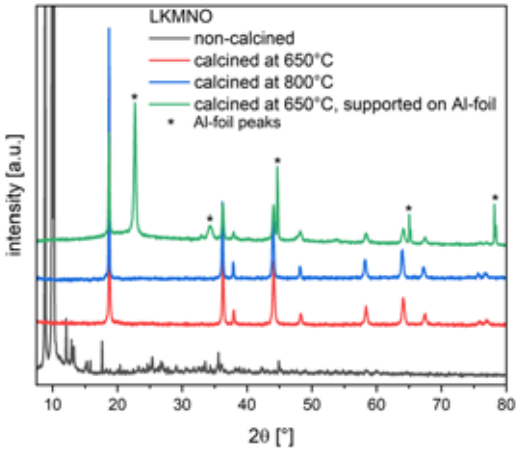

Fig.2 XRD results for the samples LKMNO, LKMNO 650, LKMNO 800 and LKMNO 650 electrode.

The size of the crystallites was measured after calcination and it was determined as 28 nm for LKMNO 650 and 43 nm for LKMNO 800, respectively.

RESULTS AND DISCUSSION

Sol-gel synthesis of LKMNO allowed for the preparation of material containing very small amounts of K and Ni. Samples were homogenous and the method was adhering to green chemistry principles. The analysis of FTIR spectrum measurements after calcination showed the disappearance of bands representing organic ligands introduced in the precursor. The XRD method also confirmed the occurring change in structure of the precursor and its transformation into spinel LKMNO. The size of crystallites is also an important parameter that can help in choice of calcination conditions, providing that we wish to produce cathode material with large active surface area and lower diffusion limitations.

CONCLUSIONS

Synthesis of LKMNO is effective and provides us with properly constructed 3D spinel structure. Calcination temperature does not have significant influence on the obtained results, so calcination in 650°C consumes less energy which is a preferable solution because of the environmental impact and maintenance cost. The size of crystallites also tells us that LKMNO calcined at 650°C has better properties for use as a cathode material. Lesser size of grains provides better diffusion in substance.

ACKNOWLEDGEMENT

ABSTRACT

The TeacHy project (Teaching Fuel Cell and Hydrogen science and engineering across Europe) is funded by the Fuel Cell & Hydrogen Joint Undertaking (FCH2 JU), as part of the Horizon 2020 Programme. The TeacHy educational material and MSc course modules have been developed for blended learning delivery and will be available through the partnering universities. 12 partners from 11 European countries have contributed to the successful development of 20 modules.

Keywords: TeacHy, Hydrogen, Master of Science, Blended learning

INTRODUCTION

The TeacHy project is designed as a tool that can be used for universities where they intend to teach a master's programme based on the hydrogen economy, the benefits of implementing hydrogen and fuel cells technology, correlations with other engineering disciplines, etc. The project aims to be a way of increasing the number of postgraduate students in the technical labour market who have the necessary knowledge and skills to implement hydrogen in the field of renewable energy and alternative fuels, providing essential tools to academics in European universities who are active in the field of fuel cell and hydrogen (FCH) technology. The project supports the need for qualified personnel that will grow as the hydrogen industry gradually develops, evolving from a niche concept to a mature market.

Training of personnel to support the emergence and growth of the FCH industry will become a critical component with multi-sectoral implications in ensuring the competitiveness of human and professional resources in the coming decades.

PROJECT DESCRIPTION

The TeacHy project aims to create teaching materials necessary for the training of students pursuing a master's qualification in the field of FCH technology, along with identifying all the steps, difficulties, and solutions necessary to accredit such a master's programme. Obviously, other forms of postgraduate training are included.
The project consortium is comprised of 12 partners from 11 countries (Fig 1): University of Birmingham – UBHAM (UK), University of Groningen (Netherland), National Technical University of Ukraine 'Kyiv Polytechnic Institute' – KPI (Ukraine), Politecnico di Torino – POLITO (Italy), Karlsruhe Institute of Technology – KIT (Germany), University of Chemistry and Technology, Prague – UCTP (Czech Republic), École Polytechnique Fédérale de Lausanne – EPFL (Switzerland), Grenoble Institute of Technology - Grenoble INP (France), Denmark Technical University – DTU (Denmark), Ulster University – UU (UK), Université libre de Bruxelles – ULB (Belgium) and University “Politehnica” of Bucharest in partnerships with ICSI Rm. Vâlcea (both from Romania).

The consortium was created around this group of experienced institutions that also collaborate with other relevant partner networks (universities, professional associations, professional groups, etc.). Through this consortium, partners can access educational materials and use the master's course modules available on the project website [1].

Fig. 1. The TeacHy consortium

The above described educational institutions have a strong pedagogical background in the field of FCH technologies, having numerous similar projects, that include educational components, co-financed by the FCH JU, such as HySafe, TrainHy, HyProfessionals, HyFacts, KnowHy, and HyResponse [2].

RESULTS AND DISCUSSION

The TeacHy educational material and MSc course modules have been developed for blended learning delivery and will be available through the partnering universities. 12 partners from 11 European countries have contributed to the successful development of 20 modules. Within the project, the partners have developed seven modules that are mandatory, another eleven that are optional, and two additional ones.

The content of the teaching material includes slides, relevant multimedia materials, diagrams, graphs, figures, or videos, as well as summative evaluations of the modules (tests and exams). Content developers also evaluate and review content produced by other members of the consortium to ensure the delivery of a high-quality and fit-for-purpose educational programme. Where appropriate, the content developers have translated the teaching material into various spoken European languages so that the national language from the respective educational institution can be used.

TeacHy has the ambition to offer interested parties strong support for conducting and accrediting FCH courses. Support will be provided to a large number of European educational institutions, in the academic field, as well as vocational training institutions. These entities will be able to deliver an FCH master's programme locally, using only 20% of their own resources and the remaining 80% will be the support provided by the TeacHy project. In this way, a significant number of institutions will have the chance to offer high-quality FCH courses across Europe.

Parts of the course content have been delivered and will continue to be delivered to students at partner universities. This is done in order to follow and analyse feedback from students and target groups. The implications of the

pandemic required that in addition to the classical approach, virtual pedagogical tools have to be considered in terms of both teaching courses and evaluating students.

CONCLUSIONS

The TeacHy project is an innovative approach that allows the partner institutions (12 universities from 11 European countries) to offer educational courses on FCH technology. This type of pedagogical content is not yet available in many universities. The project partners carry out a series of activities through which they can make available to any educational institution in Europe didactic content that covers FCH technology that meets the highest quality standards.

ACKNOWLEDGEMENT

The TeacHy project is a Coordination and Support Action funded by the European Union's H2020 programme through the Fuel Cells and Hydrogen 2 Joint Undertaking under grant agreement no. 779730.

ABSTRACT

The relevance of Fuel Cells and Hydrogen (FCH) systems as decarbonisation solutions has grown significantly during the past decade. However, a sustainable life-cycle performance of FCH systems should be guaranteed. In this sense, while the focus is typically placed on their economic and environmental performance, scarce attention is usually paid to the social dimension, which should be assessed to avoid burden shifting. In this work, a Social Life Cycle Assessment (S-LCA) of a 5 kW Solid Oxide Electrolysis Cell (SOEC) stack was carried out within the context of the eGHOST project. The system boundaries include the extraction of materials, the manufacturing of components and the final assembly of the stack parts (balance of plant excluded). Design parameters such as current density, degradation and lifetime were defined considering 2030 targets, when this type of electrolysers is expected to be commercially mature. Inventory data (including working hours) were adapted accordingly from literature sources, while trade information from the UN Comtrade database was used for the regionalisation of the supply chain. Modelling and evaluation were performed using openLCA and the PSILCA database and method. Overall, stainless steel production in Spain arose as the main social hotspot under most of the evaluated indicators.

Keywords: Hydrogen, Life Cycle Assessment, Solid Oxide Electrolysis, Social Impact, Sustainability

INTRODUCTION

In December 2020, the European Union updated its Nationally Determined Contributions (NDC) to the 2015 Paris Agreement. This update increased the greenhouse emission reduction commitment from 40% to at least 55% by 2030, relative to 1990 levels [1]. In this context, the FCH sector has been identified as crucial for the expected energy transition. Ambitious targets have been set for its short-, medium- and long-term deployment. It is expected that up to 40 GW of water electrolysis capacity will be installed across Europe by 2030, enabling the production of hydrogen at a cost lower than 3 €/kg [2]. High-temperature electrolytic processes present advantages in terms of efficiency when compared to more mature options such as alkaline electrolysis [3], but they need to be further developed in order to reach technology maturity and cost-competitiveness.

The deployment of FCH technologies needs to be supported by a holistic approach that ensures a suitable economic and environmental performance while preventing burden shifting to social impacts. Within the context of the EU-funded project eGHOST (https://eghost.eu/), this work aims to comprehensively assess the social life-cycle performance of a 5 kW SOEC stack, a high-temperature electrochemical device for hydrogen production. Although Social Life Cycle Assessment (S-LCA) has scarcely been applied to FCH systems, it is an effective and increasingly used methodology to thoroughly assess the potential social impacts of product systems [4,5].

MATERIALS AND METHODS

Goal and scope definition

The assessed product is a 5 kW SOEC stack, one of the two reference cases selected in the eGHOST project for the development of eco-design guidelines for FCH technologies. The stack specifications and bill of materials were originally retrieved from literature sources [6]. Current density, active surface, degradation and lifetime parameters were defined to meet 2030 EU targets [2], resulting in a higher unitary power per cell and thus a lower number of total cells in the stack.

The goal of the present work is to identify social hotspots of the product under study. The functional unit (FU) was defined as one SOEC stack (balance of plant excluded). Due to the lack of prospective S-LCA databases, the assumption underlying this study refers to the assessment of social risks associated with manufacturing the SOEC stack in 2030 but assuming current social risk levels (at the level of country-specific sectors) and working hours. The system boundaries comprise materials production processes, the manufacturing of components and the final assembly of the stack (including the involved energy flows). Hence, the supply chain involves three tiers: tier 1 for the stack manufacturing plant itself, tier 2 for the plants related to the production of the components and energy flows required by

the stack manufacturing plant, and tier 3 for the plants related to the material and energy flows required by the components manufacturing plants.

Countries were identified along the supply chain following available protocols used for S-LCA [7]. Spain was set as the manufacturing country of the final product and thus established as the initial declarant entity. Global trade data for each stack component were obtained from the UN Comtrade database. If the Spain's monetary export-import balance for a component results positive, then the component was determined to be manufactured also in Spain. If the balance results negative, the principal exporter was targeted. A similar procedure was used to determine the origin of the materials within the third tier: each component manufacturing country was designated as declarant for every material flow involved in the component and its trade balance was characterised similarly (but, when looking for relevant exporters, the set of those accounting for more than 50% of world exports to the declaring country was considered, not being necessarily limited to the top one as in the second tier).

The social indicators under evaluation were selected based on the eGHOST project specific purpose as well as on previous S-LCA studies in the field of energy and hydrogen. Regarding the stakeholder category "workers", the indicators “child labour”, “forced labour” and “fair salary” were examined. Moreover, “health expenditure” and “contribution to economic development” were evaluated within the stakeholder category "society".

Data implementation

The software used to implement the inventory data was openLCA. PSILCA [8] was used as an additional source of data (mainly regarding working hours per economic unit for items without specific information available, as well as country- and sector-specific risk levels) and as the evaluation method.

RESULTS

The social life-cycle profile of the SOEC stack was calculated. The S-LCA results are shown in Fig. 1 in terms of process plant contribution to the selected social indicators. As a key finding, stainless steel production in Spain arouse as the main social hotspot in every impact category except for "child labour". This finding was found to be closely linked to the high mass rate of stainless steel in the SOEC stack. Furthermore, the materials totally or partially manufactured in China (zirconium dioxide, iron oxide, and lanthanum oxide) were also found to account for relevant social risk values, especially under the “child labour” indicator.

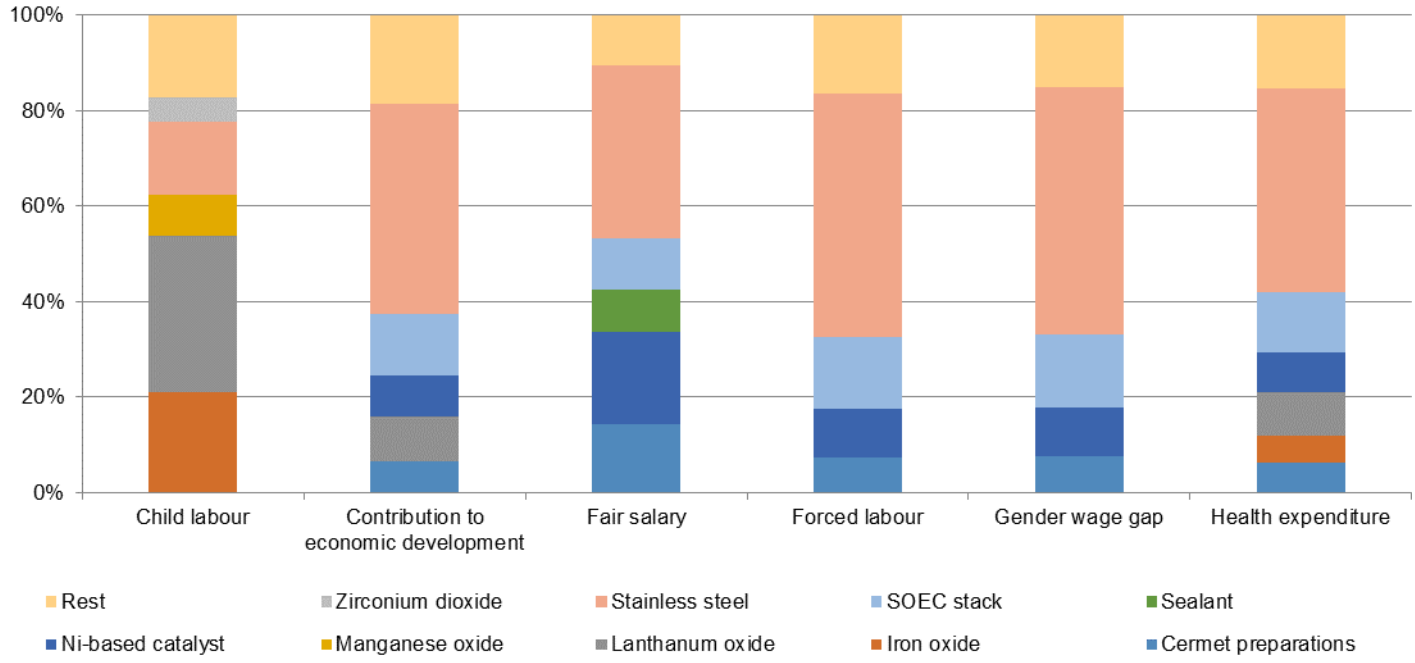

Fig. 1. Process plant contribution to the evaluated social risks of the SOEC stack under study

Overall, manufacturing processes at the level of materials were found to involve larger potential social impacts than manufacturing processes at the level of components and final product. It should also be noted that electricity flows across tiers were found to account for minor contributions.

CONCLUSIONS

In this study, an S-LCA of a 5 kW SOEC stack was performed. Stainless steel production in Spain generally arose as the main social hotspot, primarily due to the high mass rate of stainless steel in the stack. The materials manufactured in China also arose as a relevant source of social risk, mainly in terms of child labour. These results will serve as a relevant source of information for the development of eco-design guidelines for FCH technologies within the context of the eGHOST project.

ACKNOWLEDGEMENT

This work was carried out within the context of the project eGHOST. This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking under Grant Agreement No 101007166. This Joint Undertaking receives support from the European Union's Horizon 2020 Research and Innovation programme, Hydrogen Europe and Hydrogen Europe Research.

ASSESSING PUBLIC ACCEPTANCE ON HYDROGEN ECONOMY IN JAPAN: A COMPARISON OF PAST SURVEY IN 2015

[1*] *Jiazhen Yap,*[1] *Benjamin McLellan*

ABSTRACT

Hydrogen and Japan have a long, shared history, dating back to 1974 with the start of a green initiative known as the Sunshine Project. Since then, the Japanese government has actively sought to realise a hydrogen society by using hydrogen as an energy carrier in transportation, residential power systems, and industrial applications. Despite the continuous effort by the Japanese government, it remains to be seen whether hydrogen can achieve large-scale deployment. Assessing society's acceptance of a hydrogen economy is important to understanding social support and ultimately avoiding unwillingness for hydrogen technology and infrastructure deployment. This study aims to analyze the current attitude of Japanese society towards the realization of a hydrogen economy through a community survey. Given recent global interest, the results will be compared with a similar survey conducted in 2015 to see if there has been any recent changes. The questionnaire survey was designed to analyze responses under four main aspects: awareness of various energy resources and environmental policy; perception of hydrogen economy; knowledge of hydrogen technology and infrastructure; and acceptance towards the establishment of hydrogen infrastructure in the community.

Keywords: Hydrogen Economy, Survey, Public Acceptance, Japan

INTRODUCTION

The hydrogen economy refers to a vision of utilizing hydrogen (H_2) as a transition pathway to an equitable energy system that is clean, low carbon-intensive, and beneficial to society. Hydrogen is an energy carrier that can be produced by a variety of energy resources and support a multitude of end-use applications, including energy storage, transportation fuel, industrial processes, and more. Historically, the hydrogen economy has attracted the attention of many and resulted in multiple surges of interest over the years [1]. The hydrogen economy is a dynamic system that consists of economic, technological, and social structures that are constantly evolving. This dynamic system is affected by endogenous factors by stakeholders with different agendas and exogenous factors outside of a hydrogen economy's system boundary. The diversity of hydrogen as an energy solution allows people to interpret it based on their own perspectives and agendas, resulting in competing interpretations of what a future hydrogen economy may look like. This has created a gap between the public and scientific community understanding of the status of hydrogen economy and raised false expectations in the past [2]. It is widely accepted in socio-economics that the success of emerging technology depends to a great extent on public acceptance [3][4]. Emerging technologies such as hydrogen technology have received increased general coverage through the media [5], but public acceptance is still relatively unknown [6].

Literature Review

Over the past few decades, various studies have investigated the technical and economic aspects of hydrogen as a promising energy carrier to solve global climate issues and increased concerns in the fossil fuel-based energy economy [7][8]. However, studies on public perception of hydrogen have been significantly less common [9]. Country-specific studies such as in Germany [3][10], USA [11][12], UK [13], and Spain [4] have investigated the acceptance and implementation of H_2 technology. Although they use varying survey designs, the results concluded that the public seems to have a positive impression toward H_2 technology. However, the studies also reveal that the public is largely unaware of hydrogen beyond the automotive sector, and most individuals do not have firsthand experience with H_2 technology. Aside from perception, personal experience with H_2 technology can greatly influence the acceptance of hydrogen in daily life [10].

Given the long history of Japan with hydrogen [14], there have been few studies focusing on public perception of hydrogen to date. The few studies are available in Japanese and carried out by NEDO and Mizuho Information & Research Institute. The nationwide survey was conducted in 2008 [15] and 2009 [16], investigating the social acceptance of hydrogen. Their results indicated that the public perspective of H_2 technology is relatively high, although most respondents do not have experience using H_2 technology. Itaoka et al. [6] conducted an updated survey in 2015, comparing results to previous surveys and focusing more on hydrogen in the transportation sector.

The study concluded that public awareness of hydrogen energy, hydrogen infrastructure, and fuel cell vehicles had increased significantly compared to previous surveys.

In addition, there have been many hydrogen demonstrations or pilot projects involving different sectors and technology types. In some cases, the projects have been conducted in parallel with a community survey to evaluate public reactions in experiencing hydrogen in action or as a preliminary assessment of public acceptance for future investment of hydrogen technology. Notable projects include Clean Urban Transport for Europe (CUTE), the largest demonstration project of fuel cell buses in nine different cities within Europe [17][18], and Ecological City Transport System (ECTOS), a demonstration project in Reykjavik, Iceland, also using fuel cell buses [19]. However, the respondents of these studies are typically introduced to hydrogen and its benefits, thus not representing a random sampling of the entire population with regards to existing perspectives.

At present, the majority of studies focus on a single aspect of hydrogen, mainly transportation, often overlooking aspects such as production and storage, which also form the basis of a hydrogen-based society. This is partly because hydrogen technologies are not widely available yet, and most are at prototype or pilot stages, which leads to lower public engagement. Furthermore, the potential transition to a hydrogen economy is predominantly discussed among the scientific community [20]. Although hydrogen has been covered by media over the years, the interest has been a recurring hype, often associated with futuristic technology, environmental issues, and most recently COVID-19 post-economy recovery in the energy sector [21].

Aim

This study aims to analyze the current attitude of Japanese society towards the realization of a hydrogen economy through a community survey. The questionnaire survey is designed to evaluate the public perception, knowledge, and acceptance of hydrogen as an energy carrier, hydrogen infrastructure, and fuel cell technologies in Japan. This community survey is part of a parallel study with an expert panel survey that aims to quantify the different yet overlapping interpretations of hydrogen economy among different society groups, mainly academic, industry, government, and the general public, through an in-depth survey. It is crucial to understand the various interpretations of society and bring them together to exploit the diversity of hydrogen fully.

METHODS

This study was conducted from a social-economic perspective. The questions and structure of the survey were designed to allow comparison with a previous survey conducted in 2015 [6], using some of the same key questions but also adapted to the specific objectives of the current study. In total, 22 closed-ended questions were formulated under four main aspects: (i) awareness of various energy resources and environmental policy; (ii) perception of hydrogen economy; (iii) knowledge of hydrogen technology and infrastructure; and (iv) acceptance towards the establishment of hydrogen infrastructure in the community. In addition, social-demographic variables were included in determining the general characteristic of respondents and influences towards acceptance of hydrogen. The survey will be conducted in February 2022 using an internet-based survey, where respondents are panelists of a Japanese marketing research company. The respondents will be selected using a stratified random sampling method to ensure our results represent the Japanese population.

RESULTS AND DISCUSSION

Based on an earlier social acceptance study on hydrogen [9], a theoretical model was adapted to guide the formulation of the survey questions. The following model in Fig.1 was designed to evaluate and visualize various aspects that influence an individual's opinions toward the acceptance of a hydrogen economy. The three aspects are described as follow:

a. Value
   Personal values represent individual beliefs that guide everyday life, motivate actions, decision-making, and ultimately improves the quality of life [22]. Everyone holds various values with varying degrees of priority. As such, individuals with a stronger sense of environmental value would be expected to play a more active role in solving climate issues.

b. Knowledge
   The literature review has indicated the discussion of hydrogen is still novel among the general public. The level of knowledge is a good indicator to measure public understanding of hydrogen as individual opinions may be vulnerable to media hype reporting when access to hydrogen-related knowledge is still limited.

c. Perception

The nuances of a "Hydrogen Economy" provide potential points for disagreement and alternative perspectives. For example, the concept of a "Hydrogen Economy" is often referred as "Hydrogen Society" in Japan. This simple change of wording can also affect an individual perspective as the terminology of "Economy" is different to the Japanese term. Hydrogen is typically regarded as an energy carrier, not an energy source, in scientific literature (while this specific nuance is likely to be unclear to the general public). Hydrogen needs to be produced, stored, and distributed to the end-user, similar to electricity. Each stage of the hydrogen supply chain has significant implications in terms of public perception. Hydrogen can be produced from fossil fuels, renewable energy, or nuclear energy. Would people equally accept each production method as each has advantages and disadvantages? Similar questions can be asked concerning different stages in the hydrogen supply chain. Therefore, a specific image must be established to consider the acceptance of hydrogen in daily life. The association of hydrogen with everyday life can serve as an indicator of how the public perceives the issues with the system and technology.

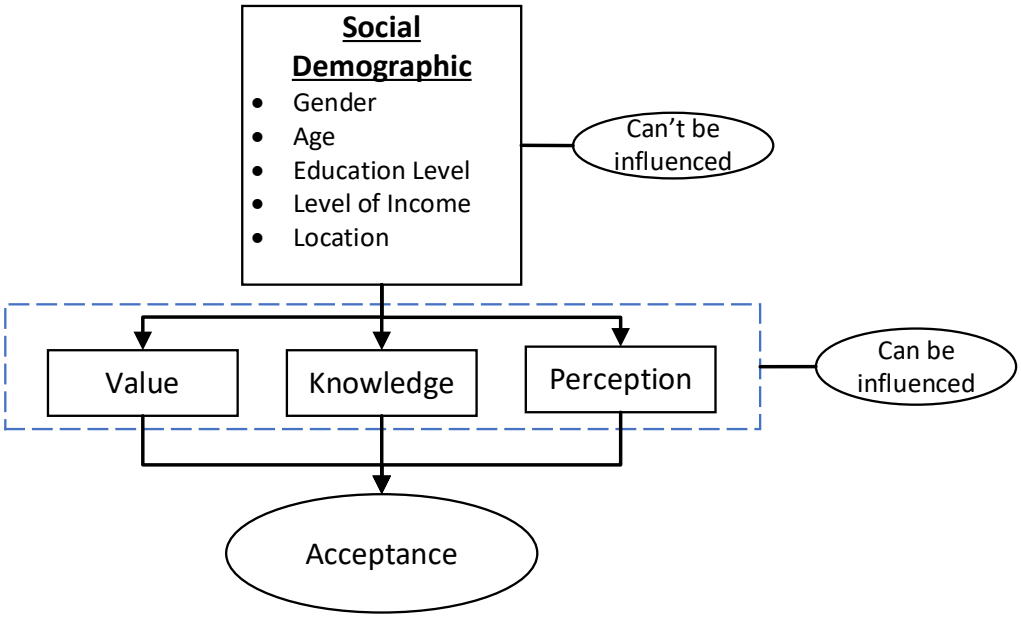

Fig. 1: Theoretical Model of Acceptance of Hydrogen Economy

CONCLUSIONS

This study offers a different perspective to the current body of knowledge as social aspects of a hydrogen economy are often discussed to a lesser extent in related reports or roadmaps. A theoretical model was developed, and a community survey will be conducted in February 2022 to evaluate the acceptance of a hydrogen economy in the Japanese community. Survey results and implications are expected to be presented in the conference presentation. The results from this study are expected to improve the current state of knowledge and serve as basic information in establishing a strategy for a future hydrogen economy transition and improving public acceptance.

GREEN HYDROGEN, AN ECONOMIC PARADIGM SHIFT – NEW PERSPECTIVES FOR THE GLOBAL SOUTH?

[1*] *Andreas Stamm,* [1] *Rita Strohmaier,* [1] *Ece Oyan,* [1] *Katharina Thoms*
[1]German Development Institute – Deutsches Institut für Entwicklungspolitik (DIE), Bonn, Germany

ABSTRACT

Hydrogen is a key element for the energy system of the future. International experts and organizations [1] forecast a rapidly increasing demand for green hydrogen in the coming decades, especially in Europe and Japan. This opens new opportunities for developing countries to position themselves beneficially in a new international division of labour. Costa Rica has locational advantages for the production of hydrogen with renewable energies. It makes sense for the country not to focus exclusively on opportunities to develop a new export sector, which may not generate very good income and employment opportunities in the future. Rather, more comprehensive strategies should be developed combining export revenues and

Keywords: Green Hydrogen, Developing Countries, Development Potentials, Decarbonisation, Employment Creation

INTRODUCTION

Since the early 1970s, the notion of a global “hydrogen economy” was launched as a concept for a visionary future. 50 years later, it seems that the future has arrived. There is an international consensus that mitigating climate change is an urgent need and that hydrogen will play a crucial role in decarbonisation efforts. Following projections of the International Energy Agency (IEA), the global green hydrogen market is going to grow from 0.3 billion USD in 2020 by exponential rates and reach the threshold of 10 billion USD in 2028. In 2050, hydrogen could cover 24% of global energy demand [1]. Substituting fossil fuels by green hydrogen implies far-reaching shifts in the global economic geography. Countries of the Global South, often well endowed with renewable energy potentials, may become mayor exporters of green hydrogen (GH2) the “oil, gas and coal” of a climate-friendly future energy systems. This paper explores the developmental potential of the paradigm shift in the global energy and industrial resource system and sketches some basic open research questions.

MATERIALS AND METHODS

The paper analyses the development potentials of GH2 for the Global South. It is based on a thorough literature review and expert interviews.

RESULTS AND DISCUSSION

The fact that hydrogen can be used as an energy carrier is not at all new. Already in the 1870s, French novelist Jules Vernes envisaged a future, when hydrogen would be employed as a powerful source of heat and light, powering steam ships and locomotives [2]. The abundance of cheap and easier-to-handle fossil fuels and electricity as energy carrier explains, why this hydrogen vision was not pursued for around a century. Only in the 1970s, the fact, that fossil energy resources are limited and that their combustion may have detrimental effects on the global climate reached the international discourse [3]. The notion of a hydrogen economy was suggested in 1970 by the U.S. electrochemist John Bockris [1]. It took another half century until concrete commitments were made to start a determined transition towards a hydrogen economy. This can mainly be attributed to the fact that very significant technological and systemic advancements have been made, since around the turn of the century, in renewable energy deployment, mainly offshore and onshore wind and solar PV. Cost reductions in renewable energies and in electrolysis turned many ambitious projects into feasible options. Clear commitments to climate action also triggered the drafting and adoption of hydrogen strategies in Europe and beyond.

A milestone was the adoption of the trillion-dollar European Green Deal Package in 2019 and the subsequent EU Hydrogen Strategy. Green hydrogen is deemed to be the key driver of the EU’s carbon neutrality target by 2050. Both the European and the German hydrogen strategies are very ambitious in terms of building up domestic capacities for green hydrogen production. The technology of choice is clearly electrolysis, powered by electricity generated without or with very small amounts of GHG emissions. European hydrogen strategies envisage 40 GW of electrolysis capacity by 2030, with France (6.5), Germany and Italy (5 GW each) having the largest shares. Just how ambitious this is becomes clear when you consider that, according to the German Aerospace Center; Germany currently has a total electrolysis capacity of 30 megawatts, powered by renewable energy. Even if the ambitious plans will be implemented, it still implies that only a minor share of the hydrogen demand will be covered by local

production. What is a rather blind spot in both the European and the German hydrogen strategies are the expected trade flows in the future. The strategies stay rather vague about where the huge amounts of green hydrogen will be produced and how they will be transported to Europe. Within Europe, a certain share will be produced via solar PV in countries like Spain and by offshore wind in the riparian states of the Northern and Baltic seas. However, large part of the demand be covered by extra-regional imports.

DIRECT BENEFITS FOR DEVELOPING COUNTRIES FROM INTEGRATION INTO A GREEN HYDROGEN ECONOMY

Countries best prepared to produce GH2 at relatively low costs are those endowed with rich renewable energy potentials. Most high potential locations are located in the Global South, most of them, with the exception of Australia Low to Middle Income Countries (LIC/MIC). What has not yet been discussed is, why and under which conditions developing countries would be willing to export GH2 to the Global North. We briefly discuss four ways, how developing countries might benefit from integration into an international division of labour in a global GH2 economy:

- Export revenues can improve the national balance of payments and generate government revenues that can be invested, for example, in social transfers or in improving the country's human capital through education.
- The direct employment effects of hydrogen projects can reduce underemployment and stimulate the economy through multiplier effects.
- With the production of large quantities of climate-friendly hydrogen, the country has a completely new type of raw material at its disposal.
- Related to this is the fact that the establishment of hydrogen projects in developing countries goes hand in hand with the transfer of technological knowledge and international cooperation in research and development.

Whether the *export revenues* developing countries may obtain for selling GH2 on the markets of Europe or Japan will be attractive or not is difficult to predict. Given the starting conditions and the clear willingness of industrial countries to promote the market launch of a global GH2 economy it is likely that countries able to supply significant quantities of GH2 in the near future may benefit from first mover advantages. In the long run, however, with an increasing number of suppliers entering the market and technologies and systems becoming more and more standardized, it is very likely that the prices will go down. Whether or not being an exporter of GH2 remains attractive then depends on the combination of prices free on board (FOB) and international transport costs, which are still very difficult to predict.

Among the socio-economic challenges, most developing countries face is the urgent need to bring young people into productive *employment*. This is especially the case for regions, often seen as quasi-natural partners of Europe in a GH2 strategy. In most countries of sub-Saharan Africa, Northern Africa and the Middle East, youth unemployment is in the range of 20% to 30% and this tends to raise governance problems of different types. Currently, there are no reliable data about the employment, which GH2 projects generate. Drawing on analogies from large utility-scale energy projects in developing countries, it is reasonable to state that significant numbers of employment are created during the building of the facilities but that a limited number of jobs in operation, maintenance and repair remain, once they are up and running.

IMPORTANT CO-BENEFITS FOR DEVELOPING COUNTRIES

Even if the direct benefits of developing countries entering a global GH2 economy might be limited, there are other benefits with huge potentials to even become game changers for sustainable development on the ground. However, this requires a change in strategies from a mere export-oriented to a multipurpose and comprehensive model of GH2 economy. Availability of GH2 in significant quantities may open new pathways for value creation and innovation.

Hence, countries may also consider the mid and long-term benefits from implementing the green H2 economy within their national borders: First, an absence of legacy energy systems and path dependencies makes it comparatively easy to leapfrog to new and environmentally friendly energy technologies that reduce dependence from international fossil fuel supply chains. Second, hydrogen is a powerful technology for storing and transporting these energy sources and thus for solving the intermittency problem and overcoming the systems integration challenge related to VRE technologies by carbon-free load balancing [7]. Furthermore, decentralized hydrogen production based on solar energy does not entail expansive infrastructure and can therefore push rural electrification, thereby also contributing to social well-being and stability. It furthermore can be used either pure, as a feedstock or as a heating source in many different pathways and in various sectors. In addition to direct use in the transport sector or as a heating source, hydrogen may also be used as a feedstock in the chemical industry (e.g. copper, steel, solvents) or in the production of derivatives (e.g. synthetic fuels, ammonia, methane and methanol) in a wide range of industries such as the transport sector, agriculture or the building sector. Thus, reduces existing import dependencies and/or emissions.

Beyond the advantages related to the energy transition, green H2 production also opens strong opportunities regarding job and economic growth. This effect works through two channels: (1) the co-benefits associated with the exploitation of renewable energy; (2) co-benefits associated with the expansion of value chains into different sectors and energy-intensive industries. Major co-benefits are related to economic performance, as the renewable energy systems create jobs (8,9,10,11), increase economic activities and diversification [12,13,14,15,16], and lead to significant savings in terms of energy [17,18] and time [19].

RE expansion also bear social co-benefits, linked to health [20, 21, 22] due to the reduction of air pollution, educational opportunities and knowledge transfer [9,21], poverty reduction [23,24] as well as to an improvement in overall welfare and resilience [14], social equity [25], better inclusion of woman [19] as well rural and indigenous communities [16,10]. Furthermore, the advantages of RES regarding decentralized power supply improves energy access and security [26, 21, 27]. Environmental co-benefits associated with the energy transition are the reduction of GHG emissions [16,22] better air quality [see, e.g., 23,25], improved biodiversity, reduced deforestation and [19], less freshwater ecotoxicity and eutrophication [8], and waste disposal reduction [16].

CONCLUSIONS

For Europe, the vision of a rapid market ramp-up for green H_2 in order to decarbonise industry and transport faces challenges in terms of the sheer quantities involved. NationAL strategies like the German NWS need to be complemented by a European and a multilateral agenda that views H_2 as an opportunity to overcome global challenges and focus on benefiting all parties. For example, the countries of North Africa are exigently dependent on creating jobs for young people in particular. However, international ventures such as the Ouarzazate solar project in Morocco, which has been supported by Germany, demonstrate that these employment opportunities are often modest once large-scale systems have finished their construction phase and enter regular operation. Germany and Europe should reach out to potential exporter countries in the spirit of partnership and scope out what mutual benefits can be achieved in order to increase the political will and local acceptance for joining an international hydrogen economy. Knowledge sharing and scientific cooperation are essential if developing countries are to be empowered to develop their own H_2-based solutions, including switching their fertiliser production from fossil fuels to H_2 or decarbonising their (petro-)chemical industries. More technologically advanced countries such as South Africa or Brazil could supply core components for electrolysers. The least-developed countries could use H_2 as an energy storage medium in power grids supplied by intermittent renewable energy sources.

ABSTRACT

Hydrogen is a key element for the energy system of the future. International experts and organizations [1] forecast a rapidly increasing demand for green hydrogen in the coming decades, especially in Europe and Japan. This opens new opportunities for developing countries to position themselves beneficially in a new international division of labour. Costa Rica has locational advantages for the production of hydrogen with renewable energies. It makes sense for the country not to focus exclusively on opportunities to develop a new export sector. Rather, Costa Rica should actively seek to create additional benefits domestically through the usage of hydrogen. In transport and certain industries, there are opportunities to lower greenhouse gas emissions while significantly reducing the import of fossil resources and creating job opportunities.

Keywords: Green Hydrogen, Developing Countries, Development Potentials, Decarbonisation, Employment Creation

INTRODUCTION

Green hydrogen (GH2) is a crucial element of any strategy aiming at reconciling socio-economic prosperity with the planetary boundaries, especially keeping climate change under control. The transition towards a green hydrogen economy will lead to significant shifts in the global economic geography. Developing countries, often well endowed with renewable energy resources, may be future focal points of GH2 production. The paper discusses the development potentials for Costa Rica of getting involved in the emerging GH2 economy. It argues for an integrated strategy, combining the export of GH2 or derivatives with actions outlined in the country's decarbonisation plan for lowering greenhouse gas (GHG) in the transport and industry sectors. This can contribute to import substitution and the building up of labor-intensive activities especially in underprivileged areas of Costa Rica.

MATERIALS AND METHODS

The paper analyses the development potentials of GH2 for a small developing country. It is based on a thorough literature review and interviews with core stakeholders of Costa Rica's energy sector.

RESULTS AND DISCUSSION

Costa Rica in a Global GH2 Economy: On Locational Advantages

Economic geography and regional economics analyse the likelihood of an industry locating in a country or region using the concept of locational advantages; such as access to raw materials, important markets, low wages and taxes. In traditional manufacturing, Costa Rica does not have major locational advantages, as the country is poor in natural resources, relatively far from major markets and has relatively high labour costs. Over the last four decades, however, it has managed to penetrate knowledge-intensive niches of the world market, from high-value agricultural exports to IT-enabled services and manufacturing and exporting medical equipment. In a coming GH2 world economy, the locational advantages will continue to shift:

- Renewable energy are "coal and oil", the most important resources of a post-fossil energy system.
- Water is the second most important resource, as current technologies require large quantities of pure water to produce GH2.
- Skilled personnel and advanced governance capacities will be crucial in the near future, as some elements of the hydrogen economy are still in flux and will require active efforts to make them work as a system under the specific conditions of each country.

In this new economic geography, Costa Rica has the opportunity to move from a rather peripheral position further into the centre. The country has excellent renewable energy potential. Hydropower, geothermal and wind power have accounted for about 98% of the country's total electricity generation in recent years. However, data from the International Energy Agency (IEA) shows that in 2019, still around 50% of the total energy consumed in the country came from oil, mainly in the transport sector and the fertilizer industry. This means that Costa Rica's energy transition

is far from complete and must now address sectors that are more difficult to decarbonise compared to electricity generation, especially passenger and freight transport and some industries.

Although water scarcity is an issue for some regions at certain times of the year, overall we can expect Costa Rica to have abundant water resources for the foreseeable future. Some high-altitude areas on the Atlantic slope are among the rainiest regions in the world, reaching about 6000 mm of precipitation per year.

Market access is a challenge for all GH2 producing countries, which are too far away to be connected to consuming regions via pipelines. The distance from Costa Rica to potential GH2 markets, e.g. Europe, is large, but not greater than potential competitors. The transport distance between, for example, Puerto Moin on the Caribbean coast and Rotterdam as the main import port for Europe can be estimated at 20 days, similar to the transport time from Namibia to Europe, shorter compared to Chile and at least ten days shorter compared to any port in Australia.

Finally, other, less quickly grasped locational advantages can be particularly important at an early stage in the development of a global GH2 economy. This is when technologies and processes are not yet fully standardised and need to be adapted to changing conditions and new knowledge in the course of the implementation process: The country has a highly skilled workforce and good institutions for academic research and education and for vocational training. The country's governance is considered capable and efficient, both in the political sphere and in terms of implementing agencies in investment promotion, export promotion and in the energy sector. In recent decades, Costa Rica has learned to negotiate and deal with large international companies that invest in free trade zones, industrial parks and agricultural exports. Despite relatively high labour costs, Costa Rica remains an attractive investment destination. There are thus good reasons to believe that Costa Rica has a good chance of positioning itself as a potentially important production location in a global GH2 economy.

Indeed, most recently, the Australia-based industrial corporation Kadelco announced its interest to establish a facility in Costa Rica to annually produce up to 50.000 tons of GH2. Investment could be as high as US$3 billion and 2600 jobs might be created. The Costa Rica government announced that at least two additional foreign companies have declared their interest in producing GH2 in Costa Rica.

Costa Rica National Decarbonization Plan

In January 2019, Costa Rica announced to "go beyond the usual" in the global efforts and commitments to aspire to become a modern, green, emission-free, resilient, and inclusive economy" and approved its National Decarbonization Plan [2]. This plan capitalizes on important environmental advances in previous decades, including an electricity network free of emissions in more than a 95% and very low rates of deforestation with a forest cover that exceeds 52% of the territory. It defines ten goals, among them ambitious targets for decarbonizing transport, housing and industry.

Possible Socio-Economic Benefits of the Country Entering the Emerging GH2 Economy

For a small developing country hosting "coal and oil" of a post-fossil energy system (renewables and water), there are four ways to benefit from these clean technology efforts.

- Export revenues can improve the balance of payments of the national economy and generate government revenues that can be invested, for example, in social transfers or in developing the country's human capital through education and training.
- The direct employment effects of hydrogen projects can reduce underemployment and stimulate the economy through multiplier effects.
- With the production of large quantities of climate-friendly hydrogen, the country has a completely new type of raw material at its disposal.
- Related to this is the fact that the establishment of hydrogen projects in developing countries goes hand in hand with the transfer of technological knowledge and international cooperation in research and development.

The latter two points open up perspectives for developing new value creation potentials and new social applications locally. The paper discusses the four potential benefits in the case of Costa Rica. We analyse this against the backdrop that the country has two major socio-economic problems to deal with. First, ways must be found to bring more people, especially youth, into productive employment. Second, the huge disparities between urban and rural areas, especially between Central High Valley and coastal areas, must be reduced when it comes to development opportunities for individuals and communities.

In terms of export revenues, it is difficult to assess the potential net benefits Costa Rica may derive from entering the emerging global green hydrogen economy. If the country acts fast and comes into a position to offer reasonable amounts of green hydrogen in the coming years, the economic prospects are good, as a large demand meets a barely developed supply (seller's market). In the long term, the conditions are less favourable, as other countries

probably have lower prime costs, due to even better ecological conditions for producing renewable energies and larger territories allowing to generate economies of scale.

There are currently now reliable data on the employment creation of a green hydrogen economy. Conclusions by analogy (large-scale renewable energy projects) indicate that positive effects on the labor markets will be generated during the construction phase, while in the long run, operation, maintenance and repair activities will only keep limited numbers of people in productive employment. For Costa Rica, large-scale investment in GH2 could be an important way to reduce the unemployment rate, which has risen from 8% to 17% (2017-2020) in the wake of the COVID-19 pandemic and from 20% to 40% in the youth unemployment sector. However, in the long run indirect and co-benefits may be structurally more important.

In Search of the Co-Benefits of GH2 Production

GH2 can be used in many ways. In some African countries, pilot projects are underway to use hydrogen as a storage medium in mini-grids fed by intermittent renewable energy sources. Energy storage can enable a 24-hour power supply. Mini grids are an important bridging technology to provide reliable electricity to communities beyond the reach of the national grid. Since almost 100 % of the population in Costa Rica has access to the grid, this benefit is not broadly relevant for the country. It may be an option, for instance, to assure reliable electricity supply for clinics or storage facilities for agricultural produce in some remote areas of the country.

Two options are important for Costa Rica and are already being explored by the national utility ICE: GH2 as a fuel for passenger and freight transport [3] and as a feedstock for industries, such as metal processing and fertilizer production. Both sectors together are largely responsible for the remaining GHG emissions of Costa Rica. In addition, they depend on imported fossil energy carriers and derivatives, such as ammonium for the fertilizer industry. United Nations data shows that in the years prior to the Corona pandemic, in 2016-2019, Costa Rica imported "mineral fuels, mineral oils and products of their distillation" worth between US$1.2 billion and US$1.7 billion, which represented about 10% of the total value of all imports in the country. Imports of fertilisers are much lower, but still represent a significant cost, amounting to US$60-70 million per year over the same period. Using GH2 to decarbonise industry is a viable option for sectors that require large amounts of process heat [4]. ICE is already working with a company that produces reinforcing steel from imported metal for the construction industry. The heat needed to melt the steel is obtained from GH2. The country's fertiliser and cement industries should be the next candidates, as imported intermediates could be saved while greenhouse gas emissions would be significantly reduced. Globally, the cement industry alone contributes an estimated 8% of greenhouse gas emissions, and the production of synthetic nitrogen fertilisers another 2.4%.

Economic Impulses for Underprivileged Areas

Costa Rica could benefit from the investment and job creation in infrastructure and facilities in the initial phase. This also has an important regional economic dimension, as the best location for a GH2 plant with an important export component (with a view to Europe) would be close to the export ports of Limon or Moin and thus in a structurally weak region compared to the Central High Valley. The creation of jobs on the Atlantic coast and possibly the demonstration effects of a "visible" future-oriented clean technology plant could help to counteract the frustration of the population in the Atlantic region. This feeling of regional marginalization has expressed itself in past elections in abstentions and high rates of support for right-wing populism.

A boost in economic activity and employment triggered by GH2 could help Costa Rica and the Atlantic coast recover from the impact of the COVID-19 pandemic. However, as large renewable energy projects in other parts of the world have shown, the high number of jobs created during the construction phase does not last once the infrastructure and equipment are up and running. This needs to be taken into account in the country's GH2 strategy. To avoid a new wave of frustration, part of the revenue generated by GH2 exports should be invested in creating labour-intensive follow-up activities, not in the Central Valley, but in the peripheral regions, especially on the Atlantic coast. One possible option, for example, would be to set up workshops to convert buses and trucks from combustion engines to fuel cell propulsion.

CONCLUSIONS

Green hydrogen is an important opportunity for developing countries to create new competitive advantages and sustainable employment in promising sectors. Costa Rica is a small developing country at a great distance from the likely major future hydrogen markets. However, the country might be well positioned to exploit first-mover advantages. The country has advanced governance capacities, an educated workforce and research and development institutes, which might collaborate with international investors in the early phase of the emerging global GH2 economy. It is fundamental that the government not only envisages large-scale export of a green commodity but also pursues an integrated strategy, which combines exports with the usage of GH2 for decarbonisation of local

industries and modes of transport, import substitution and the development of labor-intensive industries based on a new raw material in line with a future-proof climate-friendly economic development.

TURKEY'S POTENTIAL TO PRODUCE GEOTHERMAL-BASED GREEN HYDROGEN: INSIGHTS FROM INSIDE

[1*] *Ece Oyan*

ABSTRACT

As a country with high renewable energy potential but still very much dependent on fossil fuel imports, green hydrogen can yield many opportunities to the Turkish economy. This study aims to examine Turkey's potentials in producing geothermal-based green hydrogen. For such an analysis, different stakeholders like private sector, scholars, policymakers, civil society organizations and locals will be interviewed and the results will be analyzed based on techno-economic, political-economic, environmental and societal impacts argued by the interviewees.
Keywords: Green hydrogen, Geothermal, Turkey

INTRODUCTION

Paris Agreement and its goal to keep the average global warming at 1.5°C made various countries announce long-term national roadmaps to either partially or completely decarbonize their economies. To reach such targets, the application and the use of green hydrogen as an energy carrier have been gathering attention for the last couple of years. Countries like United Kingdom (U.K.), the United States of America (U.S.A.), Germany, Japan, Australia, France or Italy have already published their national hydrogen strategies and shared their estimated demand for green hydrogen in the coming decades. Therefore, it can be claimed that the global market for green hydrogen will be expanding exponentially in the near future. In such a rapidly changing environment, countries with high renewable energy potential have the chance to produce and export green hydrogen.

As a country with highly diverse renewable energy potential, Turkey has been working on increasing the share of renewable energies in its power mix. In 2021, renewables constituted 35% of the electricity generated in the country [1]. Especially the installed geothermal capacity has been increasing steadily. Although as of 2020 geothermal represents only the 3.25% (1.6 GW) of the total power generation in Turkey [2], that year Turkey was the world leader in terms of additional installed geothermal energy capacity with 98.3 MW [3]. Given the fact that Turkey consumes more energy than it generates, which makes it highly dependent on fossil fuel imports, further increasing its share of renewables can decrease the country's dependency on other energy suppliers. Additionally that can provide a greater possibility to be a net green hydrogen producer and also help decarbonize its own economy [4].

Although in the literature the major attention has been given so far to the green hydrogen production from solar and wind power, we believe that as a base-load energy, geothermal may provide additional advantages, as it is not affected by ambient conditions. Moreover, multi-generation geothermal power plants where both hydrogen and electricity are produced offer more feasible and efficient production systems [5]. Besides, it is also possible to combine geothermal energy and solar power in places where both sources are available. In this case, both efficiency and flexibility of the system increases [5]. Given these benefits of geothermal energy, this study will analyze Turkey's potential to produce geothermal-based green hydrogen. For such an analysis the following research questions will be addressed:

- Which role can geothermal energy play for future green hydrogen production in Turkey for both exports to Europe but also for local usage?
- Which factors and risks might act as barrier against its use?
- What policy instruments could help overcome these barriers?

MATERIALS AND METHODS

In order to answer these research questions, the main methodology of this study will be conducting interviews with various actors of the Turkish innovation system like private sector, policymakers, universities, scholars, civil society organizations. Additionally a detailed literature review will also support this analysis by looking at both academic and non-academic research on the subject. Both interviews and the literature review will be conducted based on the criteria matrix represented in the Table 1.

Table 1. Analysis criteria

Stakeholders	Techno-economic impacts	Political-economic impacts	Environmental impacts	Societal impacts
Private sector (large)				
Private sector (medium)				
Private sector (small, start-ups)				
Policymakers				
University research				
Non-university research				
Civil society (national level)				
Civil society (local/regional)				
Public				

Such an analysis will help us identify the capacities, positions and interest of diverse stakeholders. By doing so, it will also depict a picture of the geothermal energy sector in Turkey and its potential to support green hydrogen production.

RESULTS AND DISCUSSION

As this is a research that is still at its early stages, the results are not yet complete. However, from the literature and some already established contacts, we know that there is an interest in Turkey to explore its potential in geothermal-based green hydrogen production.

Techno-economic impacts

SHURA Energy Transition Center together with some other research partners completed two studies on priority areas for a national hydrogen strategy [4] and also a techno-economic analysis on Turkey's production and export potential [6]. According to these studies, Turkey has the potential to produce 3.4 million tonnes of green hydrogen by 2050 [6]. They forecast that by 2050 1.9 million tonnes of this potential will cover the annual domestic demand, whereas annual 1.5 to 1.9 million tonnes of green hydrogen can be exported by 2050 [6]. The estimated total annual gross benefit is between 6 to 8 billion dollars to the Turkish economy in 2050 [6].

Although in these reports, the potential of green hydrogen production from Turkey's geothermal resources has not been studied, we have already contacted some private sector actors who engage in green hydrogen production from large scale geothermal power plants. It is to our knowledge that these projects are now in the R&D phase and were able to mobilize finance for this aim. That means there is an interest from the private sector and a vision that geothermal-based green hydrogen production is expected to be a profitable business.

Political-economic impacts

As mentioned above, in terms of fossil fuels Turkey is highly dependent on imports. In 2020 the 33% of the natural gas imports came from Russia, whereas the 11% and 24% of the remaining imports were supplied by Iran and Azerbaijan, respectively [7]. Although compared to 2010 (46.2%), Turkey was able to reduce its imports from Russia and managed to diversify its suppliers to a certain extent, current international developments like Russia's invasion in Ukraine prove that further diversification of suppliers and not being highly dependent on one country in terms of energy supplies is important. For example blending green hydrogen to the natural gas pipelines can reduce the import demand. That would allow Turkey to eliminate 2.5 billion m^3 imported natural gas per year, equivalent of US$0.6 billion per year [4].

Moreover, as part of the European Green Deal, Carbon Measuring at the Border (CMAB) will be implemented as of 2026. This application aims to create an economic incentive for the trade partners of the EU to phase out coal and decarbonize their economies. Since the EU is Turkey's biggest export destination, decarbonizing especially the heavy industry through green hydrogen applications would bring Turkey competitive power.

Environmental impacts

In October 2021 Turkey ratified the Paris Climate Agreement and announced its goal to be carbon neutral by 2053. In order to achieve this goal, hard-to-decarbonize sectors like heavy industries (e.g. steel and iron, cement, petro-

chemical industry) should be addressed with certain priority. Green hydrogen can be utilized in these sectors both as an energy carrier as well as a feedstock. This would support the phasing out coal and eliminate the devastating environmental harm coal power plants have been causing for decades.

Societal impacts

Especially in the recent years, the number of news about the protests against geothermal power plants and their construction sites have been increasing [8, 9, 10]. Locals from western cities of the country announce their disapproval and they get organized to raise their voices. Like many protests, these groups are not always homogenous. Some of them are not very well informed about the geothermal energy and its effects, whereas others are informed and have still big concerns. However, in both cases, this shows that public engagement in the decision making process is not achieved. Hence, conflicts between firms, who hold licenses to build and operate geothermal power plants, and locals, who live and work on these lands, arise very quickly. In order to be able to resolve these conflicts and achieve a mutual understanding, state can act as a mediator and maybe set the rules better, by leaving no room for violation of the locals' rights.

Also from the contacts that we were able to establish so far, we know that in some cities there is no major issue simply due to the fact that geothermal energy is utilized in many diverse ways and not just in power plants. For example, via district heating systems public have access to very affordable and sustainable residential heating. Also, thermal water enables the public to engage in tourism activities and provide them economic benefit and job opportunities. Moreover, since Turkish private firms also engage in the R&D and want to found their own business models and techniques, there might be high added value employment opportunities for engineers, architects, chemists etc.

CONCLUSION

As an energy carrier, green hydrogen offers many opportunities to countries like Turkey who are rich in renewable energy sources and look for new global markets to engage. Actively utilizing all possible renewable energy sources would increase the country's green hydrogen production capacity. Geothermal energy offers great potential as it is not effected by ambient conditions and provide a base-load power generation. Given the fact that storing and transporting hydrogen pose some technical challenges, as a close neighbor to Europe, Turkey has the geographical advantage to reach that market relatively easily through pipelines. Being able to cover the domestic demand and export green hydrogen to Europe can provide economic, political, environmental and societal benefits to Turkey.

ABSTRACT

In recent years, it has become very important to examine the positive or negative factors affecting participation in Scientific Conferences and to determine the right strategies. In this study, it is aimed not only at academic research focusing on the motivating and hindering factors in the literature, but also to expand the existing academic knowledge in terms of social media platforms, together with the data obtained from the social media platforms of the WHEC2022 conference. In addition to new and established factors affecting conference attendance, an interactive management and organizational strategies are proposed. An increase of 3.2% was observed in the WHEC2022 conference participation with the social media strategy used. Research findings are important for conference administrators in addressing the higher-importance social media strategies that affect conference attendance and the factors that affect them.

Keywords: Social Media, Hydrogen Energy, Attractions, Effects, Conference

INTRODUCTION

Today, internet versions and virtual universes are developing rapidly with digitalization. The importance of social media platforms, whose popularity and usage areas have increased in a short time, and their use by researchers is in line with the interest in "big data" in the literature [1]. These social media platforms are being developed with new updates and become more suitable for the use of different communities [2].

Scientists also want to benefit from these web-based social media platforms both for their work and their own social circles. Shares made using these platforms can reach people all over the world in a short time. It is possible to quickly engage in discussions with other researchers on a topic of interest, participate in science conversations and exchange ideas. Many researchers can easily share the summary of their research findings, which they disseminate through official scientific channels such as peer-reviewed journals, by providing sufficient information in a shorter time, both with people in the scientific field and other people who are interested in this field, and increase their visibility [1-3].

Social media tools offer a new way for scientists to strengthen their professional profiles and to express and reach the public more easily. Studies show that public visibility and constructive speech on social media platforms are beneficial for scientists and can positively impact research. Although the type of online chats and shared content can vary greatly, scientists use social media to share journal articles, promote their thoughts and scientific views, and benefit from conferences and meetings. They are increasingly using it as a way to post updates and distribute information about professional opportunities and upcoming events. In addition, with the conferences and webinars that have started to be held in the virtual world, researchers save both financially and morally, they can increase their networks and participate in science conversations without leaving their place [3].

The increased use of online resources can eventually transform and expand the culture of science as a whole. Blogs and social media tools provide an ideal setting for extended scientific conversations and allow for fast-paced discussion of topics that scientists "want and need to discuss". Online platforms will increase researchers' productivity and research efficiency. Platforms such as Facebook, Twitter, LinkedIn help academics to be up-to-date on new research developments, prepare teaching materials, and guide students using the platform [4].

Other researchers use online activities as a way to organize thoughts and research notes, or as a way to encourage creativity and improve writing skills. Online communities are particularly useful for niche topics where community members have specific needs or require specific interactions. Researchers who come together at conferences or in other fields after virtual chats and discussions can communicate more easily. Posting from conferences, discussing the latest research developments, providing information on journal articles, useful resources, lab projects, and

providing links to websites can introduce other scientists, students, or other interested people to valuable content and provide networking opportunities. In this way, a scientist's influence in the research world can expand. In particular, publishing articles on platforms such as Twitter and LinkedIn acts as a research filter for many scientists, making it easier for them to access studies in that field or outside of the field [5].

METHODS

This study has been prepared by taking into account the effectiveness of social media platforms of the WHEC2022 conference in the last 8 months. The studies and interactions obtained using 4 different social media platforms, namely Twitter, Facebook, Instagram, and LinkedIn, are explained. During this 8-month period, many videos and poster posts, both animated and still, were prepared and shared on social media platforms.

In addition,
- “Weekly hydrogen news” are shared in order to increase the traffic of the internet system.
- “Abstract deadline” reminders were made periodically through the conference’s social media accounts.
- Track coordinators and track titles posts were prepared and shared. Track Coordinators have been tagged in the posts to increase the interaction of the posts.
- The posts were shared on the hydrogen energy pages on the platforms in order to raise awareness, to establish new ideas, and establish the necessary contacts to strengthen connections.
- The post designs and sharing of the speakers who made special presentations at the conference were made. Speakers are tagged in posts to increase engagement.
- The posts about the “WHEC-2022 Tutorial Session” programs have been prepared.
- The posts were prepared and reminded that WHEC-2022 has a program in the form of online and onsite presentations.
- The collaboration news such as “IEA hydrogen TPC” were shared.

Table 1. Summary of WHEC-2022 Social Media Platforms activities

	Instagram		Twitter		Facebook		LinkedIn

Post	31	9	31	28	10	9	32	28
Reaction	1166	484	989	86141	173	37452	9553	8964

RESULTS AND DISCUSSION

All social media platforms have their own separate dynamics, and accordingly, their functioning and interactions differ. Our Facebook data has low values in the first months compared to other social media applications. Although this situation seems to be related to the number of posts, we cannot explain the reason for the situation with this alone. The main reason for this situation is that our stakeholders who do hydrogen studies mostly prefer other applications and there is a scarcity of Facebook sharing groups created about hydrogen energy and people do not prefer this platform for academic use.

On the other hand, in Twitter and Instagram applications, we interact with people through the "topic tags" that we use more often. It is very difficult to use these platform dynamics to provide detailed information, either visually or due to word limitations, and interact with researchers. However, it is quite easy to reach visual or verbal information and results through a hashtag. Quickly supporting a topic tag and sharing people's thoughts on the subject in an informed way allow scientific discussions.

In this study, LinkedIn is the platform with which we can quickly reach academicians, professionals, students and interested people working in the field of hydrogen energy and with which we have the most interaction. LinkedIn is due to the fact that it connects the networks in the work area, in accordance with the purpose of its establishment. Thanks to the interaction given to the shared post, the platform, which works with the logic of automatically making the post visible to the links of the interacting person, is especially effective for researchers.

CONCLUSIONS

As a result, social media platforms have a positive impact on professional networking. Each month, by adding new ones to the work done in the previous month, more people were accessed and the effectiveness of WHEC2022 in digital channels was made more visible.

INOGEN

Knowledge Integrator

Inogen was founded in 2006 by 2 Turkish academicians as a knowledge-oriented energy company. With more than 800 employees and 4 separate companies, the Inogen Group is one of the largest renewable energy contractors in Turkey today. In line with its founding mission, Inogen carries out exemplary projects in its field such as Karapinar 1347 MW, the largest Solar Power Plant in Europe, and Kangal 50 MW, Uşak 82 MW, Sertavul 30 MW Power plants, which are the first wind-solar hybrid power plants of our country. Operating in Energy Storage, Green Hydrogen and Ammonia with many national and international collaborations, Inogen plans to become a global end-to-end solution provider in the renewable energy sector.

TEKSIS was founded as a R&D executing SME to serve in Advance Energies and create new technologies for Green Future with having mission as to provide rapid, reliable, practical and cost-effective solutions. TEKSIS designs and develops products in hydrogen energy technologies and manufactures PEMFCs, electrolysers, FC test stations since 2007 in Turkey. Since its establishment, TEKSIS has gained significant experience in all rings of the hydrogen value chain.

TEKSIS contributes to the 21st Century Energy Transition and Decarbonization targets with safe, efficient and sustainable products and services with high added value that respect nature and humanity. Goals are to contribute to a more diverse and efficient energy infrastructure globally by enabling widespread commercialization of hydrogen energy and fuel cell technologies that will reduce fossil fuel usage and greenhouse gas emissions.

NATIONAL HYDROGEN ASSOCIATION

TURKEY

AWARDS

Nejat Veziroğlu Special Award

This award was created on behalf of Prof. Dr. Nejat Veziroğlu, who is an international leader in hydrogen energy, the father of hydrogen technologies, and the permanent honorary president of the Hydrogen Technologies Association. It is given to people who have proven themselves in the field of hydrogen energy and technologies both domestically and internationally and have made internationally recognized contributions.

Service Award of Hydrogen Technologies Association

This award is given to the people who have dedicated themselves to hydrogen energy and have served for at least 20 years in the development and application of this field, have contributed to the communal, social, technological, and economic development of the country in this field, have been a pioneer in the education and training of youth, have made institutional contributions and are active in industrial applications.

Technology Award

This award has been created for institutions that work effectively on hydrogen energy technologies and develop technologies. It is given to institutions that develop a product for the development of hydrogen technology, establish a pilot or industrial facility in the field of hydrogen energy and technologies, have patents in the field of hydrogen energy and technologies or support technology development.

Young Researcher Award

This award has been created for researchers, who are under the age of 35 (not less than 35 years old as of the date of WHEC-2022 conference, where the award will be given) and have at least a master's degree. It is given to people who have done successful studies on hydrogen energy technologies that are recognized at the national and international levels.

Student Researcher Award

This award is given to undergraduate, graduate, or doctoral students. Candidates are expected to be under the age of 30 as of the date of the WHEC-2022 conference, where the award will be given. The candidates who will be nominated for this award or who will apply themselves, will be preferred for this award if they have developed an invention, a new application, or a unique method for hydrogen technologies

Winners of these prizes will be invited to attend the conference in which they will participate in the award ceremony, and their transportation and hotel expenses will be covered by the association.
